THE JOURNAL OF Tropical Medicine and Hygiene

With which is incorporated "CLIMATE"

AND

Embodying Selections from THE COLONIAL MEDICAL REPORTS

A FORTNIGHTLY JOURNAL DEVOTED TO MEDICAL, SURGICAL AND SANITARY WORK IN WARM COUNTRIES

EDITED BY

SIR JAMES CANTLIE, K.B.E., M.B., F.R.C.S.; AND ALDO CASTELLANI, C.M.G., M.D., F.R.C.P.;

IN COLLABORATION WITH

SIR W. J. R. SIMPSON, C.M.G., M.D., F.R.C.P.; C. M. WENYON, C.M.G., C.B.E., M.B., B.S., B.Sc.;

R. G. ARCHIBALD, D.S.O., M.D.; AND T. P. BEDDOES, M.B., B.CH., F.R.C.S.

SIR RONALD ROSS, K.C.B., K.C.M.G., F.R.S., COLONEL A.M.S. *(Honorary Adviser to the Editorial Staff)*

VOLUME XXVIII

JANUARY 1 TO DECEMBER 15

1925

INDEX TO VOL. XXVIII.

JANUARY 1 to DECEMBER 15, 1925.

INDEX OF AUTHORS.

ANGELIS, G. de, TIZZONI, Prof. G., and CETANNI, Prof. E.—On the modification produced by radium on an emulsion of an adeno-carcinoma of the mouse and its transformation into a curative vaccine, 438

BATTISTINI, TELÉMACO, M.D.—The immunological relationships of the leptospira group of spirochætes, 201
BAYLIS, H. A., M.A., D.Sc.—On *Gongylonema* collected in Italy during October, 1924, with some observations on the genus, 71
—— On the identity of *Gongylonema subtile*, Alessandrini, 361
—— On identity of *Heterakis neoplastica*, Wassink, 362
—— Some notes on nematode parasites found by Dr. Wassink in rats and mice, 316
——, and SAMBON, JULIET, E. B.—Some observations and experiments on *Gongylonema* in Northern Italy. A preliminary note, 413
BEZANÇON, Professor F., and ETCHEGOIN, Dr. E.—Presence of spirochætes in the sputum of tuberculous patients, 228
BLAIR, K. G., B.Sc., F.E.S.—Some notes on the insect intermediate hosts of *Gongylonema*, 76
BLAISDELL, C. BYRON, M.D., and MULLER, HENRY R., M.D.—Studies of yellow fever epidemic in Salvador, C.A., in 1924, 277

CASTELLANI, ALDO, C.M.G., M.D., F.R.C.P.—Beneficial action of raw pancreas in certain cases of sprue. Insulin in cases of sprue complicated with diabetes, 230
—— Further observations on pruritus ani and pruritus vulvæ of mycotic origin, 329
—— Notes on non-gonorrhœal urethrites, 250
—— Notes on three new yeast-like organisms and a new bacillus, with remarks on the clinical conditions from which they have been isolated, 217
—— Observations on some diseases of Central America, 1
—— Phosphorus in the treatment of various diseases, 377
—— DOUGLAS, MACKENZIE, M.D., and THOMPSON, E. T.—Notes on mixed mycotic infections of the bronchi. The mixed monilia + anaeromyces infection, 257
—— and TAYLOR, FRANK E., M.D., B.S., M.A., M.Sc., F.R.C.S.—Further observations on vaginal moniliases, 242
CAWSTON, F. G., M.D.—A contribution to the study of radulæ of fresh-water mollusca, 365
—— A study of some removable causes of unemployment and crime, 441
—— A search for intermediate hosts and a study of their radulæ, 14
—— British Indians and bilharzia disease, 193
—— *Schistosomum ? spindalis* Montgomery in Zululand schoolboy, 406
CETANNI, Prof. E., ANGELIS, G. de, and TIZZONI, Prof. G.—On the modification produced by radium on an emulsion of an adeno-carcinoma of the mouse and its transformation into a curative vaccine, 438
CHRISTOPHERSON, J. B., C.B.E., M.D., and WILSON, FREDA.—Notes by a nurse on the treatment of yaws (framboesia) with novarsan, 424
CONNAL, ANDREW, M.D., D.P.H., D.T.M. & H., and SMITH, E. C., M.D., D.P.H.—Report on fatal case of bacillary dysentery in Nigeria, 379
CRAN, Col. JAMES, O.B.E., M.D.—Results of the Noguchi treatment of the prophylactic measures employed in the 1923 yellow fever epidemic in Belize, 26
CRUTO, Dr. A., and TROCELLO, Prof. E.—On the influence of high temperature on the preservation of insulin, 103

DEEKS, W. E., M.D.—Prevention and treatment of malaria, 21
—— The ætiology of hæmoglobinuric fever, 101
DOUGLAS, MACKENZIE, M.D., THOMPSON, E. T., and CASTELLANI, ALDO, C.M.G., M.D., F.R.C.P.—Notes on mixed mycotic infections of the bronchi. The mixed monilia + anaeromyces infection, 257

EASMON, M. C. E., M.B., B.S.Lond., M.R.C.S., L.R.C.P.—Conditions of medical work in a West African bush station, 128
ETCHEGOIN, Dr. E., and BEZANÇON, Professor F.—Presence of spirochætes in the sputum of tuberculous patients, 228

FACIO, A. A., M.D., and ROJAS, M. D., M.D.—The treatment of hæmoglobinuric fever with caffeine sodio-benzoate, 86
FAUST, E. C., Ph.D., WASSELL, C. McA., M.D., and MELENEY, H. E., M.D.—A study of intensive antimony-therapy in schistosomiasis japonica, 153
FERNANDO, ANTONIO S., M.D., and NICHOLAS-FERNANDO, FELISA, M.D. — Tropical oto-laryngology with special reference to the Philippine Islands, 202
FIALLOS, JUAN MANUEL, M.D.—Observations on Castellani's fermentation phenomenon, 426. *See also* correction on p. 443

GHOSH-DASTIDAR, S. K., M.B., D.T.M.—Treatment of cholera and its complications, 261

HASLAM, J. F. C., M.C., M.D., D.P.H., M.R.C.P.E.—Observations on experimental use of fish indigenous to British Guiana for control of mosquitoes breeding in vats, tanks, barrels and other water containers, 284
HEWETSON, W. M., M.B., D.P.H.—The ætiology of blackwater fever, 88, 105

INGRAM-JOHNSON, R. E., L.R.C.P.Edin., &c. — Dengue *v.* malaria, 126

JAMISON, S. CHAILLE, M.D., and JOHNS, F. M., M.D.—A note on treatment of amœbic dysentery with stovarsol, 378
JEWELL, N. P., F.R.C.S.I., M.D.—Three cases of Castellani's endemic funiculitis in Kenya Colony, 137
JOHNS, F. M., M.D., and JAMISON, S. CHAILLE, M.D.—A note on treatment of amœbic dysentery with stovarsol, 378

LEBLANC, T. J., A.B., M.S.P.H., C.P.H., Sc.D.—Studies of yellow fever in Vera Cruz in 1920-1921, 169

MCCULLOCH, W. E., M.B., Ch.B.Aberdeen.—Relapsing fever in Northern Nigeria—a study of 300 cases, 332
MELENEY, H. E., M.D., FAUST, E. C., Ph.D., and WASSELL, C. McA., M.D.—A study of intensive antimony-therapy in schistosomiasis japonica, 153
MELLO, Lieut.-Col. FROILANO DE. — Some remarks upon *Spirochæta bronchialis* Castellani, and bronchial spirochætosis, 237
MENDELSON, RALPH W., M.D., D P.H. — Some interesting diseases observed in clinic of Bangkok Central Hospital, 393
MULLER, HENRY R., M.D., and BLAISDELL, C. BYRON, M.D.—Studies of yellow fever epidemic in Salvador, C.A., in 1924, 277

NEWHAM, H. B., C.M.G., M.D., M.R.C.P.—Pathology of *Clonorchis* infection of pancreas, 437
NICHOLAS-FERNANDO, FELISA, M.D., and FERNANDO, ANTONIO S., M.D.—Tropical oto-laryngology with special reference to the Philippine Islands, 202

NICOLE, J. ERNEST, L.M.S.S.A.Lond., and STEEL, JOHN P., M.B., Ch.B.Edin.—Acquired immunity to malarial inoculation, 428
NOGUCHI, HIDEYO, M.D., M.S., Ph.D., Sc.D.—Yellow fever research, 1918-1924: a summary, 185

ORLEMAN, MABELLE, and STILES, Prof. C. W.—The cestode genus *Hydatigera* Lamarck, 1816, species *Reditœnia* Sambon, 1924, 249

PAGNIER, A., M.D., and SCHRUMPF-PIERRON, P., M.D.—A clinical study on malaria in the Near-East and in Europe, 117

RAMSAY, G. C., O.B.E., M.D.Edin., D.T.M.&H.Eng.—The influence of climate and malaria on yaws, 85
RIDLEY, H. W., C.M.G., F.R.S.—Use of iodine in beriberi, 102
ROBERTSON, ANDREW, M.B., Ch.B., and THOMSON, J. G., M.A., M.B., Ch.B.—A note on the flagellates of anophelines and culicines previously mentioned in the literature with a description of a crithidial form in a new host *Anopheles umbrosus* from the Federated Malay States, 419
—— —— Notes on cultivation of certain amœbæ and flagellates of man, using technique of Boeck and Drbohlav, 345
—— —— The cysts of *Tricercomonas intestinalis* Wenyon and O'Connor 1917 found in human fæces, 223
ROJAS, M. D., M.D., and FACIO, A. A., M.D.—The treatment of hæmoglobinuric fever with caffeine sodio-benzoate, 86
ROSS, G. A. PARK, M.D., D.Ph.—Fly-proof latrines for coloured persons, 231

SAMBON, JULIET, E. B., BAYLIS, H. A., M.A., D.Sc., and T. C. PAN, M.B., Ch.B.—Some observations and experiments on *Gongylonema* in Northern Italy. A preliminary note, 413
SAMBON, LOUIS WESTENRA, M.D., F.Z.S.—Gongylonema, 313
—— Researches on the epidemiology of cancer made in Iceland and Italy (July-October, 1924), 39
SCHRUMPF-PIERRON, P., M.D., and PAGNIER, A., M.D.—A clinical study on malaria in the Near-East and in Europe, 117
SHAW-MACKENZIE, J. A., M.D.Lond.—Blood- and tissue-changes in cancer, with reference to diagnosis and treatment, 297
SMITH, E. C., M.D., D.P.H., and CONNAL, ANDREW, M.D., D.P.H., D.T.M.&H.—Report on fatal case of bacillary dysentery in Nigeria, 379
SPAAR, ERIC C., M.D., B.S., B.A.Lond., M.R.C.P.—Some observations on common endemic fevers of Ceylon, 349
SPENCER, H. A., M.R.C.S., L.R.C.P.Lond.—Lightning stroke and electric storms in the tropics, 138
—— Prophylaxis in malaria, 207
STEEL, JOHN P., M.B., and NICOLE, J. ERNEST, L.M.S.S.A. Lond.—Acquired immunity to malarial inoculation, 428
STILES, Prof. C. W., and ORLEMAN, MABELLE.—The cestode genus *Hydatigera* Lamarck, 1816, species *Reditœnia* Sambon, 1924, 249

TAYLOR, FRANK E., M.D., B.S., M.A., M.Sc., F.R.C.S., and CASTELLANI, ALDO, C.M.G., M.D., F.R.C.P.—Further observations on vaginal moniliases, 242
THOMPSON, E. T., CASTELLANI, ALDO, C.M.G., M.D., F.R.C.P., and DOUGLAS, MACKENZIE, M.D.—Notes on mixed mycotic infections of the bronchi. The mixed monilia + anaeromyces infection, 257
THOMSON, J. G., M.A., M.B., Ch.B., and ROBERTSON, ANDREW, M.B., Ch.B.—A note on the flagellates of anophelines and culicines previously mentioned in the literature with a description of a crithidial form in a new host *Anopheles umbrosus* from the Federated Malay States, 419
—— —— Notes on cultivation of certain amœbæ and flagellates of man, using technique of Boeck and Drbohlav, 345
—— —— The cysts of *Tricercomonas intestinalis* Wenyon and O'Connor 1917 found in human fæces, 223
TIZZONI, Prof. G., CETANNI, Prof. E., and ANGELIS, G. de.—On the modification produced by radium on an emulsion of an adeno-carcinoma of the mouse and its transformation into a curative vaccine, 438
TROCELLO, Prof. E., and CRUTO, Dr. A.—On the influence of high temperature on the preservation of insulin, 103
TROUT, CHARLES LEWIS, M.D.—The treatment of blackwater fever, 225

VISWALINGAM, A., L.M.S.—Granuloma venereum, 302

WASSELL, C. McA., M.D., MELENEY, H. E., M.D., and FAUST, E. C., Ph.D.—A study of intensive antimony-therapy in schistosomiasis japonica, 153
WILSON, FREDA, and CHRISTOPHERSON, J. B., C.B.E., M.D.—Notes by a nurse on the treatment of yaws (frambœsia) with novarsan, 424

GENERAL INDEX.

A

ABSTRACTS :—

Ankylostomiasis inquiry in Madras, report, 82
Appendicitis, *Oxyuris vermicularis* as causative factor in, 309
Castellani's glycero-vaccine, agglutinin formation following use of, 273
Creeping disease (gnathostomiasis) in China, two new cases of human, with note on infection in reservoir hosts in China area, 358
Epidemic disease, prevalence of, and port health organization and procedure in the Far East, 18
Goitre in Honolulu, absence of endemic, 182
Hæmoglobinuric fever in the canal zone, its ætiology and treatment, report of, 34
Hookworm infection as influenced by wearing of shoes, 356
Night soil, utilization of solar light and heat in treatment of, 291
Plague in Hong Kong, outline of history, 388
Sleeping sickness, prophylaxis, 256
Tropical technique, hints, 371

ANNOTATIONS :—

Accuracy of measurement of small volumes of fluid with a capillary pipette, 146
Acne varioliformis, experimental, 212
Acriflavine, action on blood and certain tissues of rabbits, 290

ANNOTATIONS—*continued.*

Addison's disease, studies, 271
Adenitis, radiotherapy in treatment of tuberculous cervical, 409
Ætiology of jagziekte, studies on, 431
Alastrim, 255
Aleukæmic leukæmia with multiple skin tumours, 429
Alopecia, persistent, in rabbits, production of by X-rays, 450
Amœbiasis cutis. With a survey of the medical literature to date, 142
——, experimental, in cats from acute and chronic human cases, 165
——, extra-intestinal, 15
——, some clinical and laboratory aspects with preliminary report on yatren treatment, 387
——, treatment by oral administration of stovarsol, 325
Amœbic liver abscess with report of two cases occurring in Connecticut, 135
Amyloid casts, question of existence, 290
Anæmia associated with sprue syndrome, *Monilia psilosis* Ashford in severe, 342
Anæsthesia produced by intra-arterial infection of apothesine, 324
Anthelmintic, factors which should determine selection in a geographical area, 324
Anticryptogamic action of fluosilicate of soda and of hydrofluosilicic of acid in coagulation of india-rubber, 370

ANNOTATIONS – *continued.*

Antigenic properties of solutions of pneumococcus, 446
Anti-leprosy treatment, I, complaints of patients, 270
—— ——, III, complaints of patients, 321
Antirabic injections, some lesions of the nervous system provoked by, 255
—— treatment, preservation of marrow, 254
Antityphoid vaccination, nervous and mental complications, 115
Antivenomous serum, effect of storage on potency of, 323
Appendectomy, diagnostic errors leading to uncalled for, 149
Arcella polypora, interactions of protoplasmic masses in relation to the study of heredity and environment, 99
Argentine tumours of appendix and small intestine, 447
Arsphenamin poisoning, clinical and experimental investigation, 265
Arthritis and rheumatoid conditions, alleged rôle of lactic acid, 145
Ascaris, question of human and pig, 214
Bacillus bronchisepticus and *Bacterium lepisepticum*, association of, with rabbit snuffles, 324
—— *coli* in water analysis, new medium for differentiation, 433
—— *dysenteriæ*, note on viability, 387
—— *typhosus*, viability in oysters during storage, 387
Bacteria, penetration through capillary spaces, 234
Bacterial agglutinin, liver as source of, 308
Beriberi from diet of raw starch, 410
Biology of *Anopheles superpictus*, study of, 451
Blackwater fever, some observations, 110
Buffered solution for perfusion of isolated organs, 342
Buried glass capillaries of radium emanation, action on plant and animal tissues, 213
Carcinoma of lungs, primary, 271
C. diphtheriæ and other members of the genus *Corynebacterium* with special reference to fermentative activity, 233
Cell-inclusions, occurrence in rabbit cornea after inoculation with vesicular contents and naso-pharyngeal secretion of varicella cases, 200
Chaulmoogra and allied preparations, chemotherapeutic experiments, 29, 146, 447
Cholera toxin, nature and pharmacological action of, 134
—— vaccination; its effectiveness as evidenced by presence of antibodies in blood of vaccinated persons, 288
Clonorchis infection in China, some recent aspects of epidemiology of, 406
—— *sinensis*, comparative study, 409
Coconut oil, detection of traces of alkali or soap in refined, 146
Colds, value of chlorin in treatment of, 326
Colon bacillus infections, 381
Coma, juvenile diabetic, with insignificant ketonuria, and with a large amount of acetone in the spinal fluid, report of a fatal case, 82
Comparative study of action on pneumococcus of bile-acids and unsaturated fatty acids found in bile in form of soaps, 450
Congenital ectodermal defect, 212
—— ichthyosiform erythroderma, 369
Cosmetics, 322
Crescent and the red cell, 143
Crescents, relative number of male and female, 144
Croonian lectures on researches on leprosy and their bearing on the treatment of tuberculosis, 264
Debab trypanosomiasis of the dromedary, treatment, 211
Dengue fever, studies upon the etiology, 232
Dermatitis in association with disease or injury of peripheral nerves, 369
—— produced by Portuguese man-of-war, 369
Diabetes, cephalandra indica in, 322
——, intarvin, 371
—— mellitus, 199
Diabetic retinitis, 447
Diagnosis, multiple electrical stethoscope and electrical filters as aids, 147
Diphtheria carriers, epidemiological importance, 323
—— of skin, 322
Diseases of the skin, calcium content of the blood, 148
Disinfection of eating utensils in U.S. Army, study of methods, 431

ANNOTATIONS—*continued.*

Dochez scarlet fever antitoxin in thirty-one cases, 386
Dracontiasis, studies in, 33
Dwarf tape-worm (*Hymenolepis nana*), experimental study on development, 433
Dye (brilliant vital red), fate of an intravenously-injected, with special reference to its use in blood volume determination, 309
Dysenteries of Cochin China, 385
Dysentery, effects of "*Castela nicholsoni*" in treatment of chronic amœbic, 269
——, further observations on latent, 33
——, therapy of amœbic, 252
Ear, painful nodular growth, 272
Ectopic gestation in Chinese women, 115
Effect of various agents, 326
Encephalitozoon cuniculi as kidney parasite in the rabbit, 144
Endamœba histolytica, cultivation, 341
Endo's medium, preparation of, 447
Epidemiology in Libia, notes on ocular, 165
Epilepsy, ketogenic diet in, 323
——, pathogenesis, 367
Epinephrine, factors concerned in the polycythemia produced by the subcutaneous injection of, 145
Equine infection, existence of, due to *Trypanosoma marocanum* on the borders of Algero-Morocco, 211
Exophthalmic goitre, iodine in, 212
Fallacy of test for lactose fermenters as indication of fæcal pollution of waters, 433
Familial blood dyscrasias, 214
Filaria recondita Grassi, observations on the morphology and life cycle, 82
Filariasis, yaws and intestinal helminthic infections in Cook Islands, observations, with notes on breeding habits of *Stegomyia pseudo-scutellaris*, 432
Flagellar and somatic agglutination, effect of heat on, 195
Flagellate infections, investigations, 98
Formol-gelification in dromedaries and bovine animals, on the subject of, 211
Fungicidal activity of certain volatile oils and stearoptens, 325
Fusiform bacilli and spirochætes, studies, 195
Gangrene, localized, following hypodermic administration of calcium chlorid, 386
Gangrenous affections of fusospirillar association by an antispirillar vaccine, vaccinotherapy in, 386
Gasserian ganglion, alcoholic injections, 213
Gastric achylia and simple and pernicious anæmia, relations between, 199
—— lesions, occurrence in rats, 199
—— secretion, influence of different kinds of oil, introduced into the rectum, 234
—— ulcer, treatment by method of duodenal alimentation, 325
Genito-urinary disease, mercurochrome-220 soluble, 322
Giardia and *Chilomastix* from monkeys, *Giardia* from the wild cat, and *Balantidium* from the sheep, 213
Glandular fever, laboratory findings in an epidemic, 211
Gonococcal infection, cutaneous, 144
Gonococcus and pneumococcus, notes on selective media for, 354
Goundou, 432
Granuloma inguinale: including a series of cases illustrating some points in prognosis and treatment, 142
Hæmolytic streptococci, contribution to biological study on, 134
Hæmophilia, 327
Hæmoptysis onset in tuberculosis, significance, 321
Hay fever, study of two hundred and two cases, 266
Heartwater, studies on etiology, 369, 370
Height, weight and chest measurements of Mongolian peoples, with especial reference to Southern Chinese, 271
Helminthiasis, eradication from Egyptian army, 268
Hemolytic proteus bacillus, study of, 449
—— streptococci, classification of, by the precipitin reaction, 17
Hepatosis (or tropical abscess of liver), 135
Hernia of the diaphragm, early diagnosis of true, 212

ANNOTATIONS – *continued.*

Herpetomonad flagellates in the latex of milkweed in Maryland, 181
Hexyl resorcinol, 410
Hookworm disease, control of, in South Alabama, 81
—— ——, experiments in the treatment of, with carbon-tetrachlorid and ascaridol, 82
—— —— in Colombo, investigations on the epidemiology, 81
—— ——, severity in a Chinese group, tested by hæmoglobin readings for anæmia, and egg counts for degree of infestation, 323
—— —— treatment with combination of carbon-tetrachloride and oil of chenopodium, 182
—— —— —— —— —— mixture of carbon tetrachloride and ascaridol, 354
——, effect of carbon-tetrachloride on the egg-laying powers of the female, 182
Human creeping disease (gnathostomiasis), two new cases in China, with note on infection in reservoir hosts in China area, 319
—— intestinal protozoa in Peking, China, a survey of, 451
Hydatid parasite (*Tænia echinococcus*) in the pig, histogenesis of, 255
Hypoglycemia, sugar-content of blood in runners following Marathon race, with special reference to prevention, 408
Immunization of rabbits to cutaneous infections with staphylococcus infection, 450
——, possibility, of tissues of nose, throat and ear by use of vaccines applied locally, 290
Immunological reactions of the isolated carbohydrate and protein of pneumococcus, 446
Inguinale hernia: report of 100 operations on Korean patients, 451
Injuries and diseases in Australia attributable to animals (except insects), 133
Intestinal parasites of man, observations on North China, 181, 384
Intramuscular injections, local effects produced in the tissues by, 32
Intratracheal injections of type I pneumococcus, effect of fatigue upon susceptibility of rabbits to, 307
Ivy poisioning, 325
Jaundice, chronic hereditary and familial hæmolytic, 325
——, determination of phenolsulphonephthalein in urine, 197
——, reaction of liver to phenol-tetrachlorphthalein in early obstructive, 146
Jute dermatitis, 32
Kala-azar endemic areas, significance of splenic-index, 324
——, final report on the use of urea stibamine, 135
—— on Pusa estate, note on incidence, 355
—— prevalence in Calcutta, comparative study of environment associated with, 309
Kidney, concentrating capacity, 145
Korsakoff's psychosis and typhoid fever, 115
Lafah in Tripolitania, 384
Lathyrism—I, studies on, 309
Leprosy, epidemiological study, 386
—— in New York City, 143
——, preparation of hydnocarpus esters and their use in, 32
——, report on the investigation of a number of cases at Nauru, Central Pacific, 147
——, treatment in Ceylon, 98
Leucocyte inclusions, disease of fowls in Palestine characterized by, 268
Leukæmia cutis, universal, 148
Leukocytes, determination of resistance of, 82
Leukoderma following dermatitis venenata (*Rhus toxicodendron*), 445
Leutic precipitation test, dissolution of the precipitates produced by the fresh serum, 133
Lichenoid sarcoid: an unusual case, 443
Liver, amœbic abscess, 367
—— fluke, human, in Korea and note on immediate hosts of liver-fluke in China, 92
—— function test, a new, 147
Lupus erythematosus, 369
Malaria among Chinese university students, 270
—— at Madagascar, fight against, 307
——, further observations made during treatment of general paralysis, 355

ANNOTATIONS—*continued.*

Malaria in communities living under hyper-endemic conditions, mechanism of immunity against, 33
——, incubation period of benign tertian, 432
—— infection as it occurs in late pregnancy, 433
—— in rural settlements in Palestine, 168
—— —— Suriname, 145
—— —— the Kirkuk division of Northern Mesopotamia during 1923, 385
——, mercurochrome in treatment of chronic, 354
——, observations on inoculated, 308
—— parasites in placental blood, 268
Malignant tumour of the rabbit, studies based on, 200
Mastigina hylæ (Frenzel) from intestine of tadpole, morphology, 433
Melanosis after arsenobenzol, 272
Melioidosis, two cases, 199
Meralgia paræsthetica: relation to ostearthritis of spinal vertebræ, 410
Mercurochrome-220 soluble and gentian violet, 267
Mercury absorption from the skin, microscopic study, 181
Micro-organisms, group, transmitted hereditarily in ticks and apparently unassociated with disease, 308
Microsporidia parasitic in mosquitoes, studies, 213
Mitral stenosis without rheumatic fever in North China, 97
Mosquito breeding in specific places, 211
—— ——, California rice-fields and, 444
Mosquitoes and coconut palms, 234
Mycetoma in Tunisia, four new cases, 235
—— report of four cases, 140
Mycorrhiza plants, *Calluna vulgaris*, nutrition, 367
Mycotic paronychia and dermatitis, 272
Myeloid leukæmia of the skin, 99
Neo-arsphenamin, treatment with intraperitoneal injection, 410
Nephritis, concentration of plasma proteins, 146
Neurosyphilis, clinical and serological studies, with tryparsamide therapy, 387
——, results secured by standard methods of treatment, 198
——, tryparsamide in treatment of, 197, 355
—— —— treatment, 370
Night soil, utilization of solar light and heat in treatment of, 291
Nitritoid crisis following intravenous injection of arsenicals, cause of, 446
Nodosites juxta-articulaires, 369
Obscure lesions, effects on organ weights of apparently normal rabbits, 386
Orchidoma or orchidoblastoma of the horse, 143
Orchitis of the rabbit, experimentally produced by inoculation with the spirochæte of rat-bite fever, 144
Ornithobilharzia odhneri n. sp. from Asiatic curlew, notes on, 369
Oxygenation and starvation, effects on symbiosis between termite, termopsis and its intestinal flagellates, 369
Paralysis, general, treatment by malaria, 271
——, treatment of general by inoculation with malaria, 267
Paratyphoid-enteriditis infection of white mice, microbic virulence and host susceptibility, 343
—— fever, report of epidemic in patrons of a cafeteria, 198
—— outbreak, certified milk-borne, 307
Parenchymal rôles in pulmonary tuberculosis, 447
Parsa hilarata Staudinger, some observations and experiments on irritating properties of larva, 269
Pathogenic fungi, reaction to ultra-violet light and rôle played by pigment in this reaction, 200
Penetration of fruits and vegetables by bacteria and other particulate matter, and the resistance of bacteria, protozoon cysts and helminth ova to common disinfection methods, 449
Peptic ulcer, focal infection, 272
Pine oil films, toxic action of oil films upon mosquito larvæ, with particular reference to, 269
Plague, bactericidal power of blood of rats as measure of their immunity to, 355
—— fleas, with special reference to Milroy lectures, 1924, 408
—— investigations in Egypt, report on, 34
——, production of immunity by vaccine, 134
—— transmission through ectoparasites of tarabagan, 307
Plasmodium falciparum, some morphological features, 143

ANNOTATIONS—*continued.*

Pneumococcus immunity, significance of anaphylaxis, 144
—— infections, blood platelets in, 18
—— pneumonia, experimental production in mice by inhalation method, 199
—— protein, production and significance of cutaneous allergy to, 144
——, studies on oxidation and reduction by, 17
Pneumonia in mice, pathology of experimental pneumococcus, 234
——, lobar, notes on therapeutic value of pneumococcus antibody solution subcutaneously administered in, 290
——, pathology, caused by bacillus influenzæ during an inter-epidemic period, 214
Poliomyelitis, anterior, in Kansas, study of the 1923 epidemic, 143
Proteus hæmotoxin, 449
Pseudo-malarial attacks in typhoid fever, 97
Psoriasis, monilia as possible etiologic factor, 326
——, treatment by intravenous injections of salicylate of soda, 142
Pulmonary infection with the spirochætæ and fusiform bacilli, 115
—— plague, investigations, 211
—— tuberculosis in Cochin China, investigations, 256
Pyrubrin, a red water-soluble pigment characteristic of *B. pyocyaneus*, 450
Quinine, concentration in circulating blood, 354
Rabies during the last ten years, works on, 148
Radium-therapy in dermatology, 445
Rat-bite fever with special reference to its ætiological agent, 291
Raynaud's disease complicated with gastric ulcer, 386
—— ——, skin capillaries, 271
Reaction product which inhibits reproduction of the trypanosomes in infections with *Trypanosoma lewisi*, with special reference to its changes in titre throughout the course of infection, 266
Reinoculations in infection due to a *M. melitensis*, especially after the experimental malady of the guinea-pig, 254
Relation of insect herpetomonad and crithidial flagellates to Leishmaniasis, studies on.—I, 448; II, 448; III, 448
Resistance to mildew in œnothera, biochemical study, 343
Respiratory infections of rabbit, epidemiological studies, 272
Rheumatic fever, attempts to transmit to rabbits and guinea-pigs, 135
River fever (Tsutsu-gamushi disease), possible incidence in the Central Yangtze Valley, 97
Rocky Mountain spotted fever, 265
—— —— —— —— in the blood, identification of organism, 266
Roentgen-ray dermatoses, chronic, as seen in the professional man, 267
—— treatment in bronchial asthma and chronic bronchitis, 449
Salvarsan treatment, effect of alcohol and nicotine, 133
Saponification of bodies in the United Provinces of Agra and Oudh, 211
Sarcoma, multiple hæmorrhagic, of Kaposi, 291
Scarlet fever and diphtheria patients, intradermal salt solution test, 178
—— ——, institutional outbreak, 321
—— ——, results with skin test for susceptibility to, 326
—— —— II, studies, 255
Schistosoma japonicum and *S. hæmatobium*, reactions of miracidia in presence of their intermediate hosts, 387
Sclerosis, multiple, treatment with silver salvarsan, 168
Scrofuloderma gummosa, 148
Shoe dye poisoning, 322
Sickle cell anæmia with necropsy, a case, 214
Sigma reaction for syphilis, observations on, 445
Silver arsphenamin, relation of, to the involuntary nervous system and to the so-called nitritoid crisis, 135
Skin infection of rabbits with hæmolytic streptococci isolated from patient with erysipelas, 307
—— reactions to simultaneous treatments with radiant and soft X-rays, 308
Sleeping sickness, report on investigation into epidemiology, in Central Kavirondo, Kenya Colony, 270
Small-pox, blood in purpuric, 309

ANNOTATIONS—*continued.*

Splenomegaly, typical case, 304
Sprue, rôle of *Monilia psilosis* (Ashfordi) in experimental, 133
——, value of estimation of ionic calcium of serum in diagnosis of, and as gauge of process, 267
Stomatitis, autumn, 254
Streptococci and pneumococci, serological relationship among and between, 145
Streptococcus group, precipitation and complement-fixation reactions with residue antigens in the non-hæmolytic, 195
Sugar content of cerebrospinal fluid and its relation to blood-sugar, 289
—— —— normal, of blood and sugar tolerance test, some observations, 342
Sulpharsphenamin, chemotherapy, 200
Syphilis, clinical studies of Kahn reaction, 267
—— —— —— on the Kahn reaction for, 213
—— —— value of bismuth in the treatment of, 17
——, contributions to pathologic anatomy, 368
—— effects of non-specific protein therapy, 148
—— experimental, of rabbit, therapeutic action of potassium iodide, 321
—— incidence of *Spirochæta pallida* in cerebrospinal fluid during early stage, 198
—— in rabbits, observations on possibility of cure with arsphenamine, 343
—— latent, 290
——, prophylaxis of congenital, 17
—— reinfection, 198
——, relation of natural anti-sheep hemolysin of human serums to Kolmer's quantitative complement-fixation test for, 233
——, serological studies of experimental, 215
——, specificity of sero-reaction in experimental, with special reference to "Sachs-Georgi" reaction, 409
——, stability of desiccated beef heart-muscle powder for preparation of antigens for conduct of complement fixation tests, 233
——, value of flumerin in treatment of, 326
——, Vernes flocculation test, 381
Syphilitic aortic insufficiency, 198
Tapeworms, treatment, 168
Termite castes, feeding habit, and its relation to their intestinal flagellates, 367
Tetanus cured by large doses of serum, 133
Tick paralysis in human beings, death from, 32
Tissue resistance and cause of permanent acquired immunity, 200
Toxicity of oxygen for protozoa *in vivo* and *in vitro*: animals defaunted without injury, 368
Trichomonas from guinea-pig, study, 325
—— *intestinalis*, pathogenicity, 388
—— *vaginalis* Donné, 268
Trypanosomiasis in Palestine, experimental study, 214
Tuberculosis of guinea-pig, influence of "Diaplyte" antigen of Dreyer on, 272
—— of vagina, 410
—— incidence and climate in India: rainfall and west winds, 143
—— in India in general and Bengal in particular, some etiological factors, 115
Turpentine industry, survey for possible larvicidal instances, 319
Typhoid bacilli, viability in shell oysters, 321
—— fever, oleum morrhuæ in, 115
Typhus fever, case resembling endemic, 181
Undulant fever, rôle of domestic cow in epidemiology, 266
Urticaria solaris, 368
Virus encephalitis, contributions to pathology of experimental, 273, 307
Vitamin content of banana, 269
Vitamins, relation to reaction induced by coal tar in tissues of animals, 370
Wadi Halfa quarantine, 98
Wassermann and Khan tests, a comparison, 443
—— —— effect of bismuth on Wassermann reaction in patients unresponsive to arsphenamin, 446
—— test, 148
Yeast absorbed complement, activation with heated sera, 266
Yellow fever, use of fish in control of, 411

Amœbæ and flagellates of man, notes on cultivation of certain, using technique of Boeck and Drbohlav, 345
Amœbic dysentery, note on treatment with stovarsol, 378
Anaeromyces infection, mixed monilia +. Notes on mixed mycotic infections of the bronchi, 257
Anopheles umbrosus from Federated Malay States, note on flagellates of anophelines and culicines previously mentioned in literature with description of crithidial form of new host, 419
Antimony-therapy in schistosomiasis japonica, study of intensive, 153

B

Bangkok Central Hospital, Clinic, some interesting diseases observed, 393
Belize, results of the Noguchi treatment of the prophylactic measures employed in the 1923 yellow fever epidemic in, 26
Beriberi, use of iodine in, 102
Bilharzia disease, British Indians and, 193
Blackwater fever, ætiology, 88, 105
—— ——, treatment, 225
British Guiana, observations on experimental use of fish indigenous for control of mosquitoes breeding in vats, tanks, barrels and other water containers, 284
Bronchial spirochætosis, some remarks upon *Spirochæta bronchialis* Castellani, and, 237

C

Caffeine sodio-benzoate, treatment of hæmoglobinuric fever with, 86
Cancer, blood- and tissue-changes with reference to diagnosis and treatment, 297
——, researches on the epidemiology, made in Iceland and Italy (July-October, 1924), 39
Castellani's endemic funiculitis in Kenya Colony, three cases, 137
—— fermentation phenomenon, observations, 426
Central America, observations on some diseases of, 1
Ceylon, some observations on common endemic fevers, 349
Cholera, its treatment and complications, 261
Climate, influence of, and malaria on yaws, 85
Coloured persons, fly-proof latrines for, 231

CORRESPONDENCE :—

Bat roost, Mitchell Lake, San Antonio, Texas, 392
Bilharzia parasites, 276
Cancer, reported in dogs successively housed in the same kennel, 236
Diseases of Central America, 115

Cultivation, notes, of certain amœbæ and flagellates of man, using technique of Boeck and Drbohlav, 345

CURRENT LITERATURE :—

Abdominal conditions, treatment of some with inflation of oxygen gas, 412
Adhatoda vasica, preliminary note on pharmacology and therapeutics, 391
Ainham, case in right leg, 360
Air embolism, experiments, 412
Aldehyde test in *Schistosomum hæmatobium* infection, 20
Amœbæ of man, chytridial parasites of, 150
Amœbiasis, urinary, 360
Amœbic abscess of liver, 452
Ankylosis of joints, 84
Ankylostomiasis, existence in Turkey, 275
Anthelmintic, notes on carbon-tetrachloride as an, 183
Anthrax, bacterial, in a severely infected area, conclusive experiments on intradermovaccination, 100
Antimalarial campaign at Gagri in 1923 and 1924, 344
Antimeningococcal infection in Belgian Congo, experiments, 274
Antiplague vaccination by mouth in man, experiments of, 274
Antituberculosis vaccination of infants in Cochin China and Cambodia, first experiments, 344
Asthma in Tangiers, frequency, 344
——, treatment, 184
Bacillus flagellatus and *Spirochæta omeliansky* n. sp., 295
Basal metabolism of young man as affected by a normal tropical residence of one year, 451

CURRENT LITERATURE—*continued.*

Batrachia which harbour and propagate certain intestinal flagella of man, 375
Bayer 205 in the treatment of human trypanosomiasis, 36
Beriberi in Annamites of Cochin China, arterial tension and blood viscosity, 360
—— investigations. Avitaminosis and infection in experimental disease of the young pig due to *Bacillus asthenogenes*, 151
Bilharziosis in French West Africa, 216
——, some considerations on the treatment by emetic, 216
Blastocystis hominis, pathogenic rôle, 236
Blastomycosis of lacrymal ducts, isolation of the pathogenic agent, 236
——, on subject of, 236
Blue tongue in French West Africa, introduction, 235
Blood-serum globulin in leprosy, 452
Box-stove, 215
Bronchomycosis due to sterigmatocystis in Urandi, 36
Carbon tetrachloride to cats, toxicity, 411
Cataract extraction, 392
—— ——, choroidal hæmorrhage following, 296
Cephalandra indica, observations on antidiabetic properties, 296
Cerebrospinal meningitis, case due to Pfeiffer's bacillus, 359
Chilomastix mesnili, pathogenic rôle, 236
—— ——, secondary infection of uterus post partum by, 275
Cholera epidemic in Bombay, some observations on the, 20
—— epidemics in Jheria coal-fields, investigation into origin, 184
—— in Bengal: past and present, 327
—— stools, cellular elements in, and their relative importance in diagnosis of the disease, 328
—— treated by various methods, notes on a few cases of, 20
——, treatment by cresol and acid, 275
Clou de Biskra, observed in neighbourhood of Algiers, 275
Coccidiosis, human intestinal, due to *Isospora belli*, 376
Coccidium persicum, nov. sp. parasite of the biliary tract of *Tropidonotus natrix*, var. *persa* Pallas, 150
Dementia præcox, observations, 411
Dercum's disease, case of, affecting whole body except face, hands, and feet in native women of Morocco, 274
Diabetes and insulin treatment in Bengal, 312
Digitalis in Bengal, clinical studies, 275
—— preparations in the Tropics, variations in the potency, 184
Diseases of heart and aorta as met with in Bengal, preliminary observations on acquired, 327
Disinfectants on microbes, action: an interesting phenomenon, 412
Disinfestation of houses by fumigation with cresol, note on, 312
Draconculosis, note on mixture emetic-extract of organs in treatment of, 100
Dropsy and beriberi, problem of epidemic, 149
Dysentery in Mayombe, notes on epidemic of bacillary, 375
——, mixed infection by *Schistosomum mansoni* and *S. hæmatobium* in case of amœbic, 360
Endemic fever accompanied by generalized lymphadenitis, researches, 100
Entamœba dysenteriæ, culture by method of Boeck and Drbohlav, 375
Entamœba from monkey, note on cultivation of, 328
Fuso-spirillary ulcers in Angola, experiments in treatment, 215
—— —— —— ——, note on amœbæ observed in, 216
—— spirochætal affections of skin and mucosæ, anti-spirillar vaccinotherapy in, 344
Glossinæ, contributions to study of geographical distribution of, 36
Glossitis, epidemic observed in Senegal, 360
—— observed in Senegal, communication on nature of epidemic, 376
Goitre, intravenous injections of sodium iodide in treatment of, 276
Hæmaturia, researches in Egypt, 100
Hæmogregarina of horned viper; its forms of reproduction, 344
Hæmorrhoids, treatment by strangulation and snipping method, 392
Helminthiasis, intestinal, in French colonies, 215

CURRENT LITERATURE—*continued.*

Herpetomonas found in gut of sandfly *Phlebotomus argentipes*, fed on kala-azar patients, note 83
—— *muscæ domesticæ*, life history, 84
Hookworm disease, combined carbon tetrachloride and oil of chenopodium in treatment of, 275
—— eggs and larvæ, animals as disseminators of, 19
—— in Palestine, 451
—— infection, notes on some methods for diagnosis, and for estimating egg output, 411
—— larvæ in soil, migration of, 184
—— —— soil acidity and survival, 434
Hymenoptera bethylide which stings man in habitations of the Congo, 36
Indian tick-typhus, 183
Insulin, note on testing in India, 84
Intestinal affections in French Sudan, 136

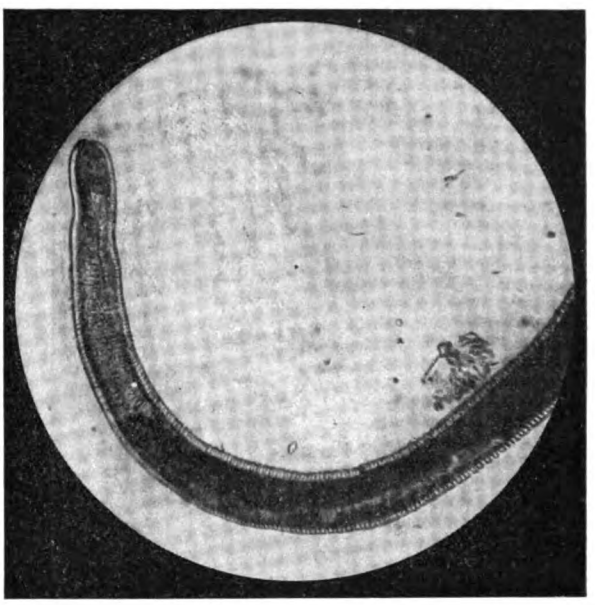
OBSERVATIONS ON SOME DISEASES OF CENTRAL AMERICA.[1]

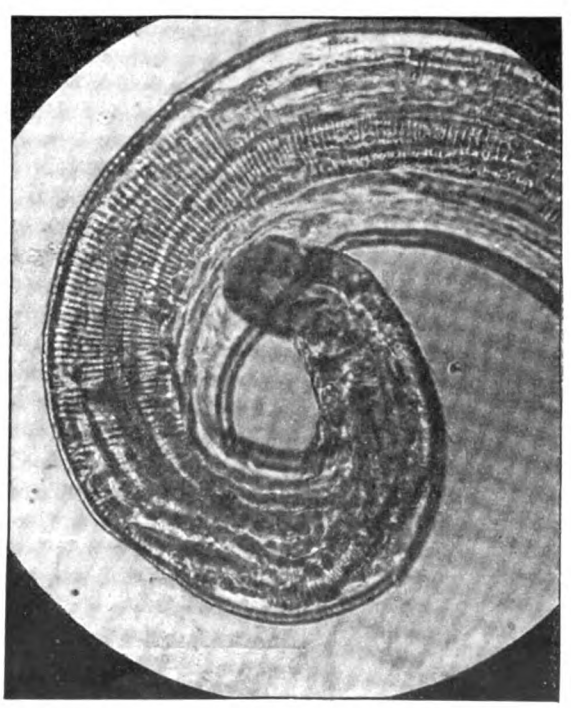
By Aldo Castellani, C.M.G., M.D., F.R.C.P.

During my recent visit to Central America, which I undertook, together with several colleagues, at the invitation of the United Fruit Company of America, I had the opportunity, thanks to the kindness of the Company's officers, to see a very large amount of most interesting clinical material, and in the brief sojourns at the various places we visited I was also given every facility to study certain cases in the magnificent hospitals and laboratories of the Company, as well as in the well-equipped local Government Hospitals of Guatemala, Costa Rica and Panama. There was, of course, no time to carry out any investigation, but I was able to collect a certain amount of material and to make a few observations, which I venture to think may perhaps be of some slight interest, as several of the diseases found in Central America are not well known to us in Europe, though most of them have been thoroughly investigated locally.



I propose touching briefly on the following subjects:—

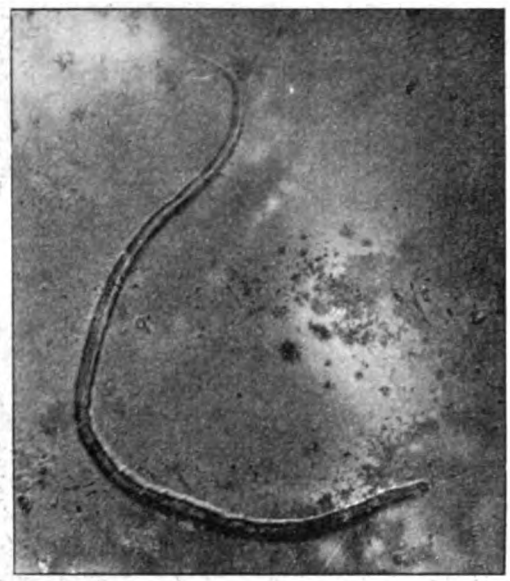
(1) Guatemala nodules (Guatemala onchocerciasis).
(2) Central American myasis (el torsalo, gusano).
(3) Tropical rhinoscleroma.
(4) Alastrim.
(5) Dermal leishmaniosis of Central America.
(6) Granuloma inguinale.
(7) Mycotic diseases.
(8) A new type of mycotic stomatitis.
(9) Pineapple estates pyosis.
(10) Dermatosis papulosa nigra.
(11) Mossy foot.
(12) The red mite of Panama.
(13) Pinta.



Guatemala Nodules.

(Onchocerciasis of Guatemala).

Historical.—For some years local practitioners, planters, and farmers of certain districts of Guatemala, on the Pacific slopes of the country, had noticed that a large number of the Indian labourers on the coffee plantations presented some peculiar nodules on the scalp. They had also noticed that these carriers of nodules often suffered from eye-trouble, and that another condition was common in the same district, characterized by swelling of the face and fever, usually known locally as "erisipela de la costa." These conditions apparently did not attract the attention of any investigator and nothing was published, even from the mere clinical point of view, until Robles, in 1915, began his researches and elucidated the etiology of the nodules by finding in them adult filariæ of the *Onchocerca volvulus* type and enormous numbers of microfilariæ. Robles came also to the conclusion that the same filaria was the cause of the eye condition so often found in carriers of the nodules, and that it was also the cause of the erysipelatous affection of the face known as "erisipela de la costa"

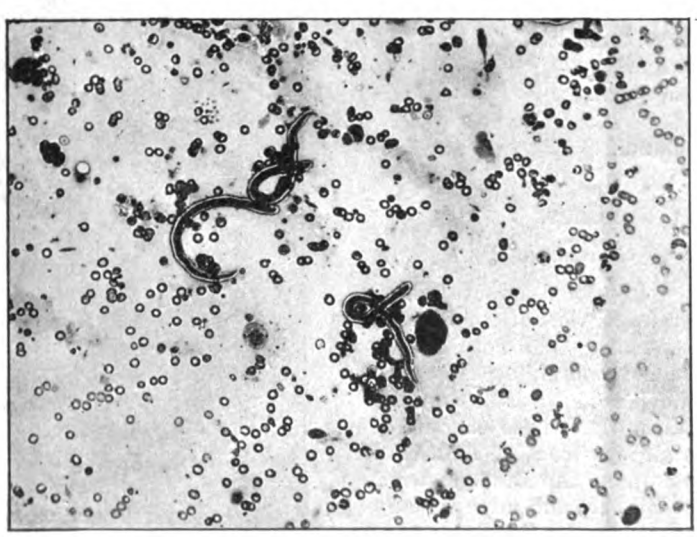


Onchocerca cæcutiens, female. (From Dr. V. M. Calderón.)

Onchocerca cæcutiens, male. (From Dr. V. M. Calderón.)

[1] Amplification of a paper read before the Royal Society of Medicine (Tropical Section), November 13th, 1924.

(erysipelas of the coast). Robles sent some of his material to Brumpt, who confirmed his findings and created a new species for the filaria: *Onchocerca cæcutiens*, Brumpt, 1919, the blinding filaria.

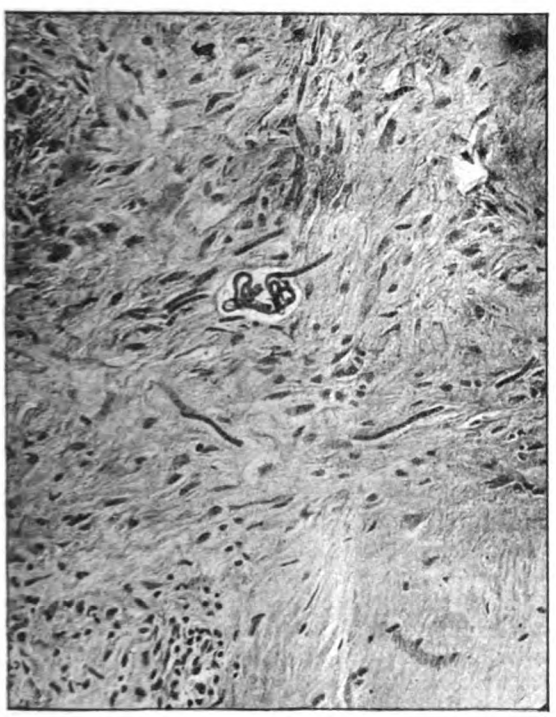


O. cæcutiens, microfilaria.

Robles' work was confirmed and greatly enlarged by Calderón, who carried out a large number of researches on the experimental reproduction of the nodules and the transmission of the filaria, and for this purpose lived for three years on a distant coffee plantation in which the disease was common. The more recent work of Fülleborn is also of great interest. He doubts whether the new species of filaria created by Brumpt is valid, as he sees no morphological differences between *O. cæcutiens* Brumpt, 1919, and *O. volvulus* (Leuckart, 1893); he does not believe that "erisipela de la costa," and the eye condition are in any way connected with the nodules and the filaria.

While in Guatemala, thanks to the kindness of Dr. Calderón, and the Superintendent of the General Hospital of Guatemala city, I had the opportunity of seeing and studying eleven cases of nodules, most of them presenting also eye trouble. Dr. Calderón was good enough to allow me to take some photographs, and also very kindly gave me some of his own photographs and drawings, and some excised nodules. Professor Fülleborn, and Dr. Zupuka too, kindly gave me some material. I was also present at the operation of the removal of the nodules from three cases.

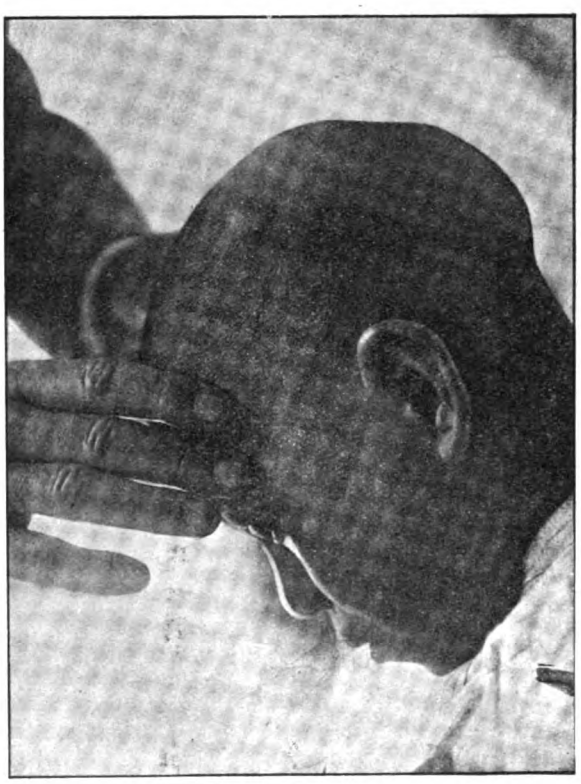
Geographical Distribution.—The geographical distribution of Guatemala nodules is extremely limited. The condition has been found, so far, only in a narrow strip of land on the Pacific Slopes of Guatemala (districts of Sacatepiquez, Escuintla, Chilmaltenango, Solola) at an altitude of 600 to 1,200 metres, and no cases have been reported from any other Central American country. Personally, I am inclined to believe that further investigation will reveal that the condition is not so limited, and is probably present in other Central American countries. Fülleborn states that a Mexican planter has described to him a nodular condition of the scalp which sounds very much like Guatemala nodules, in certain valleys of Southern Mexico, especially in the valley de Custipec, at an altitude between 800 and 1,400 metres.



Etiology of Guatemala Nodules.—The examination of the nodules, as found by Robles, shows adult filariæ of the onchocerca type and an enormous number of microfilariæ. The morphological characters of the filariæ and of the microfilariæ are apparently identical with those of *Onchocerca volvulus* (Leuckart) of West Africa; but Brumpt has created a

O. cæcutiens microfilariæ. Film made from the surface of an excised nodule.

new species *O. cæcutiens*, basing it principally on the fact that the two filariæ give rise to two somewhat different clinical pictures: in African onchocerciasis the nodules are more frequently found on the body than on the scalp, while in Guatemala onchocerciasis the nodules are mostly found on the scalp. Moreover, in the African onchocerciasis eye symptoms are rare or absent.

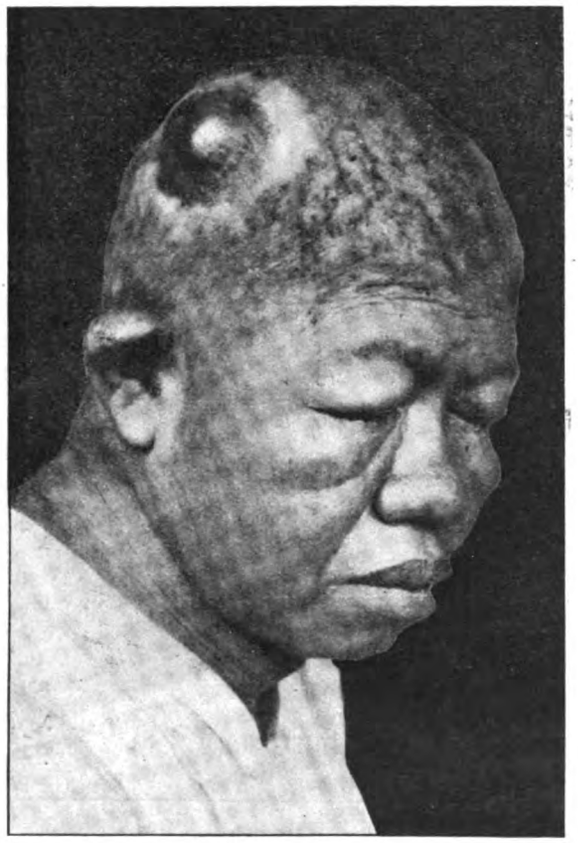


The average dimensions of the *O. cæcutiens* are as follows: male, length 24 to 42 mm., breadth 154 to 190 microns; female, length as much as 50 mm., breadth 300 microns; vulva situated about 800 microns from anterior end. Eggs oval. For further morphological details the reader is referred to the interesting paper of Brumpt in the *Bull. de Path. Exotique*, p. 442, July 9, 1919.

Guatemala nodule. Section stained with hæmatoxylin-eosin. Note microfilariæ.

Clinical Symptoms.—In a well-marked case several nodules, each the size of a pea to a large nut, are seen on the scalp, though less frequently they may be found also on the body, especially on the sides of the chest close to the ribs. The nodules are deeply embedded in the subcutaneous tissues, and the skin over them is often movable, so much so that the first impression may be when they are in proximity of bones that they form part of these. Occasionally the scalp nodules develop under the periosteum, producing concavities in the bones, and in rare cases these may become perforated, and nervous symptoms, such as Jacksonian epilepsy, may make their appearance. The nodules, as a rule, have no tendency to spontaneous cure; very rarely they may become absorbed; in exceptional cases they come to suppuration.

The Eye Symptoms.—A large number of carriers of nodules present severe eye-symptoms which, however, according to Fülleborn and others, are not related in any way to the filarial infection. The eleven cases I saw at Guatemala city, nine of them under the care of Dr. Calderón, all showed in various degrees eye-symptoms which may be briefly described as follows: There is severe photophobia; the palpebral conjunctiva is very hyperæmic; there are often signs of keratitis, so-called keratitis punctata, and later diffuse keratitis. In a number of cases the pupils are somewhat distorted and do not react either to light or accommodation, or only in a very sluggish manner. The fundi are generally normal.



-- Guatemala nodules.

Are the Eye Symptoms connected with the Filarial Infection?—As I have already stated Fülleborn and others maintain that the eye-symptoms observed in so many carriers of nodules have nothing to do with the presence of the filarial nodules; they are observed, they state, in a number of natives who do not suffer from onchocerciasis. In my opinion they are connected with the nodules and the onchocerca. Dr. Calderón showed me a number of histories of cases, from which it was clear that the eye-symptoms as a rule improved very quickly after removal of the nodules, and later on cleared up completely. It is on record that patients who were absolutely blind regained their sight perfectly ten days after the operation. Calderón is inclined to believe that the eye-

symptoms are not caused by any mechanical action of the filaria, but by toxins secreted by it.

Erisipela de la Costa (Erysipelas of the Coast).—In the districts in which the nodules are common a condition is very frequently observed characterized by the following symptoms: The patient, without practically any prodromata, suddenly develops a high temperature without rigors; the temperature very quickly rises and remains high (103-104°) for two or three days, when it rapidly falls to normal with little or no sweating. At the same time that the temperature rises, and while the temperature lasts, the skin

Guatemala nodule and "coast erysipelas."
(From Dr. V. M. Calderón.)

of the face, scalp and ears becomes œdematous and rather hard, and occasionally, especially at the tip of the nose, a peculiar bluish-greenish discoloration is seen; there is no redness as in ordinary erysipelas. The œdema gradually disappears after the temperature has become normal, but the skin on the face, and especially on the forehead, often remains somewhat rough, occasionally slightly thickened, and there may be a very slight pityriasic desquamation.

Is the so-called "Coast Erysipelas" connected with the Nodules? Is it a Manifestation of Onchocerciasis?—Fülleborn and others consider that this condition is not connected with the filarial nodules. Personally, especially after seeing two of Dr. Calderón's patients, who had just recovered from an attack of coastal erysipelas and had nodules on the scalp, I cannot help thinking that coastal erysipelas is a manifestation of the *O. cæcutiens* filariasis. In fact, in my opinion, the nodules, the keratitis, and the coastal erysipelas are manifestations of the same condition—*O. cæcutiens* infection.

Diagnosis.—In the districts in which the condition is endemic the diagnosis is extremely easy. In any doubtful case puncture of the nodules will clear the diagnosis. It may be stated here that, as first observed by Calderón and Fülleborn, microfilariæ are found in the subepidermal tissues of the skin in parts of the body which are situated far from the nodules; they are rarely observed in the blood of the general circulation.

This is perhaps the place to say a few words on Guatemala nodules in relation to African volvulosis. Are the two conditions the same? Are the two filariæ identical? Fülleborn considers the two filariæ identical; Calderón in one of his papers expresses the opinion that onchocerciasis may have been introduced into Guatemala by Jamaican blacks whose ancestors came from West Africa. It is to be noted, however, that the condition is absolutely unknown in Jamaica. Personally, I am inclined to believe that the two conditions, West African onchocerciasis and Guatemala onchocerciasis, although very similar are not identical. As regards the morphological identity or otherwise of *O. cæcutiens* with *O. volvulus* this is a subject to be investigated by helminthological experts. It should be remembered, however, that many parasites which were considered to be identical even a few years ago have now been demonstrated to be different species.

Prognosis.—The nodules, after reaching a certain size become quiescent, and the attacks of coastal erysipelas, too, after some time, seem to cease, but the eye-symptoms become steadily worse, and in a number of cases total blindness ensues.

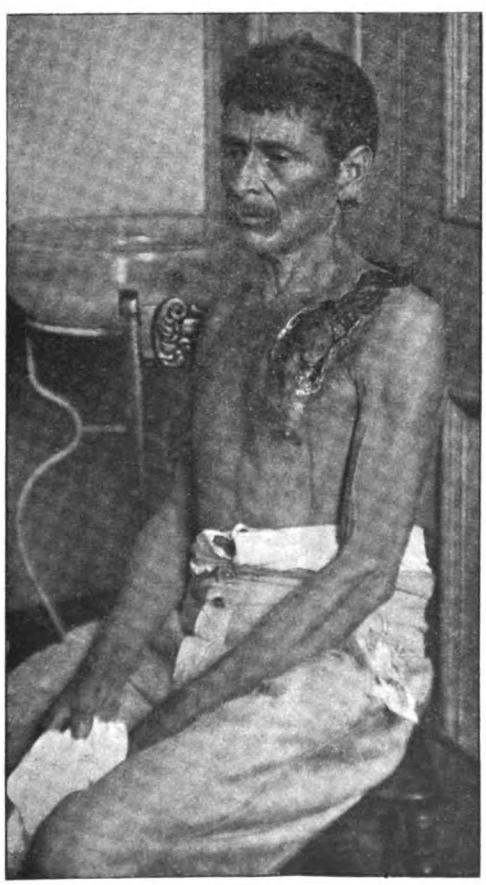
Transmission of Guatemala Nodules.—Robles suspected at first certain species of *Simulium*. Calderón's recent researches tend to incriminate a *Culex* mosquito.

Treatment.—This is surgical enucleation of the nodules under local anæsthesia. Tartar emetic, salvarsan, neosalvarsan have been given intravenously without any benefit whatever. Fülleborn has tried the intranodular injections of cocaine, but no definite results were achieved.

Prophylaxis.—Very little is known on this subject; if Dr. Calderón's researches are confirmed, anti-mosquito measures will be found useful.

In concluding this section of my paper it is my pleasant duty to express my deep thanks to Dr. Calderón for his kindness in allowing me to examine a number of his patients, and for giving me a large amount of material; my thanks are also due to Professor Fülleborn for much valuable information given me, especially with regard to the morphology of the filaria and the literature on the

Central American Myasis.

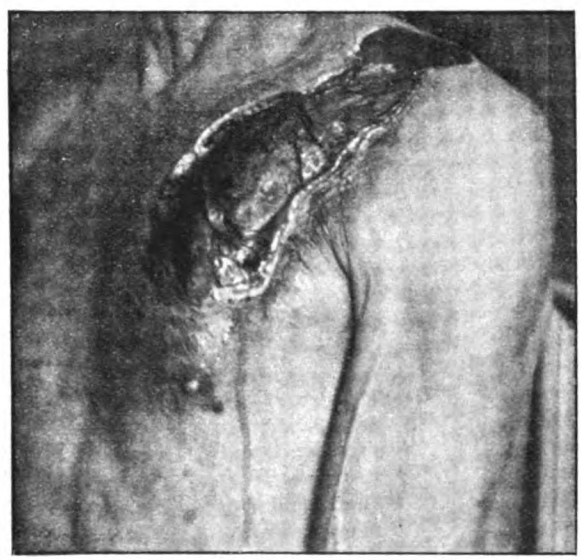


(El Torsalo, Cusano, &c.)

Myasis is extremely common in all Central American countries. Two types must be distinguished :—

(1) *Primary Myasis.*—The fly-larva is the true cause of the condition.

(2) *Secondary Myasis.*—The fly-larva is a secondary invader.



The commonest form of myasis met with is the "furuncular," or "boil-like," type. The condition is very painful, and at first looks like an ordinary large boil; later, at the apex, a small aperture is seen covered by a crust, on removal of which, not rarely, a moving body with two small brownish-yellowish spots (the posterior end of the larva) can be seen. If the condition is left to itself, in due course the larva dilates the opening by means of its posterior end and eventually escapes, and, falling to the ground, crawls away and becomes a pupa.

Case of severe myasis due to *Crysomyia macellaria*. (From Dr. Picado and Dr. Umana.)

As regards the mode of infection there is a consensus of opinion at the present time that the eggs of *Dermatobia hominis* (Linnæus, junior, 1781) better known as *D. cyaniventris* (Macquart, 1843) are carried by the female mosquito of the species *Janthinsoma lutzi* (Theobald). It would appear that the fly seizes the female mosquito and attaches her eggs to the ventral aspect of the abdomen; it has also been suggested that the fly deposits the eggs upon foliage, and these accidentally reach the mosquitoes.

The treatment is surgical; in the first stages opening of the boil and removal of the larva; in the later stages extraction of the larva by means of forceps.

From Dr. Picado and Dr. Umana.

For more details on Central American myasis the reader is referred to the recent monographs and papers on the subject by Umana, Sambon, Arias, Picato and others.

Tropical Rhinoscleroma.

Rhinoscleroma is generally considered to be a disease of Eastern Europe, principally Austria, Poland and Russia. A few cases have been reported from other countries in the temperate zone and in the subtropics. It is extremely rare in the tropics, but there is one exception, Guatemala. For reasons unknown the condition is, comparatively speaking, quite common in that country, and at the General Hospital of Guatemala city I had the opportunity of seeing six cases.

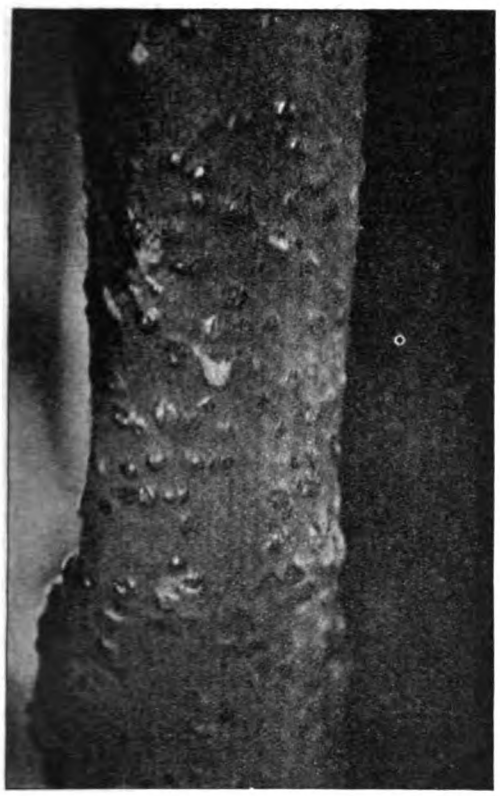
Rhinoscleroma, as is well known, is a disease of the nose which begins insidiously with the formation of a painless pink or red nodule in the anterior nares or on the surface of the nose, or on the adjacent part of the upper lip. The characteristic feature of the nodule or nodules is the peculiar cartilaginous or stony hardness. The nodules after a time may coalesce into a large mass, which often completely blocks up the anterior nares. The surface of the mass is smooth and tense, and tends to crack. The tumour has a tendency to recur after removal. The disease is believed to be caused by the bacillus of Frish, which is a bacillus closely allied to Friedländer's pneumobacillus. With regard to the cases I saw in Guatemala city, in three of them an ulcerative pro-

cess, clinically resembling leishmaniosis, was present, and in one verrucoid lesions were seen which clinically looked very much like blastomycosis. These ulcerative processes, however, were apparently secondary, and had developed on true rhinoscleroma, as certain portions of the masses were extremely hard, like bone, and such hardness is not a feature of simple blastomycosis or leishmaniosis. Unfortunately, there was no time to investigate the cases, and two slides I took from one of them were mislaid. The routine treatment of rhinoscleroma at the Guatemala City Hospital is by X-rays.

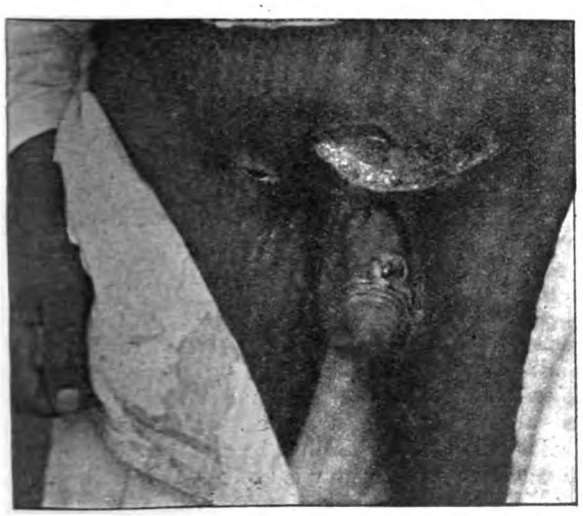
Rhinoscleroma (case seen at the General Hospital, Guatemala City).

ALASTRIM.

In Jamaica we saw a large number of cases of alastrim, and among the various colleagues who saw them the usual discussion took place. Is alastrim a synonym for smallpox, or is it a different disease? The majority, including myself, was inclined to come to the conclusion that alastrim and smallpox are due to two slightly different viruses. The eruptive elements can hardly be distinguished, but in practically all the cases we saw, even in those with a most abundant eruption, the general condition of the patient was remarkably good, and we were told that secondary fever is generally absent. The scarring and pitting in convalescents was much less marked than in convalescents of typical smallpox. The mortality, in contrast to the high mortality of smallpox, was less than 1 per cent. It is known also that Jenner's vaccination may be successfully carried out shortly

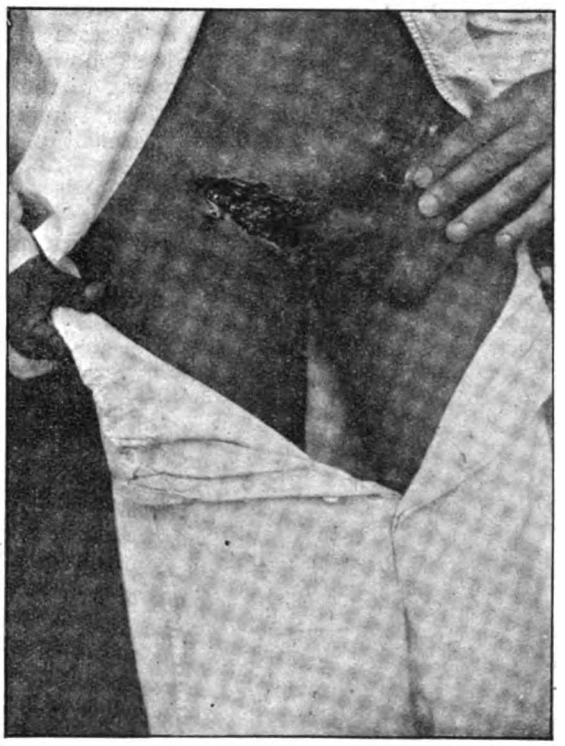


Alastrim (Jamaican case).

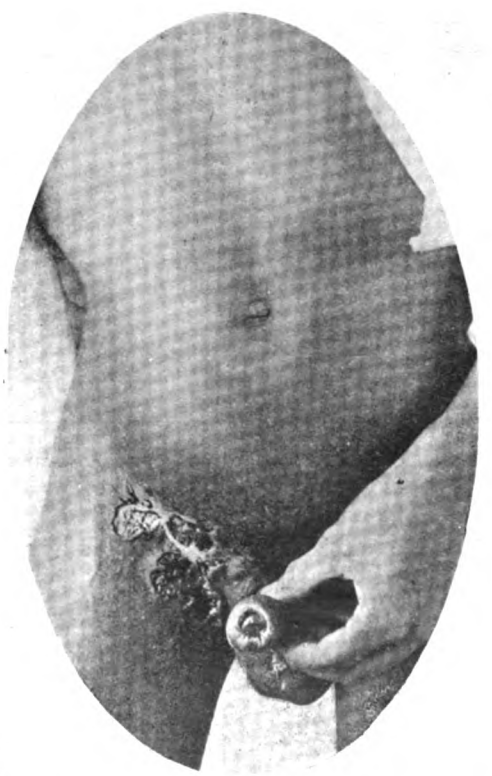


Alastrim (Jamaican case).

after an attack of alastrim. Remembering how many varieties of relapsing fevers there are, it seems to me hardly surprising that there should be at least two varieties of smallpox.



Alastrim (pustular eruption on the forearm).

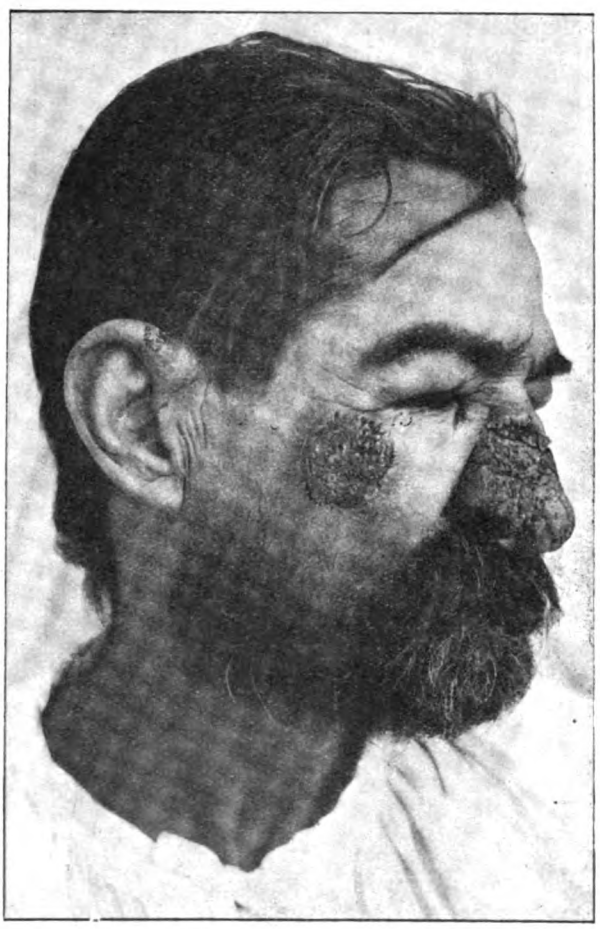


Granuloma inguinale.

Granuloma Inguinale.

This condition is common all over Central America, especially in coloured people. Bass and Jhons have found it also much further north, in the States, in

Granuloma inguinale.



Granuloma inguinale. (Courtesy of Dr. Perez Anleu.)

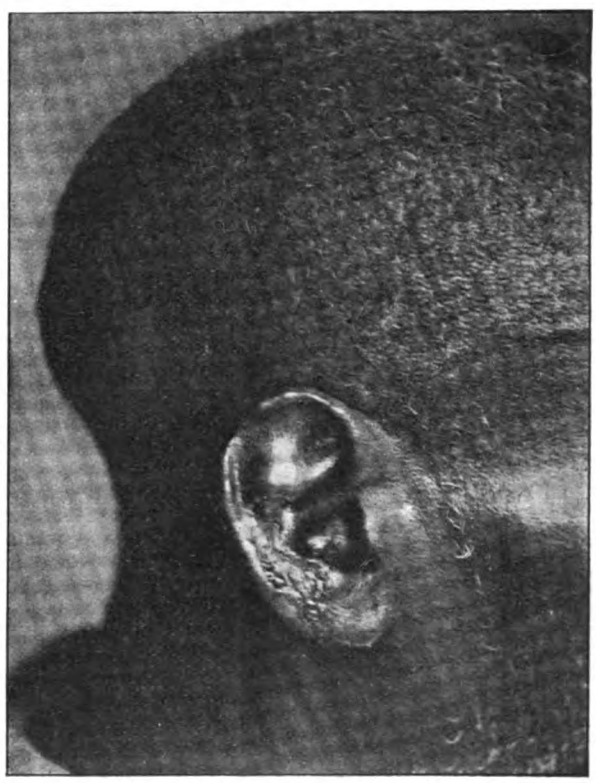
Louisiana. Some beautiful cases were shown to us in the Porto Castillas Hospital. In most cases scrapings from the ulcers made by Dr. Jhons showed the presence of Donovan bodies. According to the experience of medical men practising in Central America, tarter emetic answers well in the treatment of this disease.

Dermal Leishmaniosis.

Three types of dermal leishmaniosis are seen in Central America in my experience.

(1) The espundia type, affecting the nose, palate and throat.

Leishmaniosis of the face (Courtesy of Dr. Ovares.)



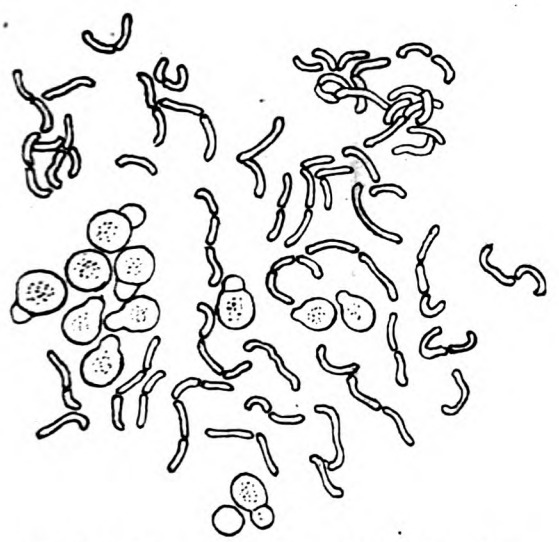
(2) The frambœsial type, characterized by the presence of large nodules somewhat resembling yaws. These nodules occasionally may resemble blastomycosis. A sub-variety of this is leishmaniosis of the lobe of the ear in which the nodule ulcerates quickly and the result is a large loss of substance.

(3) The oriental sore type. This is, clinically, absolutely identical with the conditions so common in certain parts of Asia and Africa, and which goes by the name of "Aleppo boil," "Delhi boil," "Biskra boil," &c.

It is interesting to note that Noguchi has found in Brazil that serologically the leishmania isolated from espundia cases is different from the leishmania isolated from oriental sore cases. The tartar emetic treatment answers apparently better in the espundia and yaws types than in the oriental sore type.

A New Type of Mycotic Stomatitis.

In Honduras I saw two cases of a peculiar mycotic stomatitis, quite different clinically from ordinary thrush. The patches, which were of large dimensions, situated on the oral mucosa and tongue, were much less raised than in thrush and not so creamy-white: they looked much more like a thin, translucid, whitish film covering parts of the mucosa. The



Leishmaniosis of the ear.

first impression was that they were patches of incipient, diffuse leukoplakia of the smooth type. Definite ulcerative lesions were not present. I was able to make some scrapings and immediately inoculated a few glucose-agar tubes. The result of the mycological investigation has been rather interesting; the condition is probably caused by a bacillus and a rather delicate yeast-like fungus which apparently live in symbiosis. Until very recently I did not succeed in separating the two by plating or other devices. By using certain media I have now separated the two organisms, but I have not yet completed the biochemical investigation of them. In contrast to the fungi-producing ordinary thrush the colonies of this fungus and bacillus are extremely

minute and delicate. The reactions of the associated organisms in sugar media are as follows :—

	3 day	7 day
Lactose	A	A
Saccharose	O	O

Symbiosis of yeast-like fungus and bacillus. (From glucose agar culture.)

Mycoses.

Internal mycoses, as well as external mycoses, seem to be quite common in all Central American countries. Cases of Bronchomycosis have been placed on record by Picato and others, Cutaneous Blastomycosis and Sporotrichosis are not rare. Picato has described a peculiar tinea-like affection of the scalp due to a Penicillium. From a case of peculiar ulcerative condition I grew a fungus which I have not yet completely investigated. Ringworm infections of the body are common. I saw several cases of Trichomycosis axillaris flava and rubra, but none of trichomycosis nigra.

Sporotrichosis. (Courtesy of Dr. C. Picado.)

Pineapple Estate Pyosis.

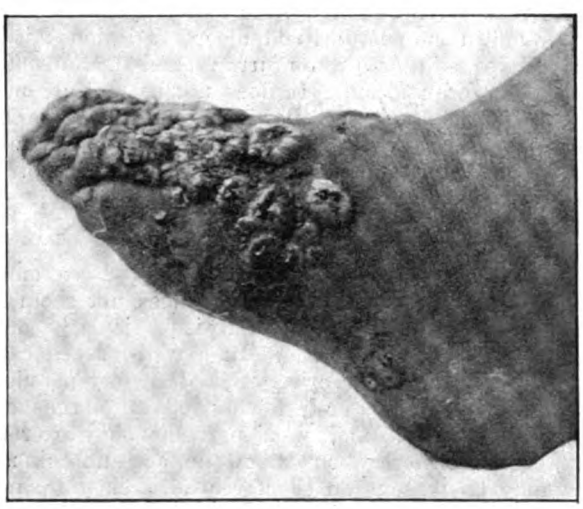
In the lower districts of Costa Rica, in the pineapple plantations, a large number of labourers suffer from a type of pyosis, affecting principally the hands and arms, feet and legs. Numerous flattened pustules are seen, some of which break, and small, shallow ulcerations are formed. The hands and arms may be somewhat œdematous. There is little or no itching and usually no fever. The condition heals under a simple antiseptic treatment within ten or twelve days.

As regards the ætiology, the usual pyogenic cocci are found in the pustules and ulcerated lesions ; it is not scabies, as there are no furrows, and the *Sarcoptes* has never been found. It does not seem to be primarily caused by some other mite, as is the case for instance with copra-itch, as pruritus is absent or only slight, but this point might be further investigated.

Dermatosis Papulosa Nigra.

In Jamaica and Central America I have cmoe across a peculiar dermatosis which does not seem to have been described previously. It is particularly common in natives of Jamaica. In a well-marked case a large number of black or very dark-brownish papules, somewhat cupoliform or flattened, are seen on the face, principally on both malar regions, while they are rare or absent on the lower parts of the face and chin : a few may be present on the forehead. They are not pruriginous and not painful. The maximum diameter of each papule varies between 1 mm. and 4 or 5 mm. At times two or three papules are very close together and seem to coalesce. The first papules appear in youth. I have seen them present in small numbers in boys and girls of 16 to 18 years of age. The condition gradually becomes more marked, and the papules increase in number and size the older the patient becomes, and it is quite common to see middle-aged men and women with their faces studded with these black papules.

Histology.—The structure can be best seen in sections stained by Weigert's iron hæmatoxylin and van Geison where the corium or true skin is stained pink and the epithelial layers yellow. The histological description will be given in a future paper, which I am writing jointly with Dr. Mackenzie Douglas.

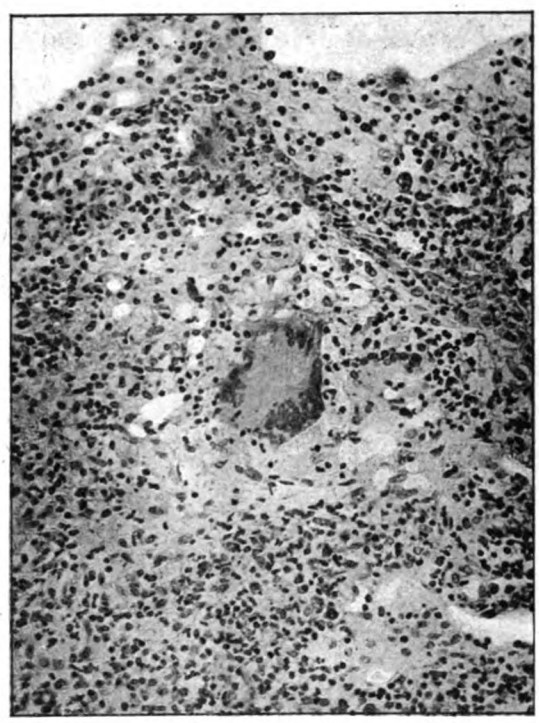


Diagnosis and Ætiology.—The papules are not ordinary warts nor senile warts, lacking the verrucose surface of the former and the greasy appearance of the latter. The ætiology is unknown.

Treatment.—This is very unsatisfactory. The papules may be destroyed by using the micro-burner,

or a strong solution of formalin, but small white marks as a rule remain permanently, and to this the coloured people object more than to the black papules.

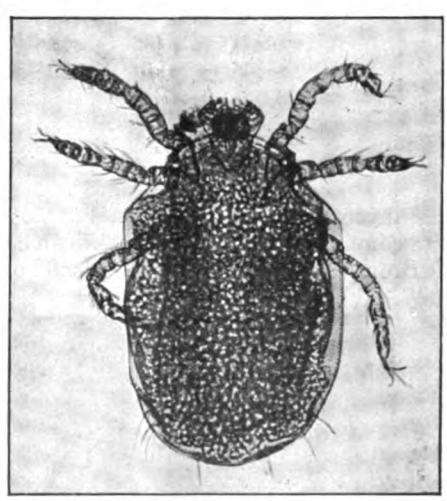
Central American Mossy Foot.



In Costa Rica and Guatemala several medical men informed me that there exists there a peculiar granulomatous condition of the foot, which was considered by some to be a type of madura foot, by others a malady *sui generis*. At Port Lemon I had the opportunity of seeing a case; parts of the dorsum of the foot and toes were covered with granulomatous nodules and masses covered by yellowish dirty crusts. Removing these, the nodules looked very much like yaws nodules but more diffuse, with a granulomatous or papillomatous red surface, exuding a thin secretion, which later on thickens into a crust. Wassermann was negative. I identified the case with the "mossy foot" described in Brazil by Thomas. The condition must be distinguished principally from madura foot,

Mossy foot.

yaws and verruga peruviana. In madura foot there are sinuses discharging a purulent secretion containing sclerotia; both sinuses and sclerotia are absent in mossy foot. In contrast to yaws, the condition is found only on the foot and occasionally the legs, but on no other part of the body, and moreover Wassermann is negative. With regard to the ætiology, nothing definite is known. The treatment is most unsatisfactory; tartar emetic, salvarsan and neosalvarsan having no effect whatever, the administration of potassium iodide and mercury is also ineffective. I suggested that X-rays might be tried.



Histology.—Dr. Mackenzie Douglas has noted that the corium is œdematous at places, at other places there is infiltration with lymphocytes and epithelioid cells, closely resembling the appearance seen in granuloma. Here and there giant cells are seen surrounded by epithelioid cells and small round cells, as seen in typical tubercular follicles. No *Bacillus tuberculosis* could be found, however, in sections stained by Ziehl-Neelson.

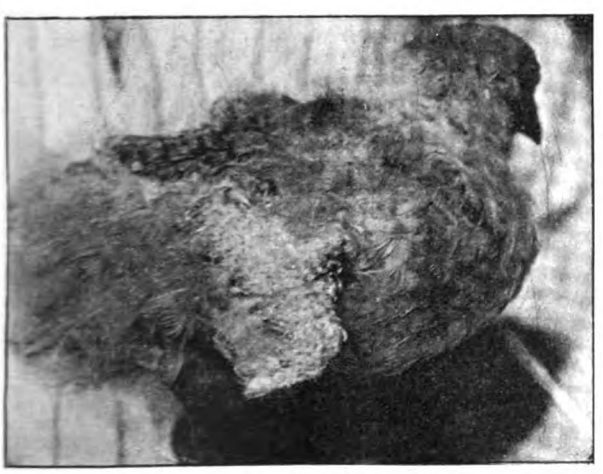
Mossy foot. Section stained with Weigert-hæmatoxylin. Note giant cell.

The Red Mite of Central America.

All over Tropical America, and principally in certain countries of Central America, Honduras and Panama, red mites are extremely common which attack man,

The "red mite" of Central America (*Trombicula tlalzahuatl*).

small mammals and birds. They are known by various names: in Mexico the red mite found there



DERMATOSIS PAPULOSA NIGRA.

PINTA.

is called *tlalzahuatl*, in Guiana a similar mite is called the *Balata* or *pou d'agoute ;* in New Granada there is the *naibi;* in Cuba the *colorado ;* in Martinique the *bête rouge*. In Argentine and Uruguay the *Tetranychus molestessimus* (Weyenberg, 1886) is a great pest ; it differs zoologically from the above-mentioned mites, belonging to the family *Tetranychidæ ;* it lives in a web on the interior surface of the leaves of *Xanthum macrocarpum* and attacks man and animals from December to February. Very little is really known of these various mites, and the whole subject in my humble opinion requires revision. I will limit myself to saying a few words on the red mite of Panama and Honduras. While there recently I collected a number of specimens of the red mite and sent them to Dr. Hirst for identification. He has kindly informed me that the mite is *Trombicula tlalzahuatl* figured under the name *Leptus* (Trombicula?) *similis* in his " Mites Injurious to Domestic Animals."

Climatology.—In Central America the red mite is met with principally in the low country, especially

Chicken heavily infested with the red mite of Central America (*Trombicula tlalzahuatl*).

the districts near the coast, but it may be found also, though apparently not in such large numbers, in the hills at a fairly high altitude.

Red Mite Dermatitis.—The mites give rise to an extremely itchy, papuloid eruption, the papules being red and at first rather scattered. True pomphi are not present. In a later stage, owing to scratching and a secondary invasion of staphylococci, a form of pyosis or impetigo may develop.

Experimental Reproduction of the Dermatitis.—If a red mite is picked up, using a toothpick or similar device, and placed on the forearm of the volunteer it will be seen that the little creature moves quickly here and there, and then stops and begins burying itself partially into the skin, and then the patient begins to experience a very severe local pruritus. It is said that the mite buries itself completely into the skin, but this is not so in my experience; the burying is apparently only partial and, after a time, the mite drops off and a papule appears at the place where the mite was.

Lower Animals.—The red mite, in addition to man, attacks many other mammals, dogs, cats, rabbits, &c., but it apparently shows a predilection for fowls and chickens. At Almarantes I have seen a number of chickens with portions of their bodies covered with red specks (the mites) and showing signs of severe sickness with loss of feathers where the mites were more abundant. Numbers of young chicks are actually killed by these pests.

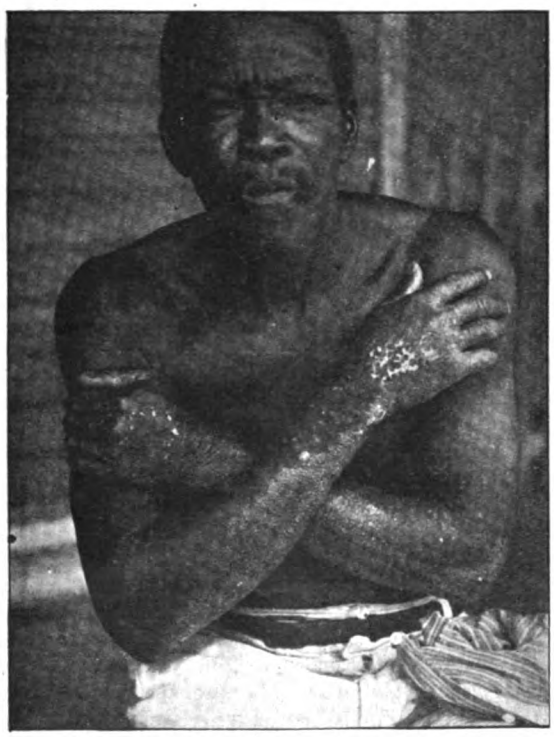
Treatment.—The usual treatment in Central America is sulphur ointment and tincture iodine. What I found most useful to allay the pruritus were carbolic and menthol lotions, especially my old prickly heat lotion which consists of :—

Ac. salicy.	...	...	...	gr. ij.
Menthol	...	...	...	gr. x.
Spir. rect.	...	...	...	ʒij.
Glycerin	...	...	...	ɱxxx.
Zci. ox.	...	...	...	ʒiij.
Calam.	...	...	...	ʒiij.
Aq. rosæ ad	...	...	...	ʒvj.

Prevention.—This consists in wearing high boots, but at times this is not sufficient. It is interesting to see how at Almarantes and other places in Central America even after a short walk in the grass the boots get covered with red mites, some of which go upwards and get inside from the top. Sulphur powder is considered to be a preventive.

Pinta (Carate).

In Honduras I had the opportunity of seeing a number of cases of pinta, more than a dozen, the diagnosis of pinta being confirmed by Dr. Urubuate, of Colombia, an expert on the malady. Two cases of pinta of Mexican origin I saw in Panama, thanks to the kindness of Dr. Connor and Dr. Bates.



Pinta is generally defined as being a dermatosis characterized by the presence of patches of various colours, jet black, bronzine black, violet, red, yellow, and white, and since the investigations of Ruiz Y. Sandoval and of Montoya the disease has been considered to be of mycotic origin. Ruiz Y. Sandoval believed that there was only one species of fungus and that the different colours of the patches were due to the different depths at which the fungus was growing. Montoya found a very large number of different fungi belonging to the genera *Aspergillus* (*Aspergillus pictor*, &c.), *Penicillium* (*Penicillium montoyai*, &c.), *Monilia* (*Monilia montoyai*, &c.), and also fungi with intermediate characters between these genera. According to him the black, blue and violet patches are caused principally by *Aspergillus* fungi ; the yellow variety by *Monilia* and *Aspergillus ;* the white variety by *Monilia*.

During my brief sojourns at Porto Castilla and at Panama, I examined several cases for the presence of fungi by microscopical and cultivation methods. I may quote the results obtained in four cases.

Case I.—Negro boy about 14 years of age, examined at Porto Castilla, Honduras, shown to

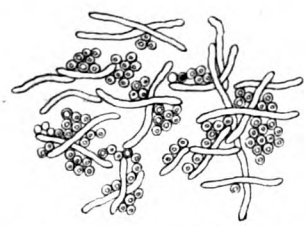
me as a typical case of pinta, diagnosis confirmed by Dr. Urubuate, of Colombia. On the face he had yellow patches which I suspected immediately to be tinea flava; on the chest were several other yellow patches, but with a somewhat different clinical appearance, smoother, with margins not so well defined. On the arms were yellow patches identical with those found on the chest; on the forearms black patches and white patches, not raised, smooth, and looking to me like patches of simple hyperpigmentation (bronzine chloasma-like) and depigmentation (leukoderma); on the dorsum of the hands, white leukodermic-like patches.

Microscopical Investigation. 1. *Yellow Patches on Face.*—A fungus was present in large amount with the characteristics of the fungus of tinea flava (*Malassezia tropica*): Numerous roundish spores, collected in clusters and some mycelial articles; did not grow on glucose agar. I have no doubt that

Pinta. (Case seen at Porto Castilla.)

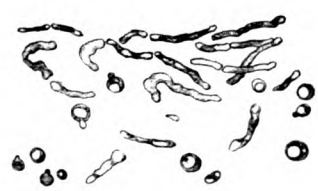
these patches were patches of tinea flava. For the description of tinea flava and its fungus the reader is referred to the "Manual of Tropical Medicine" (Castellani and Chalmers), p. 2073.

2. *Yellow Patches on Chest and Arms.*—A very few yeast-like bodies of large dimensions present, no mycelial elements. A mould-like fungus was grown which I have not yet botanically determined.



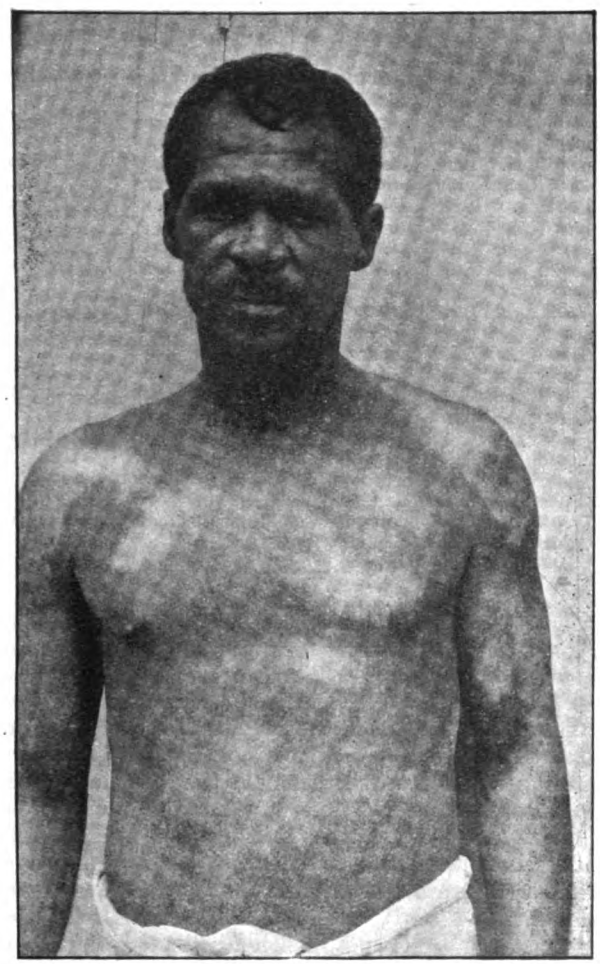
3. *Black and White Patches on Forearms.* Microscopically a few large yeast-like bodies, morphologically identical with those found on the surface of the yellow patches on the chest. The mould-like fungus grown seems to be identical with that grown from the yellow patches on the chest, and those found on the black and white patches.

4. *Normal Skin.* Some large yeast-like bodies present; a mould-like fungus apparently identical with that obtained from the yellow patches on the chest and the black and white patches on the forearms was grown.



Yellow pinta.

CASE II.—Negro, of about 40 years of age. On the forehead and alæ nasi hyperpigmented patches, some bronzine, others presenting a blue tinge (blue



Malassezia tropica, from mycotic yellow patches.

Cladosporium mansoni.

pinta); on the malar region, yellow patches, smooth, with no definite margins; on the upper regions of the arms, diffuse yellow patches; on the forearms, greatly hyperpigmented patches (black); on wrists and hands, patches of depigmentation (white) surrounded by patches of hyperpigmentation. Dr. Banting very kindly made for me sketches of this case.

Microscopical and Cultural Investigation. Scrapings from the bronzine bluish patches on the face and alæ nasi revealed the presence of a few large yeast-like bodies. Identical bodies were found in the yellow patches on the chest and in the black and white patches on the arms and hands. From various patches, and also from portions of the skin which seemed normal, the same fungus, which I have not yet identified, was grown. I am not inclined to give any etiological importance to this fungus as its situation was very superficial; moreover, after washing the skin with soap and water and then applying

Pinta. (Courtesy of Dr. Urubuate.)

alcohol no fungus was detected microscopically, or grown. Scrapings from the yellow patches on the arms contained masses of spores and mycelial elements with all the characters of *Malassezia tropica*. I have no doubt that these were patches of tinea flava.

CASE III.—Negro of about 50 years of age; patches of hyperpigmentation bronzine chloasma-like on the face; on the neck a small black patch slightly raised; on the forearms and hands several leucodermic patches. On the legs and thighs several clinically trichophytic patches with marked hyperpigmentation of the skin. Before making any scrapings all the patches were washed with soap and water and then alcohol. In none of the hyperpigmented patches on the face and apigmented zones on the forearms were fungi seen microscopically, or grown. From the slightly raised patch on the neck, clinically quite different from the bronzine chloasma-like patches on the face, a fungus was found to be abundantly present with the characteristics of *Cladosporium mansoni*. Scrapings from the patches on the legs showed presence of a trichophyton-like organism which I did not succeed in cultivating.

CASE IV.—*Case of Pinta of Mexican Origin.* Patches of different colours, bronzine-black, yellow, and white, all over the body. On the neck, and upper region of the chest typical ringworm lesions. Scrapings in liq. potassæ, from the various pinta patches revealed absence of fungi. It must be noted that scrapings of the epidermis, even of normal individuals, on which liquor potassæ has been acting for a fairly long time often show a large number of oval or roundish formations which might be mistaken for spores of fungi. In any doubtful case staining the preparation will clear the diagnosis. Cultivation showed presence of at least three different species of moulds. These three species were grown from every patch and also from portions of skin which seemed normal. Scrapings from the ringworm patches showed microscopically presence of a typical trichophyton.

Controls. Scrapings from three apparently healthy natives at Porto Castillas were examined microscopically and by culture methods. In two, microscopically, a few yeast-like bodies were found, identical morphologically with those observed in the cases of pinta. Culturally several moulds were grown which also seemed to be identical with those found in pinta. In the third case, no fungus of any kind was present, either microscopically or culturally; only the usual cocci and *B. subtilis* were grown.

Discussion and Conclusions. My investigation of pinta, for lack of time, has been only a preliminary one, and therefore I do not desire to come to any definite conclusions, but I might tentatively state my impressions of the disease *as seen in Honduras*, as follows:—

1. *Yellow Pinta.* This covers at least two conditions. In one, a fungus with all the characteristics of *Malassezia tropica* is found in great abundance; in the other, either no fungus of any kind is found, or, at times microscopically, a few large yeast-like bodies (probably spores of saprophytic fungi), as seen also at times in the black and white patches, and also on the skin of some healthy natives. The first condition is in reality *tinea flava* (Castellani and Chalmers' "Manual of Tropical Medicine," p. 2073), the second might be called yellow pinta *sensu stricto*. In most cases one can make the diagnosis on clinical grounds; the mycotic yellow patches (tinea flava) are generally more sharply limited and may be slightly raised; the non-mycotic patches are not raised and the borders are not usually so sharply defined. It is, in my opinion, probably a process of partial depigmentation, of trophic origin,

a stage in the process of depigmentation from black to white, as in certain cases one can see all the stages from black, yellow, light-yellow, white leucodermic-like.

2. *Black Pinta, including the Bronzine and the Blue Varieties.* Under this heading, too, it would appear that several conditions should be differentiated: (a) Patches of black or bronzine hyperpigmentation with occasionally a bluish tinge, not raised, not pruriginous; no fungi are found microscopically, or only a few spore-like bodies on the surface of the epidermis; cultivation methods may show absence of fungi, or presence of Penicillium-like, Aspergillus-like and other moulds identical with those which one finds at times on the skin of normal natives. The etiological rôle of these moulds, so many species of which have been described by various observers, seems to me to be doubtful and as regards the cases seen in Honduras by me they were in all probability only saprophytes. These patches of hyper-pigmentation appear to me to be very similar, or identical with the various chloasmata (bronzine chloasma, &c.) observed in natives and Europeans all over the Tropics and which are not of mycotic origin. (b) Patches of hyperpigmentation associated with or following on infections with fungi of the group Trichophytoneæ (Atrichophypons, Epidermophytons, &c.) Some years ago I made the observation in Ceylon that chronic infections due to fungi of this group had in some cases a disturbing action on the pigmentation processes of the skin, which became either hyperpigmented or less pigmented, or apigmented, and these patches of hyperpigmentation and hypopigmentation remained visible for years after the fungus had disappeared. These patches in negroes are quite common in the inguino-crural region, also on the back and chest. (c) Black patches caused by the presence in large numbers of *Cladosporium mansoni* (tinea nigra).

3. *White Pinta.* Two conditions may be distinguished. (a) Leucodermic patches, being the last stage in the process of depigmentation, which is represented first by the amycotic yellow patches, and which apparently is not caused by any fungus. (b) Depigmentation patches associated with or following on chronic mycotic infections such as infections with the trichophytoneæ and malassezia fungi.

In conclusion I should like to express my deep thanks to the Authorities of the United Fruit Company for their kind invitation to visit their stations in Central America, and especially should I like to offer my grateful thanks to Dr. E. Deeks, their medical manager. I should also like to express my obligation to all the medical officers connected with the United Fruit Company's hospitals as well as to the doctors of the local Government hospitals for their unfailing courtesy and for their generosity in placing at my disposal a large amount of clinical material.

"A SEARCH FOR INTERMEDIATE HOSTS AND A STUDY OF THEIR RADULÆ."

By F. G. CAWSTON, M.D.Cantab.

ALTHOUGH, in the hotter months of the year in South Africa, it is possible to collect large numbers of fluke-infested examples of the various intermediate hosts, those that are found in the winter months and the following rainy season are remarkably free from cercariæ. In July I examined a large number of examples of *Burnupia gordonensis* from Grahamstown, C.P., and found them all free from cercariæ. The following month I collected numerous examples of *Burnupia*, as well as at least nine other species of fresh-water snail from Avoca, Natal. No cercariæ could be found in *Burnupia*, and even the *Physopses* were free from cercariæ. In October I could find no cercariæ in several *Physopses* from a pool on the Umbilo river at South Coast Junction which, in the bathing season, swarms with the bilharzia parasites.

There would appear to be far less cases of bilharzia disease in Natal as a result of the active measures that have been taken to warn school children of its danger and as a result of the number of infected persons who have recently been effectively cured of the complaint; so that it is only reasonable to expect a correspondingly smaller pro-

portion of fresh-water snails infested with schistosomes; but a seasonal variation would appear to be the more likely explanation, because fewer snails are found infected with other trematode worms. The examples I collected from Avoca were obtained from the Umhlangana or its tributaries where they would be well exposed to possible infestation and have been found harbouring cercariæ in the summer months. For instance, in May, 1924, I found cercariæ resembling *Cercaria constricta* Faust in two examples of *Burnupia* from this same locality. I

Fifty-six rows of identical teeth in Isidora from Mauritius.

Marginal, lateral and central teeth of *Isidora tropica*.

Marginal, lateral and central teeth of *Burnupia stenochorias*.

believe that this is the first occasion that a species of this family of fresh-water snail has been implicated with the spread of distomes: though monostomes have previously been recorded in *B. trapezoidea* Bttg. on the Basutoland border of the Free State, and they also occur in *Burnupia* at Malvern. Some of the rediæ from which these distomes were escaping were equal in length to the diameter of the shell which harboured them, being 4 mm. in length.

Three different species of *Burnupia* have been described from this neighbourhood and, as the shells resemble one another very closely and are somewhat variable, even with Mr. Bryant Walker's careful description of the radulæ it is very difficult to be certain of the identity of infested examples.

In "The Ancylidæ of South Africa," which he published privately in 1923, he observes:—

"The remarkable differences that have recently been discovered in the radulæ of the various groups would certainly tend to strengthen the suggestions that have been made that the family as now recognized is not of homogeneous origin, but of diverse ancestry, and that the similarity in conchological characters should be considered rather as an example of parallel development than as indicating a common line of descent.

"Which of these theories is true can only be determined from a careful and critical study of the entire anatomy of all the genera, and, until that has been done, any general arrangement of the family based only on the characters of the shell and radula can, at the best, be considered only as tentative."

There is certainly a resemblance between the radulæ described by him for *B. stenochorias* (M. and P.) and those of *Physopsis africana, Limnæa natalensis, Isidora tropica* and *Planorbis pfeifferi*, and the resemblance is closer than that of the radula of *I. tropica* and an *I. ? borbonica* which has reached me from Mauritius.

The usual type of jaw in *Limnæidæ* would appear to be characterized by a central unicuspid or bicuspid tooth in from 120 to 150 lateral rows, about eight tricuspid lateral teeth on each side and as many as twenty-one marginal teeth in each row; though there are fewer teeth in the anterior rows. The cusps of the marginal teeth are all divided into a number of denticles. As the base of the central tooth is expanded, the base of laterals and marginals is oblique. There are a total of from six to nine thousand teeth in each individual snail. Although species as far apart as *B. stenchorias* and *I. tropica* possess such similar teeth; until the complete anatomy of the various species is studied and described, help might be forthcoming in the identification of the various hosts of *schistosoma*, were a careful study made of the radulæ of the various species found to harbour schistosomes, and this can readily be done under a one-twelfth magnification, once the radula has been separated from the rest of the snail and cleaned.

Extra-Intestinal Amœbiasis (M. Petzetakis, *Bulletin de l'Académie Royale de Med. de Belgique*, No. 8, September 27, 1924).—Two cases of cystitis and amœbic urethritis are described, both occurring in Egypt. Both patients complained of hæmaturia and urinary trouble. The first had suffered from dysentery two years previously. Examination of fresh urine showed small amœbæ 20-25 microns. Gram positive. Examination for gonococcus negative. The second patient did not remember having had dysentery. Examination of the stools for amœba negative, but living amœbæ were found in the urine, and numerous red globules. Morphologically, this amœba differs from *histolytica*, one of its interesting features is its polymorphism, for which reason the author calls it "*Entamœba polymorphe.*" The question as to how the amœba gained entrance to the bladder remains to be cleared. Injections of emetine completely cured both patients. During the author's researches on amœbic dysentery he has come across tubercular patients whose sputum, besides containing Koch's bacillus, showed the presence of living amœbæ. Injections of emetine caused remarkable amelioration in the general condition of the patient; fever ceased, and only rare amœbæ could be seen in the sputum.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank Ltd.

5.—The Subscription, which is **Thirty Shillings** per annum, may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—**Authors of original communications are entitled to 25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these,** with remittance, **is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 ,, ,, ...	1	3	3
200 ,, ,, ...	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 ,, ,, ,,	2	6	0
200 ,, ,, ,,	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

A WHITE AUSTRALIA: IS IT A POSSIBILITY?

By SYDNEY J. SKERTCHLEY, J.P.

(*Continued from page* 340.)

CHAPTER V.

The "Histories" of the Future.

(70) But we cannot dismiss the subject so cavalierly as this. A few details must be given with regard to our own race, the Fair Whites, and our forebears, the Dark Whites. And it is essential to realize the view one must take of history.

(71) I have already said (par. 7, passim) that I shall neither deal with, nor be drawn into controversy upon, side issues. But I must clearly state what, in my opinion, constitutes a side issue. It has been necessary for me to study ancient and modern history deeply and critically, with the result that I think almost all history will have to be rewritten from the anthropologist's standpoint.

(72) Until quite recently, indeed, until the rise of such scholars as my friend Dr. Holland Rose, there was an unhistorical confusion between the facts of history and the interpretation of historical facts. The seers did not all render Mene Tekel Upharsin in the same terms. To take a very early illustration. In Kings we have the bare facts concerning certain reigns; in Chronicles the same ground is traversed "with advantages," and the misfortunes of monarch and subject are attributed to a distinct cause—and a political one. "He did evil in the sight of the Lord," is simply the euphemistic way of saying, "He did not come up to the views of the compilers of the Priestly Code." Whig and Tory, Cavalier and Roundhead, Colonna and Orsini alike suffer from political chromatic aberration.

(73) In dealing with the rise and fall of nations historians have attributed most of the vicissitudes that have befallen the nations of the earth to personal courage, wise administration, the sense *of* patriotism, the civilizing effect of commerce, the potency of high ethical standards, the ties of a common faith among psychical causes, and to climate and disease, and consequent lessened fertility and increased infant mortality among physical agents.

"Assyria, Greece, Rome, Carthage, where are they?" asked Byron, and the answer tacitly assumed by the historian, as by the poet, is that they became enervated by peace and prosperity, that pleasure took the place of national forethought, and so the dry-rot of inactivity laid the people open to the successful attacks of the stronger, and often ruder, folk who fell upon their flanks.

(74) This seems to me reading history upside down. Truly the alleged causes are fruitful for good and evil. But this is largely mistaking cause and effect. The question why decay sets in is left untouched. And, above all, it fails to discriminate between the decay of a race upon foreign and upon native soil. Nations (and this term is not necessarily the equivalent of races) undoubtedly do decay on strange ground. Witness the Akkadians in Babylonia and the Hindus in Java. Races may decay at their source of origin, but it would be hard to prove it. Rome and Greece are certainly not examples. But, unless climate deteriorates, a race most certainly tends to retain its strength and civilization at home. Herein we have, I think, the true key to the shifting of the centres of power and culture. It is an anthropological question almost purely. Races by their inherent tendency to decay on foreign soil develop the very tendencies which hasten their fall. The Fair Whites are as strong as ever on their own soil, so are the Dark Whites, and

both have degenerated when transplanted. Rome planted her colonies everywhere over the Empire. "Wheresoever the Roman conquers he inhabits," wrote Seneca the Roman, but Roman blood has vanished as completely from the colonia of the province of Asia as from Cologne of Germany or Lincoln of England. Yet were the Romans so certain of their colonizing power (and they exercised it longer than we have) that "in the time of Hadrian," Gibbon points out, "it was disputed which was the preferable condition, of those societies which issued from, or those which had been received into the bosom of Rome." Of Carthage it came to be written "delenda est," and such is the epitaph of every colonia from Euphrates to Severn.

(75) Each race seems to be endowed with certain possibilities, and to possess certain ineradicable limitations, and this our kindly man-and-brother altruists never grasp. East is east and west is west, and this old order changeth not. It is simply not true that the negro and the red man are what they are from want of opportunity or from neglect. They have been on earth as long as we have: the human race started at scratch. But here we are straying somewhat from our path. What I want to insist upon is that the creeping sickness, the sleeping sickness, that comes upon nations is not due primarily to effeminacy born of luxury, but that the desire for luxury and the consequent weakness are but symptoms of the incurable disease, nostalgia. The withers of the nation get unstrung in a strange land, the lax muscle that dreads the sword grip, the half-strung nerves that only tingle to lullabies are all premonitions of the coming day when the national anthem is dethroned by the requiem.

(76) But race is well-nigh immortal on its own soil. Witness the contiguous small states of Holland and Belgium, which not even the matchless genius of Napoleon could weld. Leyden is Dutch from the summit of her Burg, symbol of Rome's powerlessness, to the sluggish Rhine waters that wash her decaying palaces, emblems of her own powerlessness as a colonizer; while Brussels is Gallic from the toe-tip of her impudent Mannikin to the topmost finial of St. Gudule's spire. And where in either shall we find the dusky blood of Alva's Spanish hosts?

Annotations.

Classification of the Hemolytic Streptococci by the Precipitin Reaction (C. H. Hitchcock, *Journal of Experimental Medicine*, October 1, 1924).—A method is described for the preparation from hemolytic streptococci of extracts containing a soluble precipitating substance. By the use of such extracts, it is shown that nearly all members of this family yield a common precipitable substance. So far, therefore, as concerns the precipitin reaction, the hemolytic streptococci form a practically homogeneous group.

The Clinical Value of Bismuth in the Treatment of Syphilis (C. H. de T. Shivers, *Archives of Dermatology and Syphilology*, October, 1924).—Bismuth should not be substituted for arsenic in primary or secondary syphilis, except in patients resistant to arsenical treatment. Bismuth is effective, clinically, in the treatment of all forms of tertiary syphilis. In the treatment of neurosyphilis, bismuth in some cases has proved itself superior to arsenic. It should be tried in all patients that do not tolerate the arsenicals, and should be given with caution in all patients with faulty elimination. The absorption of this drug should be carefully studied, and, if possible, the number of treatments given should depend on the roentgenologic findings.

The Prophylaxis of Congenital Syphilis (Prof. J. Almkvist, *Hygiea*).—That congenital syphilis is derived from the mother is not yet established beyond all doubt, as tests carried out show. It is essential, however, that every pregnant woman suffering, or who has suffered, from syphilis should be given specific treatment during pregnancy. Children born of such women should be kept under clinical and serological observation, no specific treatment being attempted before definite signs of syphilis have appeared. How long this observation period should last is not stated, as it is not yet known how long congenital syphilis may be latent in an infant. Salvarsan is considered to be the most reliable remedy for preventing transmission of syphilis from mother to fœtus.

Studies on Oxidation and Reduction by Pneumococcus (J. M. Neill and O. T. Avery, *Journal of Experimental Medicine*, October 1, 1924).—Certain enzymes of pneumococcus are destroyed by oxidizing agents formed when sterile extracts of the cellular substances are exposed to air. The carbo-hydrate enzymes (sucrase, raffinose, inulase and amylase) are the most easily inactivated under these conditions, although the bacteriolytic enzyme is also reduced in activity. Similar treatment is without effect upon the active concentration of pneumococcus lipase and peptonase. The enzymes which are destroyed during the oxidation of unwashed cell extracts are themselves non-reactive with molecular oxygen. The actions by which they are destroyed seem to represent oxidations of a type similar to those proposed in previous papers for the oxidation of hæmotoxin and of hæmoglobin. A study has been made of the relative resistance of different pneumococcus enzymes to heat and to the action of hydrogen peroxide. The various enzymes may be arranged in the same order of relative resistance whether the rating be made from the standpoint of resistance to heat or of resistance to oxidation. Nevertheless, it appears that by a proper regulation of conditions of oxidation, certain labile constituents of a mixture

of cellular enzymes may be inactivated with less effect upon the activity of other constituents of the mixture than when inactivation is brought about by heat. From this may be concluded that when sterile extracts of the cellular substances of pneumococcus are exposed to the air, oxidizing agents are formed which destroy many of the cell enzymes.

The Blood Platelets in Pneumococcus Infections (H. A. Reimann, *Journal of Experimental Medicine*, October 1, 1924).—A study was made of the behaviour of the blood platelets during the course of pneumonia in man, as also in several rabbits experimentally infected with pneumococci. The number of platelets begins to diminish after the infection has become established. A thrombopenia occurs during the febrile period. Immediately following the onset of the crisis in lobar pneumonia or after the temperature begins to fall by lysis, the platelets begin gradually to increase in number. In the post-febrile period, the platelet count increases until the normal number is greatly exceeded, and there is a return to the normal number only after two weeks. Sequelæ, characterized by fever following pneumonia, are accompanied by a renewed diminution in the number of platelets. After subsidence of the temperature their number usually increases until the normal is again exceeded. The platelets in general are smaller and contain more granules during the thrombopenic stage of pneumonia. Intravenous injection of antipneumococcus serum during pneumonia ordinarily produces no variation in the number of platelets.

Abstract.

THE PREVALENCE OF EPIDEMIC DISEASE AND PORT HEALTH ORGANIZATION AND PROCEDURE IN THE FAR EAST.[1]

A COMMITTEE of experts was appointed by the League of Nations to visit the ports of India and the Far East to investigate the arrangements made for the prevention of communicable disease. The report is of considerable length and gives a detailed account of the procedure and conditions in a large number of ports, and an amount of very useful information on port sanitation work. The conclusions of the document are as follows: Bubonic plague is, all things considered, the most important ship-borne disease in the Orient. It is essentially a disease of rats, and the human case is, for all practical purposes, not infectious. There is abundant epidemiological information, based on a quarter of a century's experience, to justify the consideration of bubonic plague and pneumonic plague as two entirely separate and distinct epidemic diseases. It is extremely doubtful whether the plague bacillus *alone* can give rise to pneumonic plague epidemics. Epidemiological facts indicate the probability that pneumonic plague epidemics are caused by the plague bacillus in symbiosis with another organism. It is probable that this "hypothetical" organism will be found to be non-pathogenic for rodents. Bubonic plague is invariably spread from port to port by means of "rat-favoured" merchandise. The fact that one is able to incriminate such merchandise in the transference of plague infection from place to place implies the relative failure of the human being and his personal effects as vectors of infection. All anti-plague regulations and conventions should be framed with due regard to these facts. Of all forms of rat-favoured merchandise, grain is of chief importance with regard to the facilities given for the transference of plague infection. The control of the grain trade and the proper storage of grain are also synonymous with efficient plague preventive measures. If the association between rats and grain and other rat-favoured merchandize could be broken in the ports of the East, plague would cease to be a ship-borne disease. If due consideration be given to the attributes of the rat, it is possible to erect storehouses that can be kept automatically rat-free. Many "rat-proof" stores now in existence harbour a large rat population. Much more might be done than is done at present to control the rat population of such rat-proof stores; certain suggestions are contained in the note. The present condition of grain storage in many ports of the East is reprehensible and dangerous. Pending improvement in such matters, fumigation at periodic and frequent intervals of ships trading in the East will continue to be a matter of extreme importance. Further work is required to devise more satisfactory methods of fumigation than those at present in use.

The disinfestation before shipment of rat-favoured merchandise from plague-infected localities demands much more consideration than it receives. Such measures should, wherever possible, be taken at the port of departure. The rat-infestation of lighters, barges, employed in Oriental ports is sometimes excessive. Cases of plague among the floating population of certain ports occur from time to time. The periodic fumigation of lighters, barges, &c., employed in all Oriental ports is an important matter that rarely receives the attention it deserves. The history of the spread of plague in the East indicates that attention paid to the usual channels of infection could secure almost absolute immunity from plague, and that without vexatious restrictions to the free flow of commerce. The tendency of the disease to die out in large areas of the East, unless reinforced by repeated introduction of infection, accentuates the importance of preventing such reinfection. From the epidemiological viewpoint, human bubonic plague cases are merely an index of a co-existent rat epizootic. This index is inadequate, or may fail altogether, in circumstances dependent upon either (*a*) the nature of the rat-infestation of the port, or (*b*) the species of fleas that infest the rat. Such facts emphasize the absolute necessity for a systematic

[1] Abstracted from the Report presented to the Health Committee of the League of Nations by F. Norman White. 1923.

and thorough routine examination of rats in all Oriental ports.

British India is by far the most important reservoir of plague infection in the East. Java comes second. The prevalence of the disease in British India is decreasing noticeably in those provinces that have suffered most. The experience of Manilla, Formosa, Shanghai, which have been plague-free for many years, promises a successful issue to a serious attempt to eradicate plague infection from many other Oriental ports at present infected. This task might not be insuperably difficult, except perhaps in the case of Bombay, which, of all large ports in the East, possesses conditions most favourable to plague. The gradual extinction of foci of plague would, by diminishing sources of possible reinfection accelerate the natural tendencies to "die out" which characterize plague on either side of the Bay of Bengal and further east.

In most Oriental towns anti-plague measures are unsuccessful, largely on account of the antagonism of the population to such measures. The disinfection of houses and their contents is the most commonly practised of all anti-plague measures; it excites great antagonism and, as carried out, is of extremely doubtful utility. Suggestions are made regarding a new orientation of plague policy in many Oriental towns

Current Literature.

THE INDIAN MEDICAL GAZETTE.

Vol. LIX, No. 11, 1924.

Animals as Disseminators of Hookworm Eggs and Larvæ (Asa C. Chandler).—It is evident from experiments performed by the author and others that domestic animals constitute an important means of scattering hookworm eggs and larvæ. They do this either (i) by acting as hosts for the parasites, (ii) by transferring fæces or earth containing eggs or larvæ on their feet or other parts of their bodies, and (iii) by ingesting egg-containing fæces and scattering the undamaged eggs in their own droppings. Although *Ankylostoma duodenale* will occasionally develop to maturity in dogs or cats, these animals are negligible as hosts of human hookworms. Pigs harbour a species of necator which closely resembles the human species and is probably only a hostal variety of it. They also occasionally harbour *A. duodenale*. The spread of eggs and larvæ by the feet and bodies of domestic animals and by the scratchings of chickens is obvious. The value of the elimination of this means of dissemination appears greater in view of the absence of active lateral migration on the part of the larvæ themselves. The passage of eggs unharmed through the digestive tract of pigs, rats, and dogs has been proved. In chickens a high percentage is destroyed, probably in the gizzard. Since these various animals feed very commonly on human fæces, this constitutes an important means of dissemination. It has been shown that after feeding on human fæces viable hookworm eggs are passed for at least seventy-two hours in the droppings of these animals. In view of these facts the devouring of fæces by pigs, rats, dogs or other animals, with the possible exception of chickens, cannot be looked upon as desirable on account of the destruction of so much refuse, but rather of a very dangerous process resulting in the dissemination and not the destruction of the most injurious component of the material, namely, the eggs of human intestinal parasites.

Indian Santonin Extracted from the Indian Species of Artemisia maritima (R. N. Chopra and A. C. Chandler).—Santonin extracted from *A. maritima* Linn (*A. brevifolia* Wall), which grows in the mountains of Kashmir (Baltistan), closely resembles in its physical, chemical and physiological properties the santonin imported from Europe. It satisfies all the tests laid down in the British and United States pharmacopœias. Its therapeutic efficacy is just as good. The present market price of the Indian santonin is Rs. 670 per pound, but if it is worked on a larger scale the price could probably be considerably reduced.

A Preliminary Note on the Pharmacological Action and Therapeutic Properties of Kuth Root—Saussurea lappa (R. N. Chopra and Captain Premankur De).—The active principles of *S. lappa* are (*a*) an essential oil; (*b*) a glucoside; (*c*) an alkaloid. The essential oil and the glucoside are pharmacologically active bodies. The alkaloid is less active. The essential oil has strong antiseptic and disinfectant properties especially against the streptococcus and staphylococcus; the alkaloid and the glucoside have little or no effect in this direction. The glucoside causes a small but persistent rise of blood pressure; the essential oil does this in a lesser degree. Both the glucoside and the esssntial oil have a slight but definite broncho-dilatory effect. The alkaloid is inactive in this respect. The powdered root and the alcoholic extract are expectorant and are beneficial in asthma. They cut down attacks and reduce their frequency. The drug has no anthelmintic properties.

Surgical Sundries (C. A. M. Gourlay).—Anæsthesia is a subject of importance to all medical men, whether dealing with accidents or disease. There have been cases of patients dying from shock where anæthesia has not been used. It is the duty of the doctor, nurses, &c., to diminish the factors of shock (anxiety, fear, pain, hæmorrhage and sepsis) as far as possible. Fear is easily overcome by the injection of one-sixth grain of morphine before the patient is carried from his bed to the theatre. A local anæsthetic should be used to ease pain; there is then no need for a heavy dose of chloroform. Some useful notes are also given with reference to the treatment of fractures.

Notes on Malaria in Hill-Stations in or near the Himalayas (C. Strickland).—The incidence of the epidemic in Kurseong is from April to July inclusive, while in Shillong it is from the middle of May to the middle of October. Malaria has been attributed to *Anopheles maculatus* in both places. The difference in the two places of the time of onset is probably due to meteorological conditions which influence the development of the parasite in the mosquito. The difference in the duration of the malady depends on the different geological structure of the two tracts. The only means of preventing malaria, according to the author, is a system of contour hill-foot drains, and as maculatus will breed in these as well as in the swamps, the drains must have either sub-soil pipes laid in them or a ribbon of jungle allowed to grow up over them, which will prevent maculatus breeding inside. If rubble be laid in such drains the effects are likely to be disastrous.

The Relative Value of Diagnostic Methods and Evidence of Cure in Kala-azar (H. E. Shortt).—The author gives a list of the methods used in the diagnosis of kala-azar in the order of relative reliability, as follows: (i) Culture of spleen or liver puncture fluid on N.N.N.; (ii) culture of the peripheral blood by Row's method or on N.N.N.; (iii) examination of spleen or liver puncture films, no cultures taken; (iv) the aldehyde reaction; (v) examination of peripheral blood films, no cultures taken. With regard to cure, where the parasites have been reduced as a result of treatment, the first method is most reliable.

Some Observations on the Cholera Epidemic in Bombay, 1923 (Dr. Purshotamdas T. Patel).—Cholera is mostly introduced into Bombay from other parts of India where it is endemic. In 1923 the epidemic started in June amongst Haj pilgrims who came in large numbers from Bengal side to go to Mecca, mostly aged and infirm; mortality, fifty-eight per cent. Inoculation with cholera vaccine stopped the epidemic after two weeks. A week later a local focus of infection revealed itself. During the months of July and August, 151 cases were admitted into hospital. The disease was spread chiefly by personal contact, food and flies. Death amongst the local cases was twenty-six per cent. This diminished percentage of mortality is due to the treatment used on the lines of Sir Leonard Rogers. It would be still further reduced if the cases were sent early to hospital.

Notes on a Few Cases of Cholera Treated by Various Methods (S. Nath Chatterjee).—The essential oils mixture, though it has diuretic properties and some stimulating effect, probably cannot prevent the absorption of toxins, either chemically or mechanically, and if there be such action it is not sufficiently strong, as is urgently required in these cases; also, it is doubtful whether it possesses any bactericidal property. Kaolin acts in two ways: (*a*) it prevents absorption of toxins mechanically by coating the intestinal wall very quickly, which gives an opportunity of treating the complications, if any; (*b*) it most probably inhibits the growth of proteolytic bacteria in the bowels and favours the growth of acid-forming bacteria—hence, indirectly acting as a bacterial agent. For these reasons, besides its cheapness, and its simplicity in administration, kaolin is to be preferred to the essential oils. It appears that kaolin acts very well when given with permanganate. The two combined form one of the most simplest methods of treatment suitable for villages, for melâs and in combating the epidemic; it is applicable to cholera in all its stages.

A Note on the Cause of Pemphigus Contagiosus (*Manson*) (J. Cunningham and S. Ramakrishnan).—This skin affection is very common in Madras during the hot weather, especially in children. The type resembles pyosis mansoni described by Castellani (1919). Both extremities and, less commonly, the axilla are the most common sites of infection. The inguinal region is rarely affected. A streptococcus has been found in numerous cases by the author which is believed to be the primary cause of the affection. All the strains isolated gave identical fermentations in Holman's carbohydrated medium (*Streptococcus subacidus*). The affection is easily cured by means of a vaccine prepared from this organism.

The Aldehyde Test in Schistosomum hæmatobium *Infection* (R. B. Lal).—The aldehyde reaction was tried in cases which showed ova of *S. hæmatobium* in the urine. The methods employed were: (i) Fox and Mackie, 1921; (ii) Modification of Napier, 1922; (iii) Exact technique of Napier, 1922. There is a probability of the aldehyde reaction being positive in some cases of *S hæmatobium*. Much reliance cannot be placed on methods (i) and (ii). The diagnostic value of the aldehyde reaction might become doubtful in places like the Sudan where both kala-azar and *S. hæmatobium* infections prevail, and in cases where the latter disease is complicated with malaria and similar fevers the test cannot be relied upon.

Medical News.

UNITED STATES PUBLIC HEALTH SERVICE.

Medical Advice by Radio.

For some years the Public Health Service has maintained a free medical service to ships at sea having no physicians on board, and many stories of its usefulness in emergencies have been recounted.

This Service which has been established on the Atlantic and Pacific coasts and on the Gulf of Mexico is being extended to include shipping on the Great Lakes. Arrangements have been made for Marine Hospital No. 6 at Cleveland, Ohio, and Public Health Service Relief Station No. 327 at Sault Ste. Marie to respond to requests from masters of lake vessels for medical advice when needed.

Original Communications.

PREVENTION AND TREATMENT OF MALARIA.

By W. E. Deeks, M.D.

General Manager, Medical Department, United Fruit Company, New York.

Clinical observations made on patients suffering from general paralysis, dementia præcox, disseminated sclerosis, &c., in whom malarial infection was introduced for therapeutic purposes, have an unusual interest. This method of treatment has been in vogue, in European countries particularly, during recent years, having originated with Wagner-Jauregg in Vienna. A sufficient number of cases have been treated to enable clinical observers to draw fairly accurate conclusions in regard to several hitherto mooted points in the prevention and cure of malaria.

Warrington Yorke and J. W. S. Macfie have reported their observations on 146 cases; and their findings coincide in general with those of other European observers. In their group of treated cases, 105 were inoculated by virulent blood: chiefly subcutaneously —occasionally intravenously. In six cases *Plasmodium malariæ* was inoculated, in one case *P. falciparum*, and in ninety-eight cases *P. vivax*. In addition to these, forty-one cases were infected with *P. vivax* through the agency of infected mosquitoes (*Anopheles maculipennis* and *A. bifurcatus*).

These observations made under direct scientific control invite discussion on the following phases of malaria prevention and cure: (1) Immunity; (2) Quinine prophylaxis; (3) Treatment of primary infections; (4) Treatment of chronic infections or relapses.

Immunity.

Some of the observations which refer to the question of immunity may be briefly summarized:

(1) In four of the six cases inoculated with *P. malariæ* parasites appeared in the blood from the sixteenth to the twenty-first day after inoculation; in one, on the forty-fourth day; and in one, on the fifty-fourth day.

(2) In those inoculated with *P. vivax* the parasites appeared in the blood in from six to twenty days, and the fever appeared in all cases about the same time, only occasionally preceding or following, by one or two days, the finding of the parasites.

(3) In the ninety-eight cases inoculated with virulent blood nine failed to become infected on the first inoculation. Occasionally repeated inoculations failed to infect. Wagner-Jauregg noted the same in his series of inoculations and met with a few cases which he was unable to infect after three or four inoculations.

(4) Van Loon and Kirschner, of Batavia, report as follows: "A great percentage of the patients, who had lived in the Tropics from their birth, and who were repeatedly (four to five times) intravenously, and afterwards also subcutaneously, inoculated with relatively large quantities of benign tertian blood, appeared to be absolutely immune; others fell ill, but slightly only, and recovered spontaneously after a few attacks."

(5) All of the forty-one cases bitten by mosquitoes became infected. S. P. James, however, reports two cases of failure to infect by this method.

(6) In four of the ninety-eight infected spontaneous cure resulted from five to fourteen days, and no relapses occurred in from three to twelve months' observation.

Immunity to malaria evidently exists in varying degrees in the human subject, as evidenced by the following facts:

(1) That notwithstanding the direct inoculation of 2 c.c. of virulent blood containing approximately a million parasites, nine out of ninety-eight cases failed to become infected and required three to four inoculations to bring about infection. In some cases infection failed after four inoculations, which demonstrates that definite immunity exists in some individuals, particularly among those long resident in tropical malarial districts.

(2) S. P. James has seen two cases whom he was unable to infect by mosquitoes which showed, on subsequent dissection, numerous sporozoites in the salivary glands.

(3) In four of the six cases inoculated with *P. malariæ* parasites appeared in the blood from the sixteenth to the twenty-first day after inoculation: in one, on the forty-fourth day; and in one on the fifty-fourth day. Although the same quantity of virulent blood containing quartan parasites was injected in different individuals, the incubation period varied from sixteen to fifty-four days—that is, before parasites appeared in the peripheral blood accompanied by fever.

(4) In four of the ninety-eight cases inoculated with tertian parasites, spontaneous recovery took place in from five to fourteen days. In the remaining cases of this group the incubation period varied from six to twenty days.

Thus in both quartan and tertian infections different degrees of resistance are seen. In other words, it requires more time in some individuals than in others for the development of sufficient parasites to produce symptoms; or, what is much more probable, the agencies concerned in the development of immunity in some individuals is stronger than in others, thus delaying or altogether preventing the onset of symptoms.

If immunity, partial or complete, were non-existent, undoubtedly the population in severely malaria-infected districts would be completely exterminated in a short time.

My experience in Panama confirms the probability of the development of immunity against malaria. Before Panama was sanitated, anopheles were present in large numbers and new-comers were constantly infected, whereas it was seldom met with in the resident population. From 1906 to 1914 I was frequently called in consultation to see members of the adult resident population, and do not recall a single individual whose illness could be directly attributed to malaria. It was not uncommon, however, to meet with malaria in children or new-comers. Several of the adult residents suffered from organic affections requiring operations, but in most instances these were not followed by malaria exacerbations necessitating the administration of quinine.

Furthermore, I have occasionally met with individuals, past middle life, who said they had never suffered from fever, although they had lived in malaria-infected districts in the tropics for fifteen or more years.

We know that partial immunity is common. An individual may harbour malaria organisms in his blood for years, and yet not be conscious of any discomfort until his general resistance is lowered through some influence, and then a fresh exacerbation of fever ensues.

Yorke and Macfie further demonstrated that immunity, partial or complete, established against one species of the malarial parasite, does not prevent infection from the other species; but it does protect him from fever exacerbations if he is again re-infected with the same parasite by inoculation, or through mosquitoes. Therefore, partial or complete immunity against malaria infection exists or can be developed; but we do not know how, or our problem of prevention and cure would be greatly simplified.

Quinine Prophylaxis.

In regard to the prophylactic use of quinine in preventing infection by mosquitoes, the results from thirty-four cases are shown in the following table:

Observations made on the Effect of Prophylactic Quinine.

From Warrington Yorke and J. W. S. Macfie.

Number of cases	Prophylactic quinine: Daily dose in grains	Prophylactic quinine: Number of days given: Before infected mosquitoes fed	Prophylactic quinine: Number of days given: The day of, and after, infected mosquitoes fed	Number of infected mosquitoes known to have bitten each case	Result	Incubation period from day of infection: Fever	Incubation period from day of infection: Parasites
5	5	—	7	2-4	All infected	12-17	14-16
1	5	1	8	2-4	Infected	20	20
2	10	5	9	2-4	Both infected	18-20	18-20
3	30	—	3	1-3	All infected	11-14	13-14
1	30	1	7	1	Not infected	Observation period six weeks	
1	10	—	35	1	Not infected	Observation period two months	
1	10	—	28	3-4	Not infected	Observation period six weeks	
3	10	—	21	2-4	None infected	Observation period three months	
6	5	—	56	1-4	None infected	Observation period after cessation of Quinine, two to three months	
3	5	7	21	2-5	None infected	Observation period six weeks	
2	5	14	14	1	None infected		
1	5	7	14	1	Not infected		
3	5	—	14	2-5	None infected		
1	5	14	10	2	Not infected		
1	5	—	10	1	Not infected		

It is to be noted:

(1) In six cases, 5 gr. of quinine given daily on the day of infection and for about a week subsequently, failed to prevent infection.

(2) In two cases, 10 gr. given five days previous to infection and for nine days subsequently, also failed to prevent infection.

(3) Three cases given 30 gr. daily for three days, beginning with the day of infection, became infected subsequently.

On the other hand

(4) In one case, 30 gr. administered daily, beginning the day previous to, and continuing for seven days subsequent to exposure, prevented infection.

(5) In five cases, 10 gr. daily, administered on the day of infection and for from three to five weeks subsequently, prevented infection.

(6) In seventeen cases, 5 gr. given daily, for from ten to fifty-six days, prevented infection; seven of these cases had taken 5 gr. daily from one to two weeks before infection, the remaining ten beginning with the day of infection.

From these observations we are justified in drawing the following conclusions:

(1) That quinine, given prophylactically in daily doses of from 5 to 30 gr., and for two or three days subsequent to exposure, does not prevent infection; in other words, that quinine has apparently no action whatever upon the sporozoites, and is destructive only to the trophozoites.

(2) That the absence of positive malarial findings in the cases recorded, in observations 4, 5 and 6, as not being infected, does *not* by any means *prove* that the cases were not infected; on the contrary, we are justified in drawing the conclusion that the infection was cured by the subsequent administration of quinine over a period of from ten to fifty-six days.

Dr. H. N. Hanschell records a series of exceedingly interesting cases which confirm these observations. He had twenty-nine white men under his medical care in Central Africa. Of this number, nine slept under mosquito nets 3 ft. wide. The other twenty slept under mosquito nets 18 in. wide—too narrow for them to avoid exposing their arms and hands to the bites of mosquitoes through the net. All of the twenty-nine men took prophylactic quinine in the form of a 5-gr. tabloid of quinine bisulphate with every evening meal, over a consecutive period of from seventy-eight to 102 days. No infected anopheles were seen about the camps for the greater part of this period. From then on, all those sleeping under 18-in. nets contracted subtertian malaria, the mosquito bites being observed in all instances on the arms and hands which had become exposed when the narrow nets were used. None of the nine men who slept under 3-ft. nets contracted the infection, nor was there any evidence that they had been bitten by mosquitoes. This experience of Dr. Hanschell confirms the observations made by York and Macfie, i.e., that quinine for prophylactic purposes does not prevent infection.

If these conclusions be true, then by the exhibition of quinine for prophylactic purposes we only cloud the issue, and in many cases are unable to determine whether people are infected or not. They may become

infected, receive only sufficient quinine to develop a temporary immunity, and remain carriers without symptoms but capable of spreading infection to others. Would it not be a better method of procedure if we permitted them to develop symptoms and thus definitely demonstrate that the organisms are present in the peripheral blood? We could then institute efficient treatment, under proper supervision, and the probabilities are that not only the individual but the community would be benefited more than by our present methods.

It has generally been considered that quinine destroys not only the sporozoites, but also the malarial organisms when they are free in the plasma, directly after sporulation, and consequently that the best time to administer it, in order to obtain the optimum results, is either about the time of infection or of sporulation, before the liberated organisms have had time to enter the red cells.

The evidence produced above proves almost conclusively that quinine has no effect on the sporozites, and probably not on the organisms in the plasma after sporulation, but only after they have entered the red cells. As stated, this is contrary to the opinion which has been generally accepted.

We have used quinine quite extensively for prophylactic purposes, giving from 15 to 20 gr. twice a week, and have noted that the number of hospital admissions was greatly reduced, and consequently also the rate of serious morbidity. Some recent work in one of the divisions of the United Fruit Company plantations has demonstrated that in those who had been taking 20 gr. twice a week for an extended period of time, infection was present, but that this amount of quinine apparently was sufficient to limit the parasitic development, prevent symptoms, and establish tolerance, as these people did not seek hospital treatment as frequently as they had done previously.

Manson-Bahr claims that there must be at least fifty parasites to the cubic millimetre in order to produce symptoms; and Darling believes that at least twelve gametes to the cubic millimetre are necessary in order to infect mosquitoes. Quinine, in prophylactic doses, may destroy a sufficient number of parasites subsequent to infection to prevent the development of symptoms, although the parasites are still numerous enough to be readily detected in the peripheral blood. In the same manner the gametes could be controlled to such an extent as to prevent mosquito infection. With such results possible, the continuous administration of quinine, under certain conditions, is not only justified but commendable.

Treatment of Primary Infections.

As has been fully demonstrated above, primary infections are readily cured by small daily doses (5 to 1 gr.) given over comparatively short periods (ten to fourteen days) or by larger daily doses (30 gr.) over even shorter periods (seven to ten days). In this connection the following observations were made:

(1) In sixty-one inoculated cases treated by the oral administration of quinine sulphate in solution, 30 gr. daily for three consecutive days, only one relapse occurred during an observation period which varied from four to eighteen months. Wagner-Jauregg, Mühlens and Kirschbaum, Grant and Silverston, and others, report similar results.

(2) In thirteen other cases treated in a similar manner, and subsequently given two or three injections of novarsenobillon, one relapse occurred during a similar observation period.

(3) In the series of forty-one cases infected by mosquitoes, thirty cases were given 30 gr. of quinine daily for three consecutive days, and five relapsed within a period varying from two to six months, the indication being that mosquito infection is more difficult to cure than infection through inoculation, probably because immune bodies were injected with the parasites.

(4) In Hanschell's twenty cases of subtertian malaria, referred to above, the quantity of quinine bisulphate (5 gr. daily) which had been given for a period of from seventy-eight to 102 days, for prophylactic purposes, did not prevent infection. Nevertheless, after the appearance of parasites in the blood it was necessary only to slightly increase the daily dosage for three or four days until a total quantity of 30 gr. had been given orally, and in addition one intramuscular dose of 9 gr., in order to effect a cure. Most authorities admit, moreover, that the subtertian infections of malaria respond more readily to quinine than quartan and tertian infection.

In this connection, I wish to record the following experience of a friend of mine. Before Port Limon, Costa Rica, was sanitated he resided there for a period of about twenty years. At that time malaria and yellow fever were endemic. In his early experience, he contracted malaria, took very little quinine and developed a chronic intermittent fever, which persisted several weeks after he came North to recuperate. When he recovered his health, he returned to Port Limon and again contracted malaria: he then adopted the following method of treatment:

At the onset of the chill he took a hot foot-bath, drank quantities of hot tea, and covered himself with a number of blankets. To favour free perspiration he retained the heavy covering during the hot and sweating stages. The same night he took two compound cathartic pills, and the next morning (about fifteen to eighteen hours after the onset of the chill) began to take his quinine, 15 gr. in powder (wrapped in tissue paper) every hour, until he had taken 90 gr. Invariably this terminated the attack, and he remained perfectly well for from nine months to two years, that is, until he again became re-infected. He treated most of the men of his camp in the same manner, with invariably excellent results. Undoubtedly these were primary infections, as will be demonstrated later on when the treatment of chronic infections is discussed. It is to be noted that the quinine administration was not begun until the spores had had plenty of time to enter the red-blood cells.

A careful study of the table, as well as these observations, favours the conclusion that in the treatment of primary infections heroic doses (30 to 60 gr. daily) of quinine should be given for the first two or three days, and reduced doses for an additional

week; or if small doses (5 to 10 gr. daily) are given, the treatment should be continued for from ten to fourteen days or longer, in order to effect a cure. The period of treatment would be largely determined by the physical condition of the patient.

In my early experience in Panama we were accustomed to give 10 gr., three times daily, until the fever disappeared; and after one or two days of normal temperature the patients were allowed to return to work. It was found that relapses were exceedingly frequent. We then changed our method, and gave 15 gr., three times daily, until the temperature became normal; and we insisted on our patients remaining in the hospital for at least five days after normal temperature, during which time 10 gr. of quinine were given three times daily, and a very liberal diet ordered. Under this method of treatment the number of relapses was greatly diminished, and the results were so striking that this procedure was officially recognized and adopted as routine treatment. In the light of these recent observations, the occurrence of so few relapses after this method of treatment is adopted can be readily explained by the fact that undoubtedly the majority of these cases were primary infections. We thus have evidence to show that in the treatment of primary infections heroic doses of quinine for the first few days, or smaller doses continued over a period of two weeks, should result in cures in the vast majority of cases.

Chronic and Relapsing Cases.

In these cases we have a different clinical picture. The patients are anæmic. Not only is the number of red cells reduced below normal, but there is also a loss of hæmoglobin of from 10 to 50 per cent. in the red cells remaining. From this we may infer that either some hæmolytic action is taking place, or else that the functions of the hæmatopoietic organs are affected. The spleen is enlarged, particularly in the tertian and quartan infections, the function of the liver and kidneys is frequently interfered with, and occasionally these organs are organically diseased. In general, there is a condition of reduced resistance on the part of the patient.

Not infrequently other complicating diseases contribute to the lowering of vitality which is manifestly present. These are the cases which tax the ingenuity of the practitioner if he is to bring about complete convalescence. That we cannot get rid of the malaria infection in many of these cases by the administration of quinine alone is patent to everyone who has concerned himself with this treatment. The following observations confirm such a statement:—

At Liverpool, during the World War, two-day courses of treatment were given in doses of from 5 to 120 gr. daily; the results, as well as the methods of administration, are shown in Table 2.

Furthermore, twenty-nine cases were given 30 gr. of quinine daily for eight weeks, and 83 per cent. of them relapsed within an observation period of two months.

These were undoubtedly cases of chronic malaria. From these observations we must conclude: First, that brief courses of quinine, no matter how large the dosage, are without value in the treatment of chronic cases; and secondly, that prolonged courses of large doses of quinine, continued over a period of eight weeks, cure only a small percentage of chronic cases. These conclusions are in marked contrast with the results obtained in primary infections—a practical point which should be stressed.

Table 2.—Summarising the Result of Various Short Courses of Quinine in the Treatment of Simple Tertian Malaria obtained at Liverpool during the War: Post-Treatment Observation Period at least Two Months.

From Warrington Yorke and J. W. S. Macfie.

Daily dose in grains and Salt of quinine used	Method of administration	Number of consecutive days quinine given	Number of cases treated	Number of relapses	Percentage of relapses
5 sulphate	Oral	2	12	11	91.6
5 hodrochloride	Oral	2	18	18	100
10 sulphate	Oral	2	10	10	100
15 sulphate	Oral	2	14	14	100
15 hydrochloride	Intra-muscular	2	20	19	95
15 alkaloid	Intra-muscular	1-2	38	31	81.6
30 sulphate	Oral	2	14	14	100
45 sulphate	Oral	2	12	9-12	75-100
60 sulphate	Oral	2	12	7	58
90 sulphate, 1st series	Oral	2	76	29	38.1
90 sulphate, 2nd series	Oral	2	89	84-86	94-97
120 sulphate	Oral	2	15	9	60
30 bihdydro-chloride	Intra-muscular	12	30	26	86.6

In order to obtain results in this class of cases, in addition to quinine, we must utilize all remedial agents which will tend to increase the natural resistance of the patient as well as combat complicating, debilitating conditions or infections, as apparently quinine alone in any amount over any period of time will not cure some of these chronic relapsing cases.

Among the numerous complicating diseases, in chronic cases resisting quinine, syphilis must be considered. I have repeatedly drawn attention to the fact that this condition must be treated simultaneously with the malaria infection, or our efforts to cure the patient will be futile. It is in this class of cases that the arsenical preparations are of great value, and the good results obtained have often been misinterpreted. Arsenic does not cure the malarial infection, but assists materially in overcoming the debilitating influences of the complicating syphilis. In the same category as syphilis we may mention hookworm disease, tuberculosis, and all other local or constitutional conditions which tend to lower the resistance of the patient.

Because of the anæmia so generally present, the administration of the arsenical and iron preparations are indicated, and our method of giving two Aiken tonic tablets three times daily over a period of two or

three months has proved to be a very useful measure. The formula is :—

Quinine sulphate	1 grain
Reduced iron	$\frac{3}{4}$,,
Strychnine sulphate	$\frac{1}{30}$,,
Arsenious acid	$\frac{1}{30}$,,
Ext. gentian	$\frac{1}{4}$,,

In some of the more stubborn cases every effort to improve the vitality of the patient must be resorted to, and frequently it has been found that a change of climate has proved to be of undoubted value.

It is advisable for us to give consideration to the preparations of quinine which should be used, and the best methods of administration. As to the first—we may administer quinine in the form of the insoluble alkaloid ; or its salts, the sulphate, bisulphate, hydrochloride or bihydrochloride. Some also recommend the tannate, tartrate, or lactate salts, as well as euquinine (an ethyl-ester of quinine-carbonic acid) which are very insoluble preparations, hence almost tasteless, and consequently of value in selected cases. The quinine alkaloid is also practically insoluble. The sulphate is soluble to the extent of one part in 800 parts of water, and the hydrochloride to the extent of one part in thirty-five parts of water. When acid is present in excess these salts enter into solution readily ; the bisulphate one in eighteen parts, and the bihydrochloride in less than its own weight in water.

For hypodermic use, the bihydrochloride salt is to be preferred because of its solubility, but if the solution has excess acid the injection is very painful. It is better therefore, to use the neutral salt, well diluted, at body temperature, and administer it very slowly.

Sir Leonard Rogers recommends cinchonicine bihydrochloride for intramuscular injections.

From observations made recently in our hospitals, the insoluble salts of quinine are as effective therapeutically as the soluble preparations. It is generally believed, however, that quinine in solutions acts more quickly than the insoluble preparations. Solutions must also be used with patients unable to swallow pills, tablets or capsules. Care must always be taken to see that pills and tablets are readily friable, otherwise they will pass through the alimentary tract without absorption.

In the treatment of malignant cases of malaria, quinine must be introduced by the needle ; either deep subcutaneously, intramuscularly, or intravenously. The solutions should always be well diluted and introduced very slowly. For intramuscular use, the dilution should be at least one to ten, or twenty. After the injection, the tissues into which the quinine is introduced should be thoroughly massaged, and then a hot-water bottle should be applied, to favour absorption—otherwise tissue necrosis may result. For intravenous use, the dilution with normal saline solution should be still greater, otherwise emboli may result and cause sudden death.

Undoubtedly the intravenous use of quinine is indicated, and is to be selected, when prompt action is necessary in order to save life. Howell claims that it takes about half a minute for a circulating particle of blood to return to any one point, and as the intravenous injection takes longer than this, all infected circulating cells are brought into direct contact with the quinine solution during the period of injection and only those escape which are plugged in the capillaries of the viscera.

It is not definitely known how quinine acts in the cure of malaria, nor what becomes of the major part ingested, but in this connection the following quotation from Cushny is suggestive :

"Quinine appears in the urine within a short time (fifteen minutes) after its exhibition by the mouth. and it continues to be excreted by the kidney in some quantity during the next twenty-hours, and in smaller amounts up to about seventy two hours. Only about one-third of that absorbed appears in the urine, however, and only traces have been found in the other excretions ; so that two-thirds or more undergoes complete destruction in the tissues. When quinine is injected into the subcutaneous tissues some of it is deposited locally and only slowly redissolved, so that traces may be found in the urine for a week or more. When it is injected into the blood it leaves the plasma within a few minutes, becoming attached to the corpuscles in some firm combination from which it is difficult to liberate it. It does not accumulate in any of the organs to any significant extent. It is sometimes stated that a tolerance to quinine may be acquired by prolonged treatment, but this seems to be incorrect, the same symptoms occurring and the same amount appearing in the urine after prolonged administration."

As based on these observations, the following measures would appear reasonable for the handling of labour camps in malaria-infected districts :

(1) Every effort should be made to obtain a maximum control of mosquito production (not overlooking the economic consideration of costs) by the methods now in general use. These include selection of sanitary camp-sites ; and the drainage of pools. Where the latter is not possible, pools should be filled or larvicided by means of petroleum products or Paris green. Seepage areas must be taken care of, and rank vegetation cut as often as necessary.

(2) Dwellings should be screened for those able to appreciate the value of this measure, and who will care for the screening. Mosquito bars also serve a very useful purpose, if properly constructed—particularly for temporary use. Unless the mosquito net has a width of at least three feet, during sleep the bare arms or legs may come in contact with the net and thus be exposed to mosquito bites. Furthermore, the net should be constructed in the form of an inverted sack and should be securely fastened at the bottom so as to prevent the entrance of mosquitoes. The use of these methods of protection against the biting of mosquitoes applies particularly to the literate and more intelligent members of the community. In order to obtain the maximum results, in conjunction with these measures, these conditions should obtain.

(*a*) Inhabitants should know that anopheles mosquitoes feed only between sunset and sunrise, and

that during this period people should remain behind the screens or bars. Some authorities believe that repellents, such as creosote, offer a satisfactory method of protection.

(*b*) The people should have more or less definite information in regard to the premonitory symptoms of the malaria infection, which manifest themselves in the form of lassitude, headache, nausea, muscular pains and fever.

(*c*) They should be familiar, also, with the recognized methods of treatment, the amount of quinine that should be taken daily, and the period over which it should be taken in order to effect a cure.

(*d*) They should further realize that, if the results of treatment are not satisfactory, skilled medical advice should be sought.

(3) In dealing with the illiterate labourers we are confronted with a more serious problem. They will not appreciate nor take care of the screens or bars, nor observe other precautionary measures. This class of people should have daily or semi-weekly supervision from a trained attendant, who would take their temperatures and obtain brief histories of physical complaints. Those who are suspected of having a malaria infection should be referred to a hospital or sick-camp for daily treatment under direct medical supervision. A trained attendant could supervise in this manner a large number of labourers if they were located in closely adjoining camps with convenient transportation. This method of handling the situation would obviate the necessity of giving large quantities of quinine for prophylatic purposes.

(4) In camps where considerable infection is indicated, a careful survey is strongly recommended, and all those found infected should be treated daily—either in sick-camps or in hospitals. The measures to be adopted would depend upon (*a*) the degree of infection, and (*b*) the general physical condition of the patient.

(5) In regard to the chronic relapsing cases: Everything must be done to increase the resistance of the patients by treating complicating diseases or conditions concurrently with the administration of quinine orally or hypodermically, and this necessitates hospitalization under direct medical supervision.

(6) The continous administration of quinine to all individuals in a camp is justifiable only when there is a high percentage of infection, and when large numbers of infected mosquitoes are present in the neighborhood.

THE RESULTS OF THE NOGUCHI TREATMENT OF THE PROPHYLACTIC MEASURES EMPLOYED IN THE 1923 YELLOW FEVER EPIDEMIC IN BELIZE.

By Colonel JAMES CRAN, O.B.E., M.D.,
Belize, British Honduras, C.A.

IN 1921, in Belize, there occurred an outbreak of yellow fever, which is of interest in that the Noguchi serum and vaccine were extensively used, and accurate records were kept.

The outbreak occurred about a mile from the outskirts of the town, in a large secondary college in the lee of the prevailing breezes.

The pupils consisted of upward of 100 day scholars from Belize, and a similar number of boarders from the neighbouring Republics of San Salvador, Guatemala, Mexico and Honduras. In the three former countries cases of yellow fever were known to have occurred within the previous twelve months.

Nearly all the boarders returned by sea to the college in the month of July, after the summer vacation, and there can be little doubt that an ambulatory case of yellow fever returned amongst them.

That Belize has been so free from yellow fever in past years in spite of its propinquity to, and daily intercourse with, infected countries is probably due to its rigid enforcement of passenger inspection.

Owing, however, to the number of arrivals at the college, and the distance from the reporting station (over two miles), permission was given to the infirmarian, an intelligent and experienced man, to take the temperatures and report any above normal. Inasmuch as the officer was one of the early victims himself, his statement could not be taken, but it is likely that there might have been a case which he failed to notice, or which was so similar to those he was treating as malaria, that his suspicions were not aroused as the possibility of its being anything else. However, on August 18, the college physician was called, and on the following morning he reported his suspicions to the health authorities. The principal medical officer on arrival at the college found three well-marked cases of yellow fever, one in its sixth day, moribund, and each of the other two in its fifth day.

The infirmarian himself had been sick for four days, although still performing his duties; and his clinical symptoms were not so definite, as he was suffering from chronic malaria and nephritis. In addition, three other cases were also found, a total of seven. All were immediately given Noguchi serum intravenously, of which fortunately there was a supply on hand. The four cases receiving the serum in the late stages of the disease died; the three receiving treatment in the earlier stages recovered.

Vigorous measures were at once taken by the authorities. The school was placed under strict quarantine; and a medical officer was established in residence, with a competent staff.

Next day every inmate, except those actually suffering from the disease, was inoculated with Noguchi vaccine, and subsequently all the day scholars were inspected twice daily for six days. None of the latter contracted the disease. The fact that they used the buildings only when the sun was at its hottest may have had some bearing on this.

All of the buildings were fumigated, so far as possible, with two pounds of sulphur to 1,000 cubic feet. It was, however, impossible to make this thorough, as the fumigation had to be done in sections, the inmates, 150 in all, being moved from one building to another as required.

Within five days after this fumigation, seven more cases occurred. During the next seven days there were no further developments, and it was hoped that all the infected mosquitoes had been destroyed, or that the vaccinations were thoroughly preventive or both. Unfortunately, this hope proved ungrounded, as on September 2 (or seven days after the fumigation) two more cases occurred, and another on the following day. It was thus evident that infected mosquitoes were still present. The authorities thereupon determined to take drastic action, which, although unpopular at the time, has since been admitted by all to have been wise.

I cannot do better than quote the description of these measures as reported by Dr. Gann, the principle medical officer.

"It was then realized that the only means of putting an effectual stop to the disease was the removal of all the inmates of the college to a place where no stegomyia existed, and a fumigation of the college and its outbuildings, during their absence, so thorough as to render it practically impossible for any infected mosquito to survive. The college authorities were very much opposed to any such complete removal of all the boys and the staff from the college building in Loyola Park, and it became necessary for the Local Board of Health to serve a notice on them, to the effect that under Public Health Ordinance such a removal would be compulsory.

"The site chosen for the segregation of the inmates of the college was a small island named Sergeant's Cay, situated about twelve miles from Belize, where, after careful inspection by the government medical officers, and by the representative of the United States Public Health Service then in Belize, it was ascertained that no stegomyia mosquitoes were to be found. This Cay had the further advantage of having an ample supply of vat-stored water and four good houses with cooking accommodations.

"The Cay was acquired by the government for the purpose. The housing accommodations were supplemented by the erection of wood-floored tents and a marquee, together with the provision of ample latrine accommodations and cooking facilities. Those preparatons took time, and it was not till September 13 that the boys were removed to Sergeant's Cay. They remained there till the 23rd under the supervision of Dr. Folse, assistant medical officer, who lived on the Cay; and all enjoyed excellent health. No case of yellow fever developed amongst either the boys or the staff. On the 23rd some of the boys returned to their homes, while those who lived in Guatemala and Spanish Honduras were shipped off to those countries, though the boat which took the Honduras boys to Puerto Cortez was refused pratique by the Port Authorities, and they were shipped back to Belize without being allowed to land, or the vessel even being permitted to procure provisions or water.

"Between the 13th and 23rd the college, with its outbuildings, was twice most thoroughly fumigated with sulphur; cracks in the windows and doors were securely pasted over with paper, while all the larger openings were closed by having tarpaulins, ground sheets and blankets nailed over them, so that it would have been impossible for any mosquito within the building to escape. In the open space beneath the main building, and in the extensive verandahs which run all around it, pots of sulphur were burnt before the fumigation proper took place, in order, as far as possible, to drive the mosquitoes haunting these situations to the interior of the buildings, where they would be killed by the fumigation.

"On October 5 Loyola Park was declared to be no longer an infected place, under the Public Health Ordinance, and it was reoccupied. As no further case of yellow fever has occurred there since, it may, I think, be accepted that no infected mosquito escaped the double fumigation, and that the precaution taken, in isolating the whole community for ten days on Sergeant's Cay, and thoroughly fumigating the college during their absence, had been successful, so far as the college was concerned, in ending the epidemic."

The outbreak had thus far proved the value of the Noguchi serum as a curative agent, but left that of the Noguchi vaccine in doubt. The efficacy of the latter, however, appears to me to have been demonstrated by the further history of the outbreak, which later on reached the town.

Immediately after the outbreak occurred at the college, free vaccination for all was instituted at the public hospital; and with a few exceptions that part of the population commonly regarded as non-immune gladly availed themselves of it, but comparatively few of the natives did so. More than 500 were vaccinated, and of this number at least 150 may be regarded as having been newcomers.

After an interval of three weeks, a negro labourer living in the heart of the town was admitted to the hospital on September 27. He gave a history of having been taken ill with fever on the 18th, and of having had complete suppression of urine since the 22nd. Yellow fever was diagnosed, and he was given the Noguchi serum on the tenth day of the disease. He died on the twelfth day of the disease, having had almost complete suppression for seven days, only a few c.c. of a bloody fluid having been drawn off. He had not received a

prophylactic. There were only two more cases in this outbreak, and although neither of them occurred in Belize, yet both of them must have received their infection there.

A young white woman, who resided in Belize for a few months, left the colony for New Orleans on November 5. On the following day she developed fever, which was diagnosed as malaria. When she arrived in New Orleans on the 8th, she had no temperature and was allowed to land. Shortly after landing, she again developed a temperature, which on the 10th was diagnosed as yellow fever. She died almost immediately afterwards and this diagnosis was confirmed at the autopsy on the 11th. This woman was one of the few newcomers who had persistently refused to be vaccinated, being prejudiced against it because she believed that an aged relative had died in Rome after receiving what seemed to be a similar injection for pneumonia.

On October 31 a young man arrived in Belize from Mobile, Alabama. He remained for twelve days and then proceeded to a coast town about forty miles distant. Next day he developed yellow fever. On the fourth day of the disease he received 60 c.c. of Noguchi serum, and made an uneventful recovery.

If it be only a coincidence, it seems a strange one, that the only two whites who contracted the disease in the town had not been vaccinated with this serum, while 100 or 200 who *had* been vaccinated escaped, although they were equally susceptible and equally exposed.

Summary.

The following are significant facts:

Of the seventeen cases occurring at the college, all received the Noguchi serum.

Of these, four were already in their fourth to sixth day. All died.

Of the other thirteen, all received the serum on their first or second day. Only one died.

No cases occurred in the town among those who had been vaccinated. Of the three cases which did take place in the town, one received the serum not until the tenth day and the case ended fatally. Another received it on the morning of the fourth day and recovered. I do not know whether the fatal case in New Orleans received the serum or not; if so, it could not have been before the fifth day.

It is my firm opinion, based on experience gained in the 1905 epidemic, that several more cases would have ended fatally but for the serum treatment; and also more cases would have occurred in the town, had not the anti-yellow fever vaccine of Noguchi been available. In the 1905 outbreak there was a mortality of over twenty per cent. distributed evenly throughout the epidemic; in the 1921 epidemic, the mortality was practically confined to those cases which were treated too late for the serum to be of any benefit. Among those cases that received the serum during the early stages of the disease only one fatality occurred.

The town of Belize, being partly at and partly below sea level, from a sanitary point of view is a hard problem. Most of the low-lying areas are in communication with the sea, and contain either salt or brackish water. This condition, while favourable to a certain species of the mosquito pest, is not much appreciated by either the stegomyia or the anopheles variety. Breeding places for these species, however, are many; (i) the rain-water containers, ranging from vats to barrels and kerosene tins, on which the inhabitants solely depend for their water supply; (ii) the numerous depressions holding fresh water during the wet season; and the empty tins and similar rubbish which accumulate in many of the yards.

Although there exist thoroughly efficient and model laws dealing with mosquito destruction, it is very difficult and irksome to be obliged to continually enforce them, and the town was lulled into a sense of security as a result of its fifteen years immunity from the plague.

Upon the discovery of the outbreak an appeal was made to the Rockefeller Foundation, and the reply was both prompt and effective. In a very short time Dr. E. I. Vaughan and Mr. B. R. Dyer, of the Foundation, arrived with an almost unlimited purse, and with an equally unlimited supply of that energy and tact which is so necessary for the successful and smooth working of all public health measures.

An executive commission was appointed, and an adequate staff enrolled, and an energetic campaign established for the systematic inspection of the town, oiling and screening of water receptacles, and the thorough cleaning of yards. Within a few months these measures were accomplished to such an extent that the mosquito index fell from fifty per cent. to within the five per cent. safety line established by the Foundation. It has remained at that point ever since. I thoroughly agree with Dr. Agramonte that the anti-mosquito work should be continued. I should consider the Noguchi treatent as being of value only in the midst of an actual outbreak.

The Foundation worked with us for a year and accomplished a maximum of work and education with a minimum of friction.

The services of a thoroughly qualified sanitary inspector were then obtained, and both the staff and the system are being efficiently maintained. This is true not only in Belize, but in all the principal towns of the colony, especially those on the seaboard.

It is interesting to note that this sanitary inspector—Mr. J. H. Peach—is gradually persuading the householders to substitute for the costly wire-screening method a system of "fishing" the tanks, with a species of small fish known locally as "Billums." They live well in the tanks, and a couple of them are able to keep any ordinary tank free from mosquitoes. All the public and many private water containers are now stocked with the

fish, and there is still so much demand that the supply is not adequate.

Belize is much in need of extensive reclamation work and a pipe water supply. The latter would be very costly, as no supply by gravity is available.

The town is not wealthy, and up to the present time no rich uncle or fairy godmother has come along; but it is still in hopes that the necessary improvements will be accomplished even if it has to apply to the "well-known uncle" for a loan.

Belize is not unhealthy. It has had only two small outbreaks of yellow fever during the last thirty years. Curiously enough, they occurred at fifteen-year intervals, and each was stamped out in less than six weeks.

Strong sea breezes blow for about eight or nine months in the year, the temperature very rarely reaching ninety degrees. Zymotic diseases, except those of childhood, are practically unknown, and the class commonly known as tropical diseases is comparatively rare. The anti-mosquito campaign is already showing results in the form of reduced hospital admissions for malaria. Europeans live there for thirty to fifty years in the best of health, and like myself, are apparently taking only one serious risk—that of dying of senectus.

Chemo-therapeutic Experiments with Chaulmoogra and Allied Preparations (Otto Schobl, *Philippine Journal of Science*, vol. 25, No. 2, August, 1924).—The aim of the author's experiments was to survey certain organic compounds belonging to various groups with regard to their growth-inhibiting activity toward acid-fast bacilli. Water soluble compounds showed an antiseptic effect, whereas the fat solvents such as benzol, toluol, &c., which have a strong hypnotic effect, were found to be only slightly antiseptic, or not at all. Sodium, copper and nickel salts of fatty acids were found about equally effective, whereas zinc, strontium, lead and uranium salts showed no effect. The double-bond-containing compounds all showed antiseptic effect, the double bond being more effective on the side-chain than on the ring in aromatic compounds. Unsaturated alcohols showed an antiseptic effect, particularly when containing the phenyl group which proved to be the most powerful toxic group. High alcohols approaching waves show no effect. Secondary alcohols were equally or less effective than primary alcohols. Hydroxy compounds are highly antiseptic toward acid-fast organisms as they are toward other bacteria. The antiseptic effect of phenols increases with the number of hydroxyl groups, the position of these groups being of importance, as the ortho-compounds are more antiseptic than the para or meta compounds. Alkylation on the ring increases the antiseptic effect of phenols, whereas alkylation on the OH group of polyhydroxyphenols has no noteworthy effect, provided at least one hydroxyl is preserved.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All literary communications should be addressed to the Editors.

4.—All business communications and payments, either of subscriptions or advertisements, should be sent to the Publishers of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank Ltd.

5.—The Subscription, which is Thirty Shillings per annum, may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—Special Notice.—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to 25 reprints, free of charge.

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints if the order for these, with remittance, is given when MS. is sent in. The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 " "	1	3	3
200 " "	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 " " "	2	6	0
200 " " "	2	17	6

Postage extra according to weight.

One page of the Journal equals 8 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

A WHITE AUSTRALIA: IS IT A POSSIBILITY?

By SYDNEY J. SKERTCHLEY, J.P.

(*Continued from page* 17.)

CHAPTER VI.

The Story of the Fair Whites.

(77) The original home of the Fair Whites, is along the Baltic shores, eastwards to the Vistula, westwards to the Rhine. We will now trace a few

of the migrations and learn if these almost unconquerable, seldom vanquished, receptive-minded people could hold by virile power what their swords won by personal valour. They were banded into many tribes, but their blood was one, and to this day we speak proudly of them as the dominant and dominating Anglo-Saxon or Teutonic race. Every one of the British colonies is due to their enterprise, and the great Republic of the United States of America (which curiously never adopted a name for itself) prides itself upon its Anglo-Saxon lineage, and shares with us the storied glories of our Valhallas —Westminster Abbey and St. Paul's Cathedral. We shall devote a special section to the consideration of their power to hold their own on what they now call their native soil.

(78) It was always a wandering, always a colonizing race, and in this last particular has surpassed all rivals. The old Viking blood that runs in (some of) our veins boils up still, ever and anon, and sends us flying to every spot on earth not covered with everlasting snow and ice.

(79) When the first migration of the Fair Whites took place we cannot stop to discuss. It must suffice us to note that the early Roman and Greek belonged to them, though no trace of these fair-haired, blue-eyed heroes is left in Italy or Hellas. We will confine ourselves to historical evidence, and begin as late as the history of Rome.

(80) Within the first three centuries of our era three confederations of Fair White barbarians harassed the Roman Empire. They are generally known as the Goths, the Franks, and the Alemanni, each an amalgamation of tribes, not always the same in composition.

(81) Now comes a curiously glossed-over fact. The Rhine, against which the Roman legions always spent their strength in vain, never proved an obstacle to the southward march of the strenuous Fair Whites. History, as I read it, on the other hand presents no case of the southern Dark Whites successfully crossing that legend-haunted frontier. "Die Wacht am Rhein" is more than an outpost ditty to the northron; it is the embodiment in ringing verse and stirring strain of a fact old as the human race itself. Who has forgotten 1870? Who that knows this frontier land can forget the miles on miles of strategic railway lines and sidings that have spun their iron web—a ghastly gossamer—along the picturesque route which is the touring ground of nations, as it is their battle-field? No race on earth has such a heritage of victory as the Fair Whites—they are unconquered and unconquerable.

(82) Eastward and southward the Rhine and the greater Danube (especially in its upper course) thread their way through the borderland across which the Fair Whites surged for centuries. But their real home is where the cold winds of the North Sea and the Baltic bite and stir the blood and make exercise exhilarating. In the warmer south muscle grows lax. It is this blood, born of the north wind, that has given, and is giving still, the stimulus that has driven the northerner to the uttermost parts of the earth; and far beyond the confines of his native soil his name is stamped upon the map.

(83) Lombardy preserves the name of the Langobardii, whose kingdom lasted well into the eighth century, but whose blood has died save where, here and there, one comes across the red-gold hair beloved of the Venetian painters. Venetia itself preserves the name of a dead race. France recalls the Franks, the Freemen of the north, but France is no more Frankish than Normandy is Norman. Burgundy still exults in foreign blood, but it is the red blood of the grape ripening on the sunny slopes of the Côte d'Or, which overlook the tulip-flecked meadows of the swift Rhone, and not the blood of the conquering Burgundian. The Antonines brought the vine, but Roman blood grew thin, and now one has to seek the even sturdier Burgundian of the north in half-forgotten graveyards. Andalusia is Vandalusia no more, and in Galatia we find no Gauls.

(84) But what of the great barbarians who have failed even to impress their names upon the map? The Alemanni were a race whose home was on the Upper Rhine. They were enemies alike to the Roman and the Gaul. Caracalla, whose baths we still visit on the Via Appia of old Rome, took the name of Alemannicus after a victory over them. They spread from the Rhine to the Danube. Julian broke their power at Strassburg. Would you find their descendants they must be sought in scattered parts of Suabia, Alsace, and Switzerland. Yet so powerful were they that to this day the French call all Germans by the name Allemand.

(85) The Heruli, early in our era, had established themselves on the northern shores of the Black Sea. In the fifth century they allied themselves with Attila, the Hun, and on his overthrow established a confederacy on the Danube, their king, Odoacer, assisting in the overthrow of the Western Empire. Within a hundred years they are dispersed, some fleeing north to their Scandinavian home, some south across the Danube. Another century, and history and anthropology know them no more.

(86) But the greatest of the Fair Whites were the Goths and Vandals. Their very names have become but a byword and reproach, though they alone enjoy the proud distinction of being conquerors of Imperial Rome; to them alone the Cæsars had to bow, and yet, of all their conquests, from the Crimea to Spain and Africa, not a trace remains save the one mutilated name—Andalusia. Even in the north the Swedish Gothland is the record of the Getae and not of the Goths. The historian Freeman is himself struck with this, and writes: "No Teutonic people fills so great a place in the political and military history of the Fourth, Fifth, and Sixth Centuries, and no Teutonic people has left behind us such early remains of a written native literature. The real greatness of the Goths quite accounts for the many vague uses of the Gothic name. Alike in scorn and in honour, the Goths have been, not unreasonably, taken as the representatives of the entire Teutonic race. The wonderful thing is that a people who have taken so great a part for several ages should have wholly

passed away. The Goths have not for many ages existed anywhere as a distinct nation, nor have they given an abiding name to any part of Europe. Franks, Angles, Saxons, Burgundians, Frisians, Thuringians, Lombards, perhaps Vandals, are all visible on the modern map. So several parts of Europe have at different times been known as Gothia; but the name was never borne by any large country, and it has nowhere lasted down to modern times."

(87) Take the case of the Vandals. They were closely allied to the Goths and in the first century were located in Brandenberg and Pomerania. They spread southward to the Bohemian border in the next century. In the fourth century they settled in Pannonia, and the fifth finds them across the Pyrenees, settled in Spain in two divisions—the Asdingians in Galicia, the Silingians in Andalusia. In 428-9, at the request of Boniface, ruler of the province of Africa, they sail for those romantic shores, and under their warrior king, Genseric, soon became masters instead of mercenaries. St. Augustine, eloquent father of our Church, advised Boniface to call these fair-haired invincibles to his aid, and now they are thundering at the gates of Hippo as the saint lies dying. Soon Carthage itself shall fall, and for a century serve a Vandal king. By the year 440 Genseric, from his Vandal kingdom of Africa, is sweeping the Mediterranean as precursor of the Barbary pirate of yesterday. Five years after he enters Rome and loots it as leisurely as if he were selecting stock in a warehouse, and the spoils of the Temple of Jerusalem, won by Titus, fall into Genseric's hands and are henceforward lost to history. Can triumph be more triumphant? Yet in less than a hundred years the Vandal is but a name; he had overshot the anthropologic boundary beyond which the Fair White may not step and live.

(88) Stranger still, if that be possible, is the history of the Goths. They seem to appear in history as the Guttones or Gothones, on the south Baltic shores. They spread southwards, and just as in England the Saxons became divided into East-Saxons and West-Saxons, so the Goths became Ostro (Eastern) and *Visi* (Western) Goths. But ere the great split happened the Goth had become a factor in the story of the Roman Empire.

(89) In the third century of our era the Goth had travelled south to the Danube and established himself pretty firmly in Dacia, and was already harassing the borders of the empire. It is even said that the Emperor Maxamin was himself a Goth, though perhaps this is a confusion of the terms Getae and Gothi. In the middle of the century they defeat the Romans, having crossed the Danube and ravaged Moesia. They spread themselves further east, founded a settlement in the Crimea, and ravaged all the coasts of the Black Sea. Passing through the Dardanelles they swept over Greece, not even Athens being able to withstand their onslaught. So important was a victory over them deemed that Claudius, the hero of Natissus, in Dardania, assumed the cognomen of Gothicus, just as Caracalla had taken that of Alemannicus. The Gothic defeat was in 269, but it was only a temporary check, and five years after the Romans permanently withdrew their legions south of the Danube, and the Goths claimed dominion from the Danube to the Baltic. They were the peers of Rome already, soon they were to be her overlords.

(90) This was the high water of the prosperity of the Goths in eastern Europe. They were on foreign soil, and though they had hurled the legions back, they in turn were stunned beyond recovery by the impact of the Huns, whose story we have already sketched. Many of the Goths remained in the Danubian provinces, retaining their autonomy under their own chiefs, but with the Huns as suzerains, whose banners they were bound to follow in war.

(91) Then a great migration southwards ensued. The Goths split into the Ostrogoth and the Visigoth. Received with cordiality into Italy they settled in the north, but friction soon arose, and finally, in 395, the Ostrogoths became independent, under Alaric, who ravages Greece and sacks Rome itself. This Gothic kingdom lasted till 553. If now you would seek Gothic blood in northern Italy you must look at golden-haired Alexander the Great, as painted by Paul Veronese,[1] or perchance, as I did once, find it in a flower-girl on the Rialto,

> Shylock's bridge with houses on it,
> Where they kept the Carnival.

As in Europe, so in Asia; neither in the Ukraine nor in that Tauric Chersonese we now call the Crimea, is Gothic blood to be found, though Gothic speech still lingered on for centuries, and now it, too, is forgotten.

(92) Turn we next to the Visigoths, the Goths of the west, the conquerors and rulers of Gaul and Spain. So powerful were the Goths that Ataulf, the brother-in-law and successor of Alaric, had married Placidia, the daughter of the Emperor Theodosius, and had not their only son (named Theodosius after his grandfather) died young, a dynasty might have arisen uniting the Gothic and Roman claims. Ataulf at first meditated the entire overthrow of Rome, and making and calling the empire Gothia, but realizing that stable government depended upon Roman law, he, with his hosts, went westward into Gaul to restore the Roman power threatened by Frank and Burgundian, Fair Whites like himself. This was the beginning of the kingdom of the Visigoths.

(93) As the Roman power waned the Visigothic waxed strong, and from receiving Gaulish territory as recompense for services rendered to the empire, they speedily assumed the purple for themselves, and in 414 the Visigothic kingdom of Toulouse was established. By 475 all Gaul west of the Rhone acknowledged their sovereignty, and the western Roman empire itself lasted but two years longer. But another Fair White star was rising—that of the Franks, and Clovis, their king, after slaying Alaric near Poictiers, drives the Goths south of the Pyrenees, and Gaul becomes France.

---

[1] Alexander and the Persian queen, &c., are said to be portraits of the Pisani family.

(94) Yet the Visigoths were not subdued, and in Spain they founded a greater kingdom still, expelling the Romans finally in 468. Apparently secure they ruled the great Iberian peninsula. But the doom of the Fair White was impending, and 300 years after their coming they fell before the scimitar of the Saracen, and not even their name is left to show the swarthy Spaniard he ever bowed the knee to the blue-eyed stranger from the north.

(95) Here, reluctantly, one must close the story of the Fair Whites. It has only been sketched in barest outline—could it be filled in it would be but piling Pelion on Ossa, for surely the deduction is startlingly apparent! Could any better chance be offered to man than Vandal and Goth had in Europe? Practically every foot of European soil has felt their conquering footfall—their dominion overlapped Europe into the Crimea on the east and Africa in the south—they not only shook but destroyed imperial Rome—and yet! What their swords won they kept, and kept it for centuries. Still the stern anthropologic law held good—thus far shalt thou come and no further. Truly the experiment has been tried often enough, over wide enough areas, over sufficient time. And to-day if you seek the living blood you must hie to those Baltic shores that engendered it, for elsewhere the Vandal and the Goth are but dust.

Annotations.

Death from Tick Paralysis in Human Beings (E. W. Ferguson, *Medical Journal of Australia*, October 4, 1924).—The cases on record of paralysis in human beings as the result of tick infestation in the eastern coastal regions of Australia are few, although it is a well recognized affection. The tick responsible for paralysis and death in human beings is the common scrub tick *Ixodes holocyclus*, Neumann. The female tick alone appears to be toxic and symptoms do not supervene until the tick has been attached for at least three or four days and has reached a certain stage of repletion. It is commonly believed that the paralysis is due to a toxin secreted by the tick. Five cases are reported, in four of which the legs appeared to be most affected.

The Local Effects produced in the Tissues by Intramuscular Injections (H. W. Acton and R. N. Chopra, *Indian Journal of Medical Research*, October, 1924).—The three drugs antimony, emetine and quinine, when injected intramuscularly for the treatment of kala-azar, amœbiasis and malaria respectively, all produce local effects on the tissues. Antimony causes œdema, irritation and pain; emetine, petechial hæmorrhages and bruising; and quinine, œdema and necrosis. Quinine bihydrochloride exerts its effects on the tissues in two ways: (*a*) The liberation of the acid radicle causes œdema, irritation and pain: (*b*) the base, acting as a protoplasmic poison, causes death of the surrounding tissues. Cinchonine hydrochloride, when injected into the tissues, produces necrosis and œdema, and is the weakest alkaloid therapeutically. The salts of the four main alkaloids of cinchona bark all cause œdema, irritation and necrosis of the tissues. The injection of these alkaloidal salts into the muscles of man should be considered as malpraxis, as this tissue is unable to live in the presence of these bases at a high concentration, viz., 1-2000, and there is also a slight danger of tetanus. Tetanus following an intramuscular injection of quinine is due to the introduction of tetanus spores owing to imperfect sterilization; the necrosed area forms a suitable nidus. There is only one method of administering the cinchona alkaloids and that is by the mouth. Very rarely in grave cases, e.g., cerebral malaria, when an immediate action is required, quinine base should be injected intravenously.

Jute Dermatitis (Dagmar F. Curjel and Hugh W. Acton, *Indian Journal of Medical Research*, October, 1924).—Jute dermatitis is a non-suppurative folliculitis, caused by the mechanical blocking of the sebaceous gland orifices by plugs of the unexfoliated stratum corneum. The mineral oil used for softening the jute does not irritate the skin, but protects the skin from water and so increases the accumulation of the stratum corneum. The disease is more commonly seen amongst the lower class Hindus, who have generally a coarser skin and do not use much soap, &c., for washing. The disease has escaped adequate description as a trade dermatitis amongst workers in the tropics, for the eruptions are not associated with subjective symptoms and occur in a class who are indifferent to their personal appearance.

The Preparation of Hydnocarpus Esters and their Use in Leprosy (E. Muir, *Indian Journal of Medical Research*, October 1924).—Hydnocarpus oil is derived chiefly from *Hydnocarpus wightiana*, which belongs to the same family as *Taraktogenos kurzii*, from which chaulmoogra oil is derived. *Hydnocarpus wightiana* has many advantages over *Taraktogenos kurzii*, the chief being that it is more easily accessible and can be cultivated in countries where it is not indigenous. In common with the oils derived from other trees of the same family, hydnocarpus oil contains hydnocarpus acid, chaulmoogric acid and other fatty acids of the chaulmoogric series. A description is given of the preparation of esters, which is extremely simple. The esters should either be bottled in glass-stoppered bottles or filled into ampoules of suitable size. The latter are safest for the treatment of single cases, but the glass-stoppered bottles are more convenient and cheap for large numbers of cases. The preparation can be administered either intravenously or subcutaneously. To obtain successful results in treatment care should be taken that injection is made into loose subcutaneous tissue. Esters of hydnocarpus oil mixed with an equal quantity of pure olive oil can be injected in doses ranging from 0·5 c.c. to 10 c.c. Thymol added to hydnocarpus oil enhances its therapeutic value. Of course suitable cases must be chosen for treatment, not those where permanent lesions already exist.

The Mechanism of Immunity against Malaria in Communities living under Hyper-endemic Conditions (S. R. Christophers, *Indian Journal Medical Research*, October, 1924).—In endemic malaria there is a regular co-ordinated sequence of events connected with the infection rate, numerical value of the infections, the spleen rate, the average size of the spleen and the numerical prevalence of the different degrees of enlargement of this organ. A proper numerical and precise study of the intercorrelated phenomena constitutes a science or study that deals with the malaria of communities, and is more especially concerned with conditions that necessitate the investigation of the effects of overlap and superposition of infections in malaria, conditions that are among the most important in the science of malaria, since they are normal to a large proportion of the human race living in the subtropical and tropical zones, and are especially those that are involved in the malaria of tropical population. In the particular community studied, the spleen rate among the children was approximately 70 per cent., and that among the adults 10 per cent. The parasite infection rate in the children was of the usual high character, being 85 per cent. The details of the malarial happenings in this community formed the subject of the present investigation. They confirm the results of Schnuffer for the hyperendemic communities in Sumatra and further extend precise methods of observation in such investigations. All the community are probably continuously infected.

Studies in Dracontiasis. Part IV. The Clinical Picture. An Analysis of 140 Cases (N. Hamilton Fairley, *Indian Journal of Medical Research*, October, 1924).—Generalized urticaria was observed in fifty-four out of 138 patients (39 per cent.) investigated during the present seasonal attack. A marked individual predisposition to it was found in certain cases. Attacks during a previous season did not confer immunity to urticarial eruptions in subsequent years, but it was distinctly rare to find a history of more than one bout of urticaria during any given season even though many worms were present. Perhaps *temporary* desensitization to helminthic toxic substances supervenes on the urticarial syndrome. The onset of urticaria was generally at night, and in forty-six out of fifty cases it appeared before the blister or other localizing features were noted. In a majority of cases its duration was under twenty-four hours. Other signs and symptoms were frequently associated with the urticarial eruptions, and varied according to whichever system was dominantly affected. Gastro-intestinal features including nausea, vomiting, hiccough and diarrhœa. Cardio-vascular involvement was indicated by giddiness, syncopal attacks and other symptoms. Dyspnœa was a prominent feature in certain cases. The pulmonary dyspnœa and other systemic manifestations were immediately relieved by the subcutaneous injections of adrenalin. The local lesions caused by *Dracunculus medinensis*, including the blister and the resulting ulcer, are described. Death of the worm prior to pointing may be followed by calcification *in situ* or the formation of a deep sterile abscess caused by liberated embryos. The distribution of the local lesions was recorded in 252 instances. The lower extremities were implicated on 218 occasions, the upper extremities in fourteen, the trunk in eleven, the buttock in five, and the scrotum in four. All complications (except calcification) were dependent on secondary bacterial infection. There were fifty-five cases of acute and subacute abscess, seventeen of cellulitis, while many showed associated tender glandular enlargements or even buboes. Instances of synovitis, tenosynovitis, epididymo-orchitis, acute arthritis and permanent deformaties due to fibrous ankylosis of joints or contraction of tendons were observed in the series. The value of the hæmatological data was curtailed by the fact that in most instances of dracontiasis there was associated helminthiasis.

Studies in Dracontiasis. Part V. Observations and Reflections on Intravenous Medication with Special Reference to Tartar Emetic (N. Hamilton Fairley, *Indian Journal of Medical Research*, October, 1924).—The majority of guinea-worm cases did not present themselves for clinical examination until the blister had ruptured and bacterial contamination of the ulcer surface ensued. In 43·7 per cent. septic complications were already established. In this group of cases mechanical extraction of the parasite is necessary whether the worm is living or dead, and it is the writer's contention that delay by medical treatment under these circumstances is inadvisable. Specific drug therapy, if lethal to the parasite, would be of real value in the minority of cases seen prior to rupture of the blister. Under these circumstances death of *Dracunculus medinensis* is followed by its absorption *in situ*. In a carefully selected and controlled group of early cases tartar emetic was found neither to exert lethal action on the female worm and its embyros nor *per se* to modify the clinical course of the disease. Its use in this clinic has been entirely abandoned.

Further Observations on Latent Dysentery. The Practical Value of the Discovery of Latent Dysentery Cases as a Method of Dysentery Control (J. Cunningham and K. V. Krishnan, *Indian Journal of Medical Research*, October, 1924).—An account of three investigations in which the macroscopic method of detecting latent dysentery cases has been utilized as a means of controlling dysentery is given. The first of these was carried out by Lieutenant-Colonel Bateman, R.A.M.C., in a military community, the second and third by the authors in the Bellary and Cannanore jails respectively. The dysentery index in each of these series was found to be as follows: Colonel Bateman's series, 27·0; Bellary series, 30·9; Cannanore series, 27·6. The detection and segregation of the cases of latent dysentery was immediately followed by a rapid and continuous diminution in the dysentery rates in each case. In the Bellary and Cannanore series 92·5 per cent. and 94·5 per cent. respectively of the subsequent admissions into the

hospital for dysentery were divided from the latent dysentery groups which had been previously isolated. Forty-eight out of 184 men working in the cook-house in Bellary and fifteen out of fifty cooks in Cannanore were discovered to be suffering from latent dysentery. The improvement in the conditions in these communities was due chiefly to the detection and segregation of the latent dysentery cases from the normal population. The detection and isolation of latent dysentery cases is thus of the greatest importance as a practical measure of dysentery control. The systematic macroscopic method of examining the stools is the best and surest method of discovering these cases in that it is rapid, cheap, requires no special skill or apparatus, is eminently efficient, and can be applied to large communities.

A Report on Plague Investigations in Egypt (G. F. Petrie, R. E. Todd, R. Skander and F. Hilmy, *Journal of Hygiene*, November, 1924).—The summary of this paper is as follows. The extent of the disease at any moment in the epidemic period is determined not by the strictly contemporaneous weather conditions, but by those which existed four to six weeks previously. The interval is attributable to the effect of atmospheric conditions on the various stages of development of the rat flea (*X. cheopis*). When this lag period is taken into account, there is found to be an optimum range of temperature from 20° C. to 25° C., and of vapour pressure deficiency from 1 to 10 millibars for plague prevalence; these too are the optimum limits for flea development. The degree in which the climate of a locality approximates to the optimum determines to a definite extent the normal character, whether mild or severe, of its plague history. In maritime localities the atmospheric temperature is a more important factor in regulating the prevalence of the disease than the vapour pressure deficiency. In places with a hot dry climate the rise of the epidemic is correlated with the temperature variations; a high prevailing temperature or excessive dryness of the air (vapour pressure deficiency) or a combination of these hastens its decline by increasing the mortality in the infected part of the rat-flea population, and thus restricting the transference of the infection. In certain localities, when the temperature is favourable, a dry atmosphere with a vapour pressure deficiency above the optimum limit is able by itself to check the spread of the disease. In the dissection of the climatic factors associated with plague the diurnal temperature variations deserve attention. The gradually increasing delay in the onset of epidemic plague from south to north of Egypt is correlated with the seasonal variations in the climate throughout the country. The analysis leading to this conclusion indicates that, in agreement with the data from India and elsewhere, the seasonal prevalence of human plague in Egypt, as deduced from the massed statistics, is dependent upon the factors governing the prevalence of rat plague, and, in particular, the climatic factors that influence the life-history of the rat-flea (*X. cheopis*).

Abstract.

REPORT OF HÆMOGLOBINURIC FEVER IN THE CANAL ZONE, ITS ÆTIOLOGY AND TREATMENT.[1]

THE history of hæmoglobinuric fever proves that the symptomatology of the disease was recognized and recorded prior to the time when the malady was distinguished either as an entity or as a symptom-complex of malaria. There is no proof that blackwater fever has spread from one country to another, or from one part of a country to another, as have kala-azar, yellow fever and sleepy sickness. On the contrary, the disease invariably manifests itself when certain conditions relative to the epidemiology of malaria, and to that of no other disease, are present. These conditions are:

(1) The presence of a population non-immune against malaria.

(2) The prevalence of malaria in such quantity as to produce an almost continuous infection in this population.

(3) A large proportion of æstivo-autumnal malaria; because the amount of blackwater fever is in direct proportion to to the intensity of this variety.

(4) The neglect of prompt and continued administration of quinine, especially in primary attacks, to persons non-immune against malaria.

In every locality without exception where these conditions obtain, hæmoglobinuric fever is found.

The conditions may vary from time to time in the same or in different localities, with a corresponding increase or decrease in the amount of hæmoglobinuric fever. They are present in restricted areas and absent from those contiguous. When any condition varies, hæmoglobinuric fevers vary in proportion. In this respect the malady differs from every infectious disease other than malaria, for it does not enter a hitherto non-malarial district except by the introduction of æstivo-autumnal malaria; when this malaria becomes prevalent in a region formerly free, blackwater fever follows in proportion to the intensity of malaria and the capacity of the population to acquire immunity. Also, æstivo-autumnal malaria may obtain very extensively among children when in places where the adult population, by reason of continued attacks in childhood, has acquired immunity. If non-immunes do not enter such places, or if, after their entrance, prompt prophylactic and therapeutical measures are instituted against malaria, blackwater fever does not prevail.

These propositions are supported by positive evidence and do not admit of controversy. Every statement made in support of them has concrete facts and the witness of authoritative observers as its basis. The conditions necessary for the generation of hæmoglobinuric fever explain clearly why the disease is absent from places where it once prevailed, or is

---

[1] Abstracted from W. E. DEEKS and W. M. JAMES, A Report on Hæmoglobinuric Fever, Isthmian Canal Commission.

present in those from which it was formerly absent; why it obtains in certain areas only in a malaria-infected district; and why in restricted localities, or even in certain houses, the malady may present itself, while those adjacent are free.

Although the evidence associating hæmoglobinuric fever with the presence of malarial parasites is circumstantial, since it relies in great part on the skill and experience of observers, it is none the less strong and authoritative, in actuality far more so than that which implies a lack of such association. Notwithstanding the reported absence in isolated instances of proof of malarial infection in blackwater fever during life or at autopsy, the connection between the two is not materially affected thereby, for when all circumstances of the relationship are considered in their entirety, the dependency of the latter upon the former is manifested to an extent unparalleled in the etiology of infectious diseases. When to the epidemiological evidence of this relationship is added these proofs, that in no other malady is malarial infection so constantly present; that in malarious countries other diseases fail to show even an approximate amount of such infection; that mechanical and therapeutical measures instituted against malaria are equally efficient against hæmoglobinuric fever; that prompt and efficient treatment against the one, no matter how greatly it obtains, is successful also in reducing the prevalence of the other; either the truth of the relationship as asserted must be admitted, or the existence of an organism dependent upon the conditions enumerated must be assumed. Such an assumption is not supported in biology, either by analogy or fact, unless some vague conjecture of an improbable symbiosis be so included.

In our opinion it is better to describe hæmoglobinuric fever as Marchiafava and Bignami have done, as "a syndrome which is encountered not rarely, especially in hot climates, in the course of a malarial infection." For, although medical usage may sanction in some instances the classification of different conditions dependent upon the same etiological factor as distinctive "diseases," there is no need for such application to the description of the hæmoglobinuria and associated symptoms that "occur in the course of a malarial infection."

Since it is not possible to predicate the amount of infection that results in the determination of any of the other malarial syndromes otherwise than to say that they occur in proportion to the intensity of malaria, it is illogical to assert, as some have done, that blackwater fever should invariably follow when a certain degree of personal malarial infection has been attained. One might as well say that every infection with *Bacillus tuberculosis* is followed by the same symptoms, or that meningitis ensues when a certain number of the diplococci of pneumonia are present.

We know that when such organisms are localized in certain parts of the body definite symptoms follow, and we believe that under certain conditions the toxins of malaria poison produce hæmolysis; but why some persons are thus acted upon while others with equal amounts of infection are not, is a problem that still awaits solution, nor does our lack of knowledge in this respect affect our cognizance of the primary cause. The primary cause in hæmoglobinuric fever is either prior or coincident malaria, or both; the immediate cause is sometimes the administration of quinine, but this never acts unless the primary cause has been present. With this knowledge we are able to treat the syndrome intelligently and often to prevent occurrence by the removal of the primary cause and by sending away from the source of infection those who, since by reason of personal idiosyncrasy they cannot take quinine at any time without the production of blackwater fever, should not remain in a malarious country.

Current Literature.

ANNALES DE LA SOCIETE BELGE DE MEDECINE TROPICALE.

Tome IV, No. 2, November, 1924.

A Case of Creeping Pseudomyasis at Boma (A. Fornara).—This is apparently the first case reported in Boma. A boy of one year was brought to the hospital with a cutaneous lesion on the left leg; it began a month previously with nocturnal itching. The lesion began on the dorsal region of the foot, continued round the external side of the leg, across the sole, and along the internal side of the leg up to the ankle and up the leg. A circle was traced around the lesion with nitrate of silver, which immediately changed the direction of its course. Curettage and examination revealed no parasite, and the case was diagnosed as creeping pseudomyasis, or "oerbis of the ouolofs." After curettage and dressing with alcohol the lesion rapidly healed; the nitrate of silver possibly contributed to the cure.

Treatment of Yaws by Dermatol (J. Miguens).—Fourteen children suffering from yaws, ages between two and eight years, were treated by the author. Three were treated with neosalvarsan and the rest with dermatol (oil suspension of sous-gallate of bismuth), intramuscular injections. The results obtained with dermatol are as favourable as those obtained with the arsenics. The action of dermatol is very rapid; the product is not expensive, it is easy to use, does not cause pain, and is within easy reach of every medical man. In some cases the lesions were of long duration and had not been previously treated. The preparation used was dermatol powder mixed with olive oil, previously washed in alcohol; as soon as it was taken out of the bain-marie (boiling), boiled filtered water was then added. Put into a corked bottle, it is ready for use several days afterwards. It can also be used without the addition of water, and perhaps is better tolerated, if the bottle is shaken before putting in the syringe.

The Pathology of the Natives of the Region of Lokandu (M. Kadaner).—During the author's two

years' sojourn at Lokandu nearly all the maladies met with in Europe have been treated by him. The natives have not much faith in white doctors, but with careful management, and after seeing the good results in others, they readily come for treatment. Macular leprosy is to be found in four to five per cent. of the population; it is known under the name "Bukoma." Tubercular leprosy is rare (half to one per cent.). Injections of atoxyl-emetic have given good results in the treatment of this disease. Yaws is very common and nearly every black has had it at some time or another. 914 is the best remedy for yaws. Bismuth has also given good results, but can only be given intramuscularly. Trypanosomiasis exists along the river from Kindu to Ponthierville, in about one per cent. of the population. The natives willingly undergo ganglionic puncture and injections in this district. Syphilis is very common, especially along the river, but nervous symptoms are less frequent than in Europeans. Small-pox is rare, especially since vaccination (*largomanu*) has been practised. About forty cases of amœbic dysentery have been treated in the two years. Helminthiasis is frequent among the blacks of this region, and malaria also. Phagedenic ulcer is widely spread; goitre is found in certain parts. Tuberculosis in the interior part of the country is rare.

Some Observations on Pneumonia in the Black Race (M. Kadaner).—Lokandu is a military centre where pneumonia among the black race is very common. Most of the recruits are affected during the first few months after their arrival. Some races are more susceptible to the disease than others. The cause is attributed to the change of life and food, and the men's coming into contact with other races for the first time. The first symptom is simply high fever, the local symptoms not appearing till after the second or third day. Symptomatic treatment is generally sufficient. Complications are sometimes observed.

A Hymenoptera Bethylide which stings Man in the Habitations of the Congo (J. Bequaert).—An insect exists in the Tropics, which frequently stings man, and which has been defined as a female hymenoptera without wings, with all the characters of the genus *Sclerodermus* Klug (*Scleroderma* Westwood). The total length of the insect varies from 2 to 3·2 centimetres. They live on the larvæ of *Coleoptera xylophagus* found in books and furniture.

Bronchomycosis due to Sterigmatocystis in Urandi (G. Mattlet).—Five cases of pulmonary affection have been met with due to parasites of the genus sterigmatocystis, which can be divided into two series; those in which the parasite causes benign symptoms and those in which the parasite produces grave symptoms resembling those of pulmonary tuberculosis. Potassium of iodine associated with terebinth or with guaiacol or emetine have given good results.

Contributions to the Study of Geographical Distribution of the Glossinæ (G. Trolli).—During investigations on sleeping sickness of 1908 and 1909 along the River Congo and its tributaries, numerous glossinæ were met with, nearly all being *palpalis*. In 1912 and 1913 investigations in Katanga showed *G. morsitans* present almost everywhere, and *G. palpalis* was entirely absent; other species existing in these parts are described.

"Bayer 205" in the Treatment of Human Trypanosomiasis (F. Van Den Branden and L. Van Hoof).—In man Bayer 205 has a strong trypanocidal action, which, however, is slow. The blood sterilization is more rapid in patients injected intravenously than in those injected intramuscularly or subcutaneously. Bayer 205 and atoxyl do not cure trypanosomiasis once it has reached the second stage; clinical benefit can be obtained more by the latter than the former. The number of deaths recorded in the second stage in sixteen months is forty-eight per cent. Bayer 205 injected intrarachidianly in doses from 0·05 grm. may cause grave accidents, and in doses from 0·30 grm. mortal accidents. Duration of the sterilization of the blood after a single dose of one grm. may be very long. Sterilization is also of long duration in patients treated in the second period of the disease. A cutaneous eruption has been noticed after treatment, similar to urticarial plaques, and a herpetiform eruption on the lips; renal irritation has also been observed, which, in some cases ends with nephritis.

THE UNIVERSITY OF LIVERPOOL.

EXAMINATION LIST.

December, 1924.

Faculty of Medicine.

Diploma in Tropical Medicine.—H. S. Bilimoria, M.B., B.S.; B. L. Davis, M.B., Ch.B.; C. B. Jennings, M.B., B.Ch., B.A.O.; S. W. S. Lee, M.B., B.Ch., B.A.O.; G. Macdonald, M.B., Ch.B.; J. M. Mitchell, M.B., Ch.B.; D. U. Owen, M.B., Ch.B.; Beryl Palmer-Jones, M.B., B.S.; E. J. Sankeralli, M.B., B.Ch., B.A.O.; H. Singh, M.B., B.S.

Recommended for the Alan H. Milne medal: Dr. B. L. Davis.

EX-OFFICER, 33, joined up in 1914 (married, one child), wants a berth where steady application is needed. Gets on well with the crowd (natives or otherwise) both in the Army and out. Careful at keeping records and the in- and out-goings of big concerns. Overseas position not objected to. Fuller details from E. C., c/o *Tropical Life*, 5 Great Tower Street, London, E.C.3.

Tropical Medicine and Hygiene

FEBRUARY 2, 1925.

SECOND SPECIAL CANCER NUMBER.

Notices.

BUSINESS AND GENERAL.

1.—**The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.**

2.—**Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.**

3.—**All literary communications should be addressed to the Editors.**

4.—**All business communications and payments, either of subscriptions or advertisements, should be sent to the Publishers of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank Ltd.**

5.—**The Subscription, which is Thirty Shillings per annum, may commence at any time, and is payable in advance.**

6.—**Change of address should be promptly notified.**

7.—**Non-receipt of copies of the Journal should be notified to the Publishers.**

8.—**The Journal will be issued about the first and fifteenth of every month.**

TO CORRESPONDENTS.

9.—**Manuscripts if not accepted will be returned.**

10.—**As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.**

11.—**To ensure accuracy in printing it is specially requested that all communications should be written clearly.**

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—**Authors of original communications are entitled to 25 reprints, free of charge.**

14.—**Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.**

15.—**Correspondents should look for replies under the heading "Answers to Correspondents."**

REPRINTS.

Contributors of Original Articles will be supplied with reprints if the order for these, with remittance, is given when MS. is sent in. The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 ,, ,, ...	1	3	3
200 ,, ,, ...	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 ,, ,, ,,	2	6	0
200 ,, ,, ,,	2	17	6

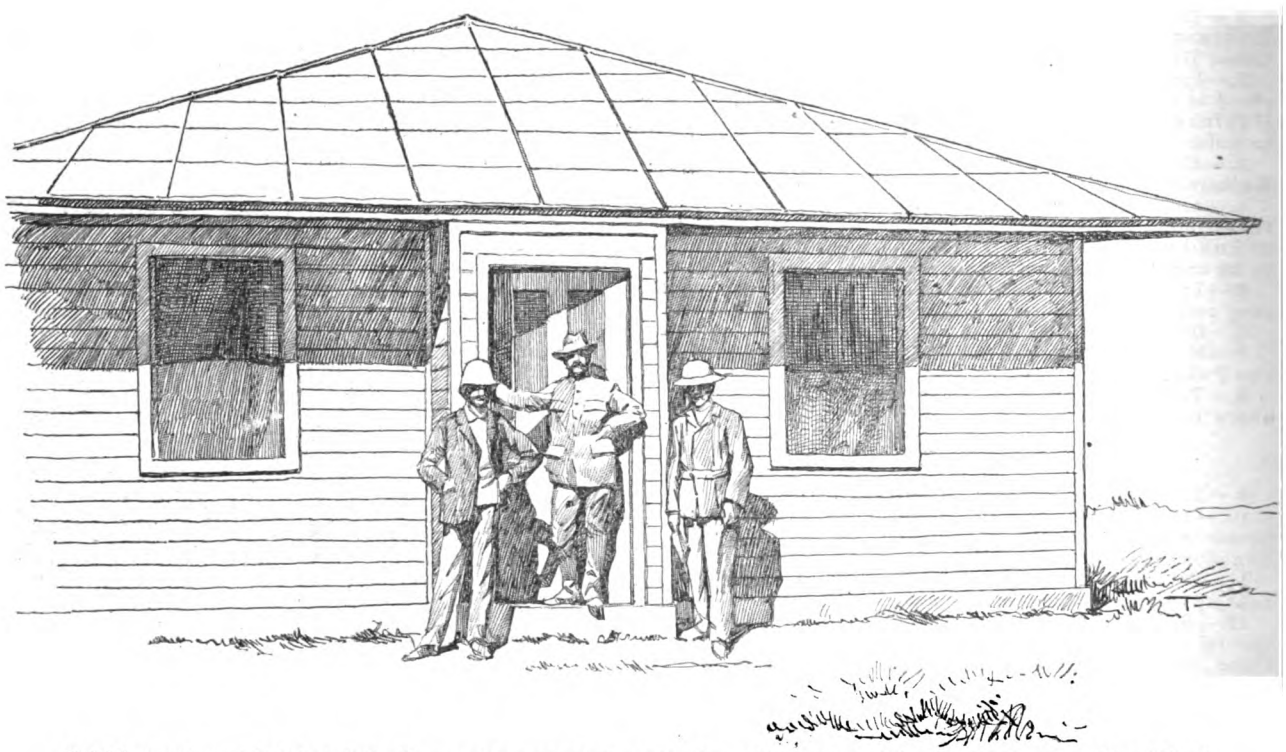
Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

THE CANCER PROBLEM.

ON June 2, 1924, we published a paper on the Elucidation of Cancer by Dr. Louis Westenra Sambon, a remarkable paper, the result of a few weeks' field-work in certain districts of Romagna (Italy) greatly afflicted by the fearful tumoral disease. That paper was much appreciated, not only here, but even more so abroad, witness that it was translated into French by Dr. Nègre of the Pasteur Institute, Paris.



To-day, after a few months only, we publish a second, larger, more imposing report by the same investigator, the outcome of subsequent researches made in Iceland and Italy last summer and autumn. This report, given in the shape of a lecture, read on December 10 last at the Pasteur Institute, Paris, laden, as it is, with important, irrefutable documents, stands as a finger-post indicating the straight road to the elucidation of cancer. After reading it, one cannot fail to see that Sambon has overthrown all the theories, speculations and vagaries that barred the way to an understanding of the cancer problem. The clear, incisive views stated in his essay strike one forcibly. We understand and sense that cancer is an infective disease caused by some intracellular micro-organism which attacks tissues of low or lowered resistance, favoured by the agency of diverse factors among which parasitic worms seem to play the major part and are themselves subject to intermediary hosts which determine the peculiar distribution of the malady. The epidemiology of cancer, hitherto unsuspected, emerges clear as a sunlit landscape out of the fog of our ignorance, as we read Sambon's report of his travels and study the charts and maps with which it is illustrated. One does not know what to admire more, whether his comprehension of epidemiological facts, or his parasitological knowledge, the beauty of his narrative, touched up here and there with short word-pictures which bring the very places before one's eye, or his logical, far-seeing, penetrating mind. But above all stand out two important facts: (1) cancer is a parasitic disease, (2) its control is within our reach.

It is fortunate that, at last, our foremost epidemiologist has taken up the question of cancer and placed it where it should have been long ago.

An epidemiologist is a quantity but little known amongst us. Few men in the world, in ancient or modern times, have devoted themselves to the study of epidemiology pure and simple. No one can earn a livelihood by it, and no man in this country has ever attempted to do what Sambon has done. He has devoted his life to the subject. There is no brass plate on his door; no patients call upon an epidemiologist for advice. The writer once heard Sir Patrick Manson say: "Sambon should be supported by the State," but that day has not come to pass and, in Sambon's lifetime, in all probability it never may. The writer, perhaps more than any other man, has had a glimpse into Sambon's "inner

life " and his struggles to live and carry out the work for which he is so eminently fitted. What a wonderful story he could tell! Sambon has braved even starvation for the sake of Science, but what a splendid record of work in archæology, geology, medical entomology, protozoology, helminthology and epidemiology! His is the many-sided knowledge, the broadmindedness necessary to form a true epidemiologist.

It fell to the lot of Professor F. Mesnil, a great French scientist, to place before us Sambon's work and tell the world what he has done. Acting as chairman of the meeting at the Pasteur Institute, after the words " Ladies and gentlemen " to the assembled host, turning to Sambon he said: " Dr. Sambon, I have had the honour of knowing you for

British experimental hut at Ostia (Roman Campagna), June-October, 1900. (From left to right Mr. A. J. Engel Terzi, Dr. L. W. Sambon, Dr. G. C. Low.)

over a quarter of a century; I remember when, sent by the British Colonial Office and the London School of Tropical Medicine, you went to the Roman Campagna to put the finishing stone to the great malaria edifice. I remember how, on your return, you laid before us the most definite, conclusive proofs of the truth of the mosquito-malaria theory. I remember the views you expressed with regard to the non-malarial origin of black-water fever, views adversely criticized at the time; we are proud that two of our own countrymen have proved that you were right. I remember how you worked out the ætiology of sleeping sickness, its transmission by a tse-tse fly, the necessary sexual cycle in the fly; you were right. I remember your indictment of the body-louse as the carrier of typhus fever: there again men of the Pasteur Institute proved, by actual experiment, that you were right. Dr. Sambon, you are going to speak to us about cancer, and we feel that what you are going to say, again, is going to prove true; therefore we will listen to you with attention, devotion and admiration.

The triumph of Dr. Sambon's life was reached at that great meeting at the Institut Pasteur in Paris, where, under Calmette's leadership, scientific France assembled to do him honour, and where, later, in the evening of the same day, at a splendid banquet, he was entertained in a fashion worthy of French hospitality.

In thanking Sambon for his address, the world-known scientist, Professor Emile Roux, Director of the Pasteur Institute, said that it was by means of researches so highly documented and scientifically conducted as those of Dr. Sambon that one could hope clearly to peer some day into a question hitherto so obscure. Therefore it was to be hoped that similar explorations should be continued and multiplied as much as possible.

The day after, Professor Calmette wrote to Dr. Sambon a letter in which he says: " The Pasteur Institute is very grateful to you for the address you so kindly delivered before its members, as also before the members of the Société de Pathologie

Exotique and its guests, the Professors of the Natural History Museum of Paris, the Faculty of Medicine, and the members of the French Association and of the Anglo-Franco-American Association for the fight against cancer.

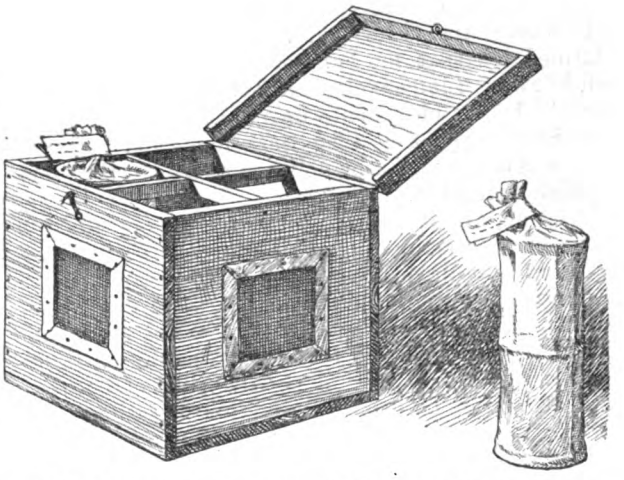
"We are fully disposed to enter into the views which you have declared to us and to collaborate with you in the researches which obviously it would be extremely useful to carry out in different countries on the ætiology of cancer, and particularly on the part played by parasites in its genesis, a rôle which has been so well demonstrated by the researches of Professor Borrel in this Institute, Professor Fibiger at Copenhagen, Bullock and Curtis in America, and by your own."

Professor Borrel, Director of the Bacteriological Institute of Strasbourg, who had purposely come to Paris to attend Dr. Sambon's lecture, invited our epidemiologist to go with him to Strasbourg, and the result of that visit—some hours spent in Borrel's laboratory—is highly interesting. It was a great compliment from one scientist to another, and one pregnant with possibilities.

Another development which has emerged from Dr. Sambon's work is that his researches have stimulated others to follow in his path. Dr. Nègre, who translated his first report, went soon after to the south of France, there to carry out similar researches. These fully confirm Sambon's views and add much to our knowledge of the epidemiology of cancer. Then Dr. Ciurcentaler, recently Chief Medical Officer of the Trentino, after having assisted Dr. Sambon in his work in that province, continued the researches and has produced very valuable evidence in support of the parasitic nature of cancer, notably the striking map of Villa Lagarina (see p. 59), in which village during fifty years cancer attacked practically only a single street.

Dr. Sambon's paper is followed by two other important contributions by British Museum experts. The first is by Dr. H. A. Baylis, who, by kind permission of the Trustees, took part in Sambon's recent researches in the Trentino and Romagna and made a special study of the Gongylonema and other worms collected. If nothing else had resulted from the labours of the Commission, this one paper "On Gongylonema collected in Italy during October, 1924, with some observations on the Genus," would amply repay the few weeks and pounds spent in Italy.

Mr. K. G. Blair's contribution, "On some notes on the insects intermediary hosts of Gongylonema" is no less interesting.



Finally must be mentioned the inimitable pen drawings of insects by Mr. A. Terzi, who, when asked the price, said it was his mite towards the furtherance of Sambon's unpaid work on cancer.

It was by means of a few pounds put up by some of his personal friends, chiefly physicians, and his own savings, that Sambon was able to go to Iceland and Italy and give us this invaluable report.

Sambon's work must be continued and without interruption. It is for us to see that some means be found to help him in his great fight to vanquish our most deadly malady.

In a brilliant article on our "Epidemiologist" published in the January last number of the *Whitehall Gazette and St. James's Review*, occurs a paragraph which we cannot refrain from transcribing here. It runs: "Dr. Sambon's report upon his inquiries in Romagna is a remarkable document of curiously wide learning and close argument, and it cannot fail to impress upon the medical world the importance of pursuing the investigation of cancer upon an epidemiological basis. It is to be hoped that this will be done with all the support which the British Empire Cancer Campaign can give, and, although the question in Ecclesiastes, "Where shall wisdom be found?" has not yet been finally answered, it may be suggested that it would be found in giving to Dr. Louis Westenra Sambon the charge of these inquiries."

JAMES CANTLIE.

Sambon's gauze tubes, suggested by cobwebs, and box in which malaria-infected mosquitoes travelled from Ostia to London in 1900.

RESEARCHES ON THE EPIDEMIOLOGY OF CANCER MADE IN ICELAND AND ITALY (JULY—OCTOBER, 1924).[1]

By LOUIS WESTENRA SAMBON, M.D., F.Z.S.

Lecturer in the London School of Tropical Medicine. Corresponding Member of the Société de Pathologie Exotique.

THE solemnity of this meeting, Professor Mesnil's far too flattering introduction and the generosity of your welcome, make me feel very keenly the inadequacy of my efforts.

The cancer problem which you have asked me to discuss is, without doubt, the gravest, most difficult and urgent with which modern science has to grapple. It is a problem which has baffled the

[1] Lecture delivered at the Institut Pasteur, Paris, on December 10, 1924.

centuries and one on which to-day medical opinion is so greatly divided that we see the layman take up our rattle and presume a knowledge of the causes which give rise to the awful malady.

I propose to lay before you a few epidemiological and parasitological facts bearing on the etiology of cancer gleaned during researches recently made in Italy and Iceland. These facts I owe, in considerable measure, to the courtesy and keen observation of local physicians and district health officers.

Expect nothing startling, only carefully ascertained facts which confirm similar observations made repeatedly in different countries and at different times, yet strangely ignored.

Early in life was I taught the truth of the old saying: "Nothing new under the sun." When about twelve, I lived in Naples. Large oleanders adorned our garden; these, full of fragrant rose-like blossoms, were infested by yellow aphids. I noticed that ants visited the parasitised branches and collected from the aphids droplets of a syrupy secretion which oozed out of long horn-like tubes upon the backs of their sap-distended abdomens. I told a family friend, the Italian zoologist Francesco Gasco, that I knew how and where the ants got their sweetmeats. He informed me that my Lilliputian confectioners were well-known; Linnæus had called them the "ant's cows." It was pleasant to hear that my observations were correct and that they were confirmed by those made a century earlier by no less a man than the great Swedish naturalist.

Later on, archæological studies taught one that no man can ever claim to have discovered or invented anything himself outright, because all discoveries, all inventions depend on previous successive discoveries and inventions, themselves the outcome of the labour of countless individuals through untold ages. They are the result, not only of positive, but of negative data also; not only of correct interpretations, but also of mistakes. This latter truth centuries of experience have crystallized into the proverb: "*Errando discitur.*"

On this occasion, I am not going to touch upon clinical, pathological, histological, or cytological questions concerning cancer, but, with all due respect to the successors of Bichat, Dupuytren, Laënnec and Cruveilhier, indeed because of the great regard I entertain for sound pathological work, I must express surprise at certain fantastic theories, such as those which ascribe malignant tumours to rebellious cells, embryonic remains or strange conjugations between blood and tissue cells! Nor can I here, in this sanctuary, where burns so vividly the flame of Pasteur's genius, pass unchallenged the claim of the pathologist who vaunts that he can produce cancer *de novo* by means of a few strokes of the magic tar-brush! Why, it is Van Helmont's trick reversed. You will remember, the good friar, physician and chemist claimed that he could produce mice out of soiled rags, a few grains of wheat or a morsel of cheese! It is all so simple, toasted cheese in the case of mice, coal-tar derivatives in the case of cancer. Surely you have not forgotten Pasteur's words to Pouchet in his memorable debate on spontaneous generation: "I will show you how the mice entered Van Helmont's pot."

The treatment question is deplorable, but I have neither aloetic pills, nor plague-preventing thieves' vinegar to propose. Certainly, in the course of my researches, I have come across some extraordinary remedies, but are they more efficacious than those now in common use? In Iceland, of old, a large crab was allowed to die over the homonymous tumour. In the Trentino, I was informed by Dr. de Bellat that lizards (*Lacerta agilis* and *L. muralis*) are still used in the treatment of cancer. These swift little reptiles, sunning themselves on the walls, or flashing across the road, are caught with the hand, or by means of a horse-hair noose, chopped up and fed raw to patients suffering from cancer. This remedy of raw minced-lizard is based on a very old folk-belief that cancer is an animal—a tiny snake or worm—which devours the tissues. Give it plenty of raw flesh and it will spare the tissues of its host! Dr. Vezzetti, of Borgo, vaunted the merits of violet tea, a very old remedy commended by Pliny the elder, agreeable to the poet-physician Francesco Redi and taken up nowadays by Professor Fichera of Rome. "What is your opinion?" asked Dr. Vezzetti, and I praised the exquisite beauty and delicious fragrance of the sweet violet, even suggested that like emetine in amœbic dysentery, so also violine might have some action on the cancer germs and agreed that tea, syrup or conserve of violets must prove as pleasant a cordial in the treatment of phthisis, rheumatism and cancer as strawberries in the treatment of sprue, but I felt that the Violet's reproach to Alice (Through the Looking-glass): "I never saw anybody that looked stupider than you do" must have applied forcibly to me.

Let us get rid of baseless theories and mock cures while we seek for solid facts which alone can lead us in the way of truth.

During my recent researches in Italy I had the valuable assistance of Dr. H. A. Baylis, helminthologist in the Natural History Department of the British Museum. He kindly undertook to help me in my field work and study any helminthological material which we might come across. Dr. Baylis has made some interesting observations on some of the worms collected and these he will describe to you presently himself. The determination of the entomological material has also been made by British Museum experts, of whom I am indebted particularly to Mr. K. G. Blair, Dr. W. T. Calman, F.R.S., F. W. Edwards and A. S. Hirst.

In the time at my disposal it would be impossible to give a full account of the numerous epidemiological and parasitological observations which I had the opportunity of making in Iceland and Italy. I must perforce limit myself to a very summary exposition of some of the more important.

Allow me to begin with Iceland.

In 1905 Professor Lazarus Barlow published a short note on cancer in Iceland based on data furnished by the Royal Board of Public Health in Copenhagen and by Dr. Jonasson, Chief Medical Officer at Reykjavík. He stated that cancer still

appeared to be an uncommon disease in Iceland though known at all times and fairly evenly distributed throughout the country. The available reports seemed to indicate that, though previously extremely rare, cancer had become more prevalent in 1896 when several medical men reported the occurrence of unusually numerous cases. Three years later, when the largest number of cases was recorded—27 in a population of 76,383—the ratio was 3·66 to 10,000 of population and 3·34 per cent. of all deaths above the age of 35 years. Nearly half the cases registered were cases of gastric cancer and Professor Barlow pointed out particularly the exceptionally large proportion of cancer of the alimentary tract. Uterine and breast cases were infrequent and cancer of the penis completely absent.

In 1922, Professor Gudmundur Hannesson, then Chief Medical Officer of Iceland, published a remarkable statistical work on the public health of his country covering the period 1911-20. Speaking of tumours, he points out that the cancer statistics are unreliable. "Some of the patients do not seek a doctor and are not registered, others are seen by more than one physician and are listed often twice over. The number of cancer cases reported by the doctors does not agree with the number of deaths due to cancer, the diagnosis is often merely clinical, and not confirmed either by post-mortem finding or

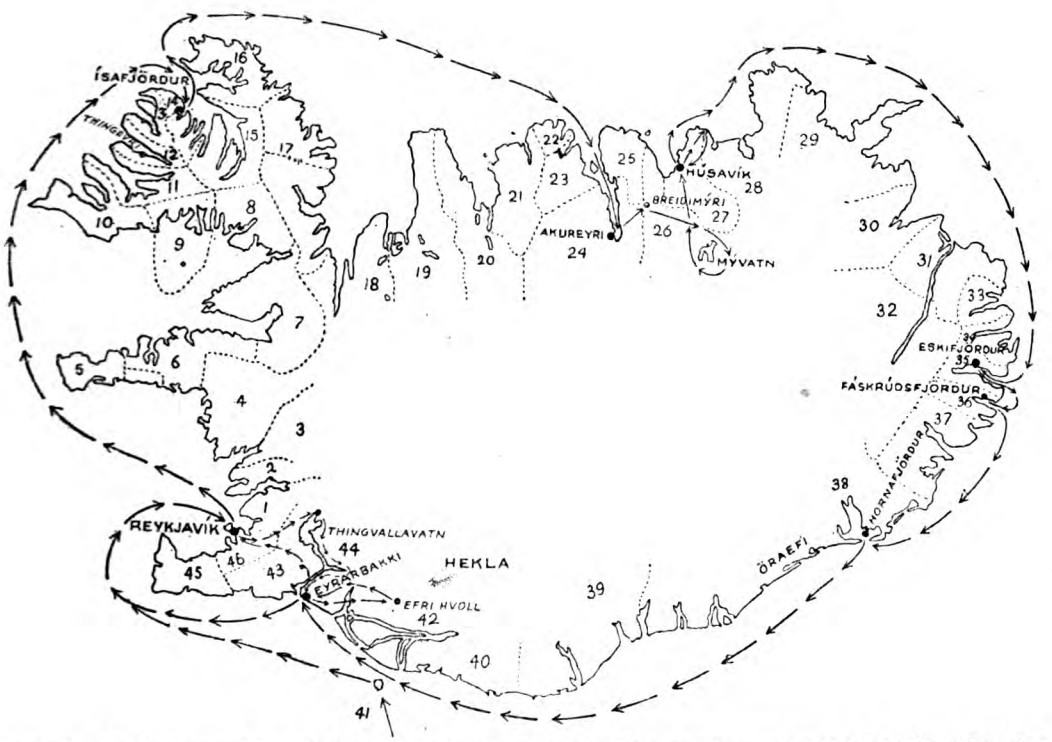
microscopical examination. However, the figures show that there were fewer cases recorded in the first five years than in the last, but the increase seems hardly greater than would be expected on account of the increase of population from 85,573 in 1911 to 94,690 in 1920. In the years 1911-15 there were reported on an average, 8·6 cases and 9·9 deaths per 10,000 of population, whilst in the period 1916-20 there were reported 9·2 cases and 10·6 deaths per 10,000 of population. With regard to site-incidence, the disease affected, more especially, the alimentary tract. After the stomach (46·9 per cent.), the œsophagus (9·7 per cent.), the liver (8·6 per cent.), and the intestine (3·3 per cent.), came the female breast (10·5 per cent.), and the uterus (3·8 per cent.).



Invited last summer to revisit Iceland and attend the *Lœknafundur* or National Medical Congress which was to be held in Akureyri, I left Leith by the Icelandic steamer *Lagarfoss* and reached Reykjavík on July 26. On landing, I was met by Professor Gudmundur Finnbogason, an eminent philosopher and writer, Rector of the University, and by Mr. Örn Benediktsson, my assistant, who had preceded me to make all arrangements. The very next day I left for Akureyri on board the Danish steamer *Island*, together with Professor Gudmundur Björnson, Chief Medical Officer of Iceland, Professor Hannesson, Doctors Thórdur Thoroddsen, Gudmundur Thoroddsen, Thórdur Edilonsson, Konrád Konrádsson, Jón Kristjánsson and other physicians from the capital and the southern districts, who were going to attend the congress. Unfortunately, a severe epidemic of acute poliomyelitis, which greatly hampered my researches, already had spread widely throughout the

island and this prevented the majority of physicians from joining us.

After leaving Reykjavík, our first landing was at Isafjördur, the principal trading station on the north-west coast. The district of Isafjördur has a population of 2,500 or a little more. Together with Professor Hannesson, most agreeable of travelling companions, who everywhere kindly acted as my guide, interpreter, and instructor, I called on Dr. Jonsson, who had been medical officer of the district for about five years. We sat on chairs made of the bones of a whale, round a table of the same material, and were regaled with excellent coffee and cakes. Dr. Jonsson told us that in the five years he had seen twenty-one cases of cancer distributed as follows: stomach six, œsophagus four, peritoneum four, liver two, colon one, rectum one, breast one, urinary bladder one, epididymis one. He had performed orchotomy in his case of cancerous sarcocele and had been anxious to watch the outcome, but, unfortunately, the patient was drowned soon afterwards whilst out fishing. The microscopical examination of the neoplasm made at Reykjavík proved it to be a carcinoma. Rats and mice abounded in Isafjördur, whilst every boat that approached the landing-stage brought cockroaches (*Blattella germanica*), but he had not seen these insects in any of the houses and remembered one only infested by bedbugs. We visited the old hospital and there I had the opportunity of examining a woman about 32 years of age, suffering from cancer of the œsophagus. From the old we went to the new hospital, which was being erected on plans drawn by Professor Hannesson, who excells in architecture as he does in medicine and philosophy.

From Isafjördur we steamed to Akureyri, a bright little town charmingly situated near the head of the Eyjafjördur, on the north coast of Iceland. There met, on July 31, the Icelandic Medical Association and there, in a superb school building, I had the honour of addressing them on the elucidation of cancer.

From Akureyri, accompanied by the son of my distinguished friend Dr. Steingrimur Matthiasson, I travelled on pony-back across mountains and valleys, rivers and snow drifts, scaring the sheep and reindeer, putting up ptarmigan, plover and curlew. We passed a small forest of beech which nestled in the Fnjóskadalur or "Touch-wood Valley," skirted the Ljósavatn or "Lake of Sparkling Water" and tarried to watch the roaring, deafening Godafoss or "Fall of the Gods," arriving in the small hours at Breidimýri, where we were most hospitably received by Dr. Sigmundu Sigurdson, the district medical officer of Reykdæla.

Map of Iceland showing position of places visited or mentioned. (The numbers indicate the Medical Districts and correspond to the numbers placed before the District names on mortality charts.

The district of Reykdæla has a population of about 1,200 inhabitants, scattered over a vast volcanic region which enchases a wonderful sapphire, the Mývatn or "Midge Lake," full of trout and wild duck. In this district, during a practice of over sixteen years, Dr. Sigurdson had seen only eleven cases of cancer: one in 1912, one in 1913, one in 1920, four in 1921, four in 1922. With regard to site incidence, they were distributed as follows: stomach six, breast two, lip one, maxilla one, intestine one.

Poliomyelitis was rampant at Breidimýri and all Dr. Sigurdson's children had contracted it. In a cottage built of lava slabs and turf, close to the doctor's house, I had the opportunity of examining two grave cases with multiple paralyses. However, Dr. Sigurdson and I were able to make a journey of three days' duration round the lake and visited not only farms and patients, but saw also vast craters of explosion, mud volcanoes and painted solfataras, beautifully variegated with indigo, yellow, white and crimson, but belching forth acrid, suffocating vapours. We passed through great lava fields with petrified torrents wedged and twisted into nightmare forms, more terrible than the Dinosaurs of the Mesozoic era, more grotesque than the gargoyles of Nôtre Dame. In these Phlegræan haunts we were assailed by thick black clouds of sand-flies (*Simulium vittatum*) which harassed us exceedingly, entering eyes, ears, mouth, nostrils, and giving us a foretaste of the Inferno.

Whilst riding to the south-west of lake Mývatn, picking our way under a downpour of rain through swamp and beech-covered frost-knolls, we met a tall, lean, red-haired man who dismounted and approached the doctor. He exhibited a growth with hard, indurated base, which protruded from the middle of the lower lip and had appeared three months previous at the edge of a leucoplasia. "An epithelioma!" exclaimed Dr. Sigurdson whilst feeling the man's submaxillary glands, and then we both examined the patient, a very poor farmer, 57 years of age. The doctor advised him to go to the hospital at Akureyri, and the farmer gave us a grip of his hand, cold and boney, like the hand of death. He left us with calmness and resignation in his saddened face.

How strange that weird consultation, under a pelting rain-storm in the middle of the wild, desolate moor! Sigurdson was obviously moved; he knew the man. I followed in silence, full of admiration for the country doctor, truly a good Samaritan, who faces daily endless difficulties, fatigues and perils in the execution of his duties. I have seen him at work in tropical jungles, beneath a blistering sun; I have seen him in northern latitudes fitted with "ski," braving the blinding snow-storm; I have seen him tear himself from his own sick child to go and aid a parturient woman in the middle of the night. He has given me freely all the knowledge he had acquired in long years of study and practice; first-hand knowledge, true, accurate, valuable. Indeed, forget not, out of his ranks rose the Hameaus and the Brettoneaus!

On the morrow, I left for Húsavík, a small station on the eastern shore of the bay of Skjálfandi. On arrival I called on Dr. Björn Josefsson whom I had met at Akureyri. He informed me that the district of Húsavík has a population of 1,598 inhabitants. During his sixteen years practice in this district he had seen eight cases of cancer (breast four, stomach two, lungs one, maxilla one). For six and a half years before he had practised in the district of Öxarfjördur and there had seen one case of gastric carcinoma in a woman whose sister some years later died also of cancer of the stomach in Húsavík. Dr. Josefsson had seen cancer of the glans penis in a pony and cancer of the maxilla in a sheep.

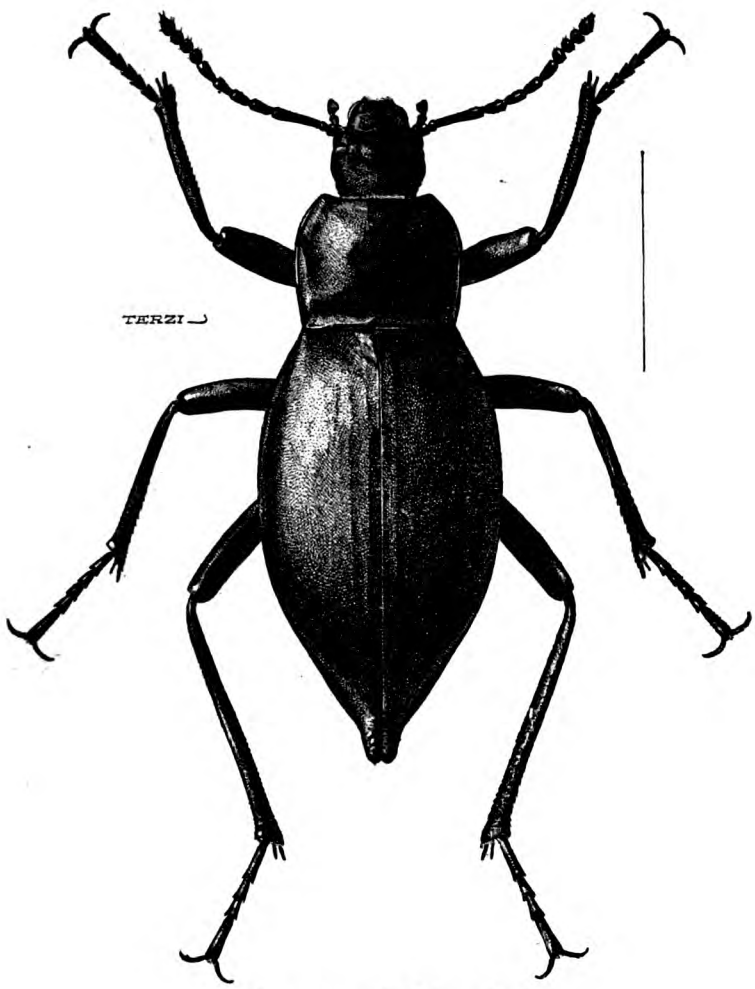
Poliomyelitis was still rife at Húsavík; the first case had occurred on June 13, since when the doctor had treated one hundred and eleven cases. Almost every family with children had been attacked. One was reminded of the tenth plague of Egypt, the death of the first-born!

Whilst in Dr. Josefsson's consulting room, I caught some flies which were walking leisurely on the window panes, they were specimens of *Fucellia fucorum* which had come in from the shore strewn with great brown seaweeds (*Fuchus* and *Laminaria*) and with countless heads of cod drying in the sun to serve as fodder for sheep and cattle in winter.

From Húsavík I embarked on the Icelandic steamer *Esja* and, so doing, rejoined the Congressmen who had boarded her at Akureyri.

Stopping at Reydarfjördur, on the East Coast, I landed, whilst our ship took in cargo and, together with Professors Björnson and Hannesson, called on Dr. Sigurdur Kvaran who had been for eleven years in the district of Reydarfjördur. He told us that he saw, as a rule, from two to three cases of cancer each year. He had seen malignant tumours in stomach, œsophagus, lip, liver, breast and uterus. He believed the disease to be infectious. People, whether related or not, seemed to contract it, not from one another, but from some common source whilst living in or frequenting the same house. He remembered two cases, one of the lip, the other of the stomach in persons distantly related, but living in the same house. More than once had he observed a case in one farm followed by another case in a neighbouring farm.

Our next landing was at Fáskrúdsfjördur where we were lavishly entertained by Dr. Georg Georgsson in a palatial residence built, like the adjoining hospital, by the French Government. Dr. Georgsson was also French Consul and the tricolor flag fluttered coquettishly over his dwelling. In his study was a beautiful bronze bust of Liberty and on the dining table other penates in the shape of champagne bottles, together with dishes of cakes and boxes of fragrant Havana cigars. Our stay was short at Fáskrúdsfjördur and Dr. Georgsson so much in demand by the *Esja's* passengers, who had turned out *en masse* to pay him homage that my notes on cancer from this locality are scanty in consequence.

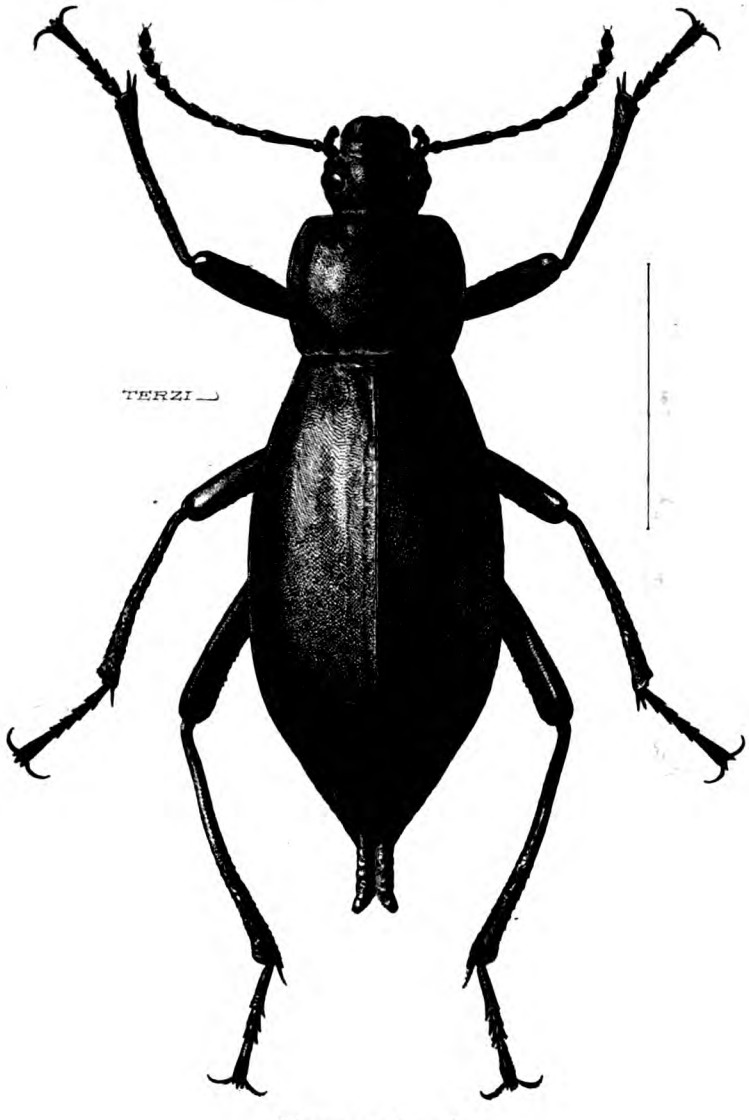


Then we went to Hornafjardarós near the Vestrahorn or Cape West. It is a small maritime station at the bottom of a lagoon formed by two gulfs, the Skardsfjördur and the Hornafjördur, and divided from the sea by a long sand-bar. Taking advantage of the tide, we crossed the land-spit through a narrow shallow passage, whilst clouds of sea birds rose shrieking from the bar. In this very lagoon had alighted on August 2 and 3 respectively the two American aviators Nelson and Smith in their great world flight.

Landing at a stage strewn with coarse salt, where cod was being split, cleaned and salted, I went with Professor Hannesson to visit the district physician, Dr. Henrik Erlendsson, a short, square sturdy man of pleasant appearance and charming manners who spoke Danish, English, French and Italian, almost as fluently as his own language. He told us that he

had practised in the Hornafjördur district for over twelve years. His district was wide and difficult. It took him no less than five days hard pony-riding to travel from the furthest eastern farm to the most southern or western, crossing innumerable glacier-streams and rivers, swollen and dangerous in winter. The population under his care numbered about 1,200. During his twelve years of practice he had seen but five cases of cancer, all gastric. He well remembered a young man from the Lagoon parish who had died of carcinoma of the cardiac portion of the stomach at the age of thirty-seven. He used to gulp down his coffee boiling hot. Another case was that of an old clergyman whose gastric tumour was complicated by hepatic metastasis.

The district of Hornafjördur is divided into five parishes: Mýrar (the northern parish), Sudursveit (the southern), Nesjar (the Peninsula), Lón (the Lagoon) and Öræfi (the Desert). Dr. Erlendsson had never seen cancer cases in Öræfi, and it is noteworthy in this connection that neither rats, nor mice, nor cockroaches have ever been seen in this parish. Rats and mice are great travellers, as everyone knows, but they had never been able to reach the parish of Öræfi on account of the vast sand stretches, glaciers, wide rivers and many streams which barred their way. This parish contains about twenty farms or collections of cottages with a total population of about 250 inhabitants. The farmers have to drive their flocks of sheep miles over the glaciers to bring them to the rare pasturages, scattered like oases over a wild, inhospitable land of sliding glaciers and drifting volcanic sands.

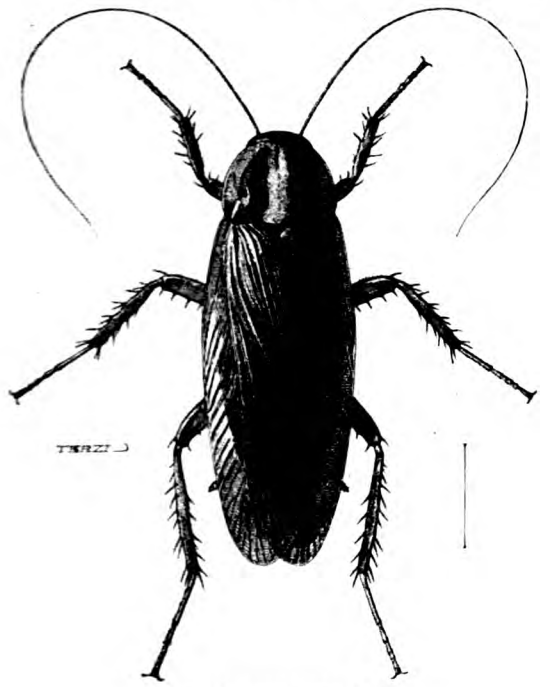


The last landing, before we returned to Reykjavík, was Eyrarbakki, a port, or rather anchorage, on the south coast, bad but necessary, in the waters of which we saw some seals. Here I called on Dr. Peturson, the district medical officer whom I had met two years before at the time of King Christian's visit to his island kingdom. Dr. Peturson had practised there ten years, and he told me that since 1915 he had seen twenty-one cases of cancer distributed as follows: stomach, thirteen; œsophagus, one; tongue, one: larynx, one; maxilla, one; liver, one; colon, one; breast, one; urinary

Blaps mucronata Latr. ♂

bladder, one. The district has a fishing population of 3,540 inhabitants.

With Professor Hannesson and Dr. Peturson I visited two bakeries, one of which was forty years old and had a large brick-built oven. It was managed by a Danish baker who had lived in Eyrarbakki since 1909. This man told us that occasionally he found meal-worms in meal imported from Britain and America, but that he had never seen either the cockroaches or the crickets, which are such frequent sub-tenants of Danish bakehouses.



Blaps gages L. ♂

On my return to Reykjavík I made inquiries concerning the presence of *Blattidæ* and *Tenebrionidæ* in Iceland. Dr. Bjarni Sæmundsson, Director of the Natural History Museum, showed me specimens of *Blaps mucronata* and of *Blaps gages* found at or near Reykjavík, but he could not tell me whether they had been found elsewhere on the island. Probably the museum specimens had been imported from abroad with merchandise. The insect which seems to take their place in Iceland is a coal-black beetle of which there were a few, as yet undetermined, specimens in the museum. It is very common throughout the country and is popularly known everywhere by the name of "járnsmidur," the "blacksmith." I have collected specimens myself at Húsavík, Thingvellir, Ægisida and Eyrarbakki. Mr. Blair believes it to be a species of *Pristonychus*, probably *P. terricola*. It had not been recorded previously from Iceland.

At the Reykjavík museum there was a specimen of the American cockroach (*Periplaneta americana*) which had been found in 1915 in a barrel of apples as well as some specimens of *Blatta orientalis* found in a Reykjavík storehouse. There were specimens also

of *Blattella germanica*, which is scattered widely throughout the island, though apparently restricted to certain localities. The specimens in the museum collection came from two very different places: from Reykjavík and from Thingeyri in the Dyrafjördur on the north-west coast of Iceland. Dr. Sæmundsson himself had collected *B. germanica* at Reykjavík in 1922 from a lowly hostel called the "Sudurpoll," or "South Pole," which harboured also numerous bed-bugs. He had found them again on the good ship *Ceres*, a Danish boat in which he travelled from Akureyri and, on reaching home some were discovered in his luggage.

With Professor Björnson I visited several private dwellings, eating-houses and stores in Reykjavík where cockroaches were said to have been found and I succeeded in collecting them in plenty from a well-furnished flat, inhabited by a charming newly-wedded

Blattella germanica (L.) ♀

couple, from a bakery, a pastry-cook's, a first-class restaurant and a barber's shop. They were all specimens of *B. germanica*. Whilst hunting in the last-named place the director of the Reykjavík lunatic asylum came in and, seeing me bottling cockroaches, invited me to visit his establishment. Professor Björnson was highly amused, but the alienist explained that he was offering me big game, because the asylum was infested by larger and darker cockroaches.

On all the ships I visited in the port of Reykjavík, as in those in which I travelled, I found *B. germanica* very much at home, so I have no doubt that, as in the case of rats, cockroaches must have been imported into Iceland by means of sea-commerce since early days.

The chief veterinary surgeon at Reykjavík told me that on several occasions he had observed cancer of the penis and sheath in ponies and malignant tumours of liver and ovaries in cattle. Frequently he had found worms in the intestines of sheep, cows and ponies, but he had not looked for, or seen Gongylonema. He had not preserved his material and the museum did not contain any parasitological collection.

The physicians told me that in man the pinworm (*Oxyuris vermicularis*) was very common, but that the eelworm (*Ascaris lumbricoides*) and the whipworm (*Trichuris trichiura*) were practically unknown. Already, in 1874, Finsen had pointed out the great frequency of the pinworm and the rarity of the eelworm.

Iceland has long been known as the classic land of hydatid disease, but nowadays echinococcosis has diminished in frequency as strikingly as yellow fever at Panama, following the application of preventive measures judiciously based on true and precise etiological knowledge. Fifty years ago, when echinococcosis was believed to be a hereditary disease (Skaptason), the proportion of Icelanders affected was about 1 in 40, to-day it is below 1 in 2,000, and varies from one district to another in accordance with the stringency used in the application of preventive measures (destruction of infested viscera, systematic treatment of dogs).

Another disease which has diminished greatly in Iceland, as in other European countries, is leprosy. Some cases do still crop up from time to time, especially on the eastern and northern coasts, but they are very few.

Syphilis is of particular importance in view of the ætiology of cancer, because, apart from the error of believing cancer to be a modification or degeneration of the venereal disease, the syphilitic lesions are looked upon by some as "pre-cancerous" conditions. Now, in Iceland, although cases of syphilis have been observed not only in foreigners, but also in Icelanders at some of the principal ports such as Reykjavík, Akureyri, Siglufjördur, Seydisfjördur and Eyrarbakki, the country may be said to be still free from this loathsome disease. Professor Hannesson's statistics prove it. At Hornafjördur, Dr. Erlendsson told me that he had never seen syphilis in his district, excepting once only in a foreign seaman. Dr. Sigurdsson assured me that in the district of Reykdæla he had never seen either syphilis, gonorrhœa, or chancre.

I regret that time will not allow me to mention all the observations made in Iceland anent cancer, because they overturn many theories which may seem plausible enough in the places in which they originated, but appear absurd elsewhere. For instance, the eating of pork frequently has been adduced as a cause of cancer; certainly in France the hog's flesh forms the basis of the animal food of the great majority of the rural population, but in Iceland there are few, if any, pigs at all and the Icelanders (save very few in Reykjavík) do not eat pork either fresh or salted. It is true that swine were imported into Iceland in 890 by Helgi "the lean" and that we find them often

mentioned in the old sagas, for the most part wild and wandering in droves, others, a ring through the snout, tended by slaves, but, though pork was esteemed and sucking-pig relished, pigs were dwindling in the fourteenth century and gone in the fifteenth. In 1910 a few swine were imported again into Iceland for the purpose of breeding them, but the experiment seems to have failed. Possibly there may be a few domestic swine in Iceland, but I never saw any.

The absence or rarity of the hog in Iceland might well explain the absence or rarity of certain parasitic diseases such as the cysticercosis of porcine origin and trichinosis. Maybe it might explain also the absence or great rarity of *Trichuris* and *Ascaris* among the Icelanders. The absence or quasi-absence of these two round worms in a country devoid of swine and their frequency in other northern countries (Finland, Greenland), where hogs are raised, would tend to confirm a doubt long entertained that *Ascaris suum* and *Trichuris crenata* of the hog might not differ specifically from *A. lumbricoides* and *T. trichiura* of man, but represent merely varieties, or rather host races—human and porcine—interchangeable.

Similarly, one might demolish other alimentary theories such as those which ascribe cancer to the eating of tomatoes, water-cress or white bread. The food of the Icelander consists of milk, eggs, fish, meat, rye-bread and one or two vegetables. The milk is taken cold or in the form of "skyr," a soft white cheese of attractive texture and flavour, made from fresh milk curdled by souring and rennet, and served with cream and sugar. The fish is eaten boiled and served with melted butter. It may be cod, ling, hake, haddock, pollock, herring, mackerel, plaice,skate, lump-sucker, cat-fish, shark, turbot, halibut, trout or salmon; fish dried into biscuit-like crispness (hardfiskur) or salted (saltfiskur), cured herring and smoked salmon or trout. The meats are usually mutton, either fresh (September, October) or salted and smoked, sometimes beef or seal, rarely horse-flesh, often feathered game such as swan, duck, ptarmigan, puffin, plover and curlew. Of vegetables they have few: potatoes, turnips, sorrel, angelica, rhubarb and sweet laminaria; of fruit: red-currant, wild strawberry, bilberry and crowberry. Their bread is usually unleavened and made either entirely of rye or of a mixture of rye and wheat, but of wheat flour they make excellent cakes and the best of pancakes served hot or cold with currant, strawberry or prune-preserve between their folds, with sugar sprinkled over. They use imported cereals such as rice and oats as well as lentils, currants and spice; they are, with the French, the best coffee-brewers in the world. Yet they have not the scarlet tomato, neither have they watercress.

Let us not forget that hardly half a century ago, echinococcosis was believed to be a food disease. To Thorstensen, chief medical officer of Iceland, it was the excessive use of cold meat which caused the disease, to another Icelandic physician, mentioned by Schleisner, it was the unleavened bread, to others again the paucity of vegetable food. If to-day we knew not the actual cause of hydatid disease, I have no doubt it would be put down either to lack or to excess of vitamines.

Let us turn to Italy.

In the first place I must mention briefly a few facts gleaned the summer before last when first I began my cancer researches in the fertile alluvial plains of Romagna, on the Adriatic coast, between Ravenna and Rimini. These observations, already published in the *Proceedings of the Royal Society of Medicine*, and, more fully, in the *Journal of Tropical Medicine*, have had not only the honour of a translation by Dr. Nègre of this Institute, but confirmation also from the results of similar researches which he has carried out recently in France.

I pointed out that the topographical distribution of cancer in Romagna presented striking inequalities well known to the local physicians.

Already, in an unpublished work, kindly placed at my disposal, Professor Testi and Dr. Galli, of Faenza, had described the irregular distribution of the disease in the town and territory of Faenza.

Professor Ortali, chief surgeon in the Ravenna hospital, informed me that at Mezzano, a village of about 1,500 inhabitants, he had found cancer cases in almost every family.

At Castiglione di Cervia, a locality long immune, he had seen four cases which had occurred suddenly in different families all at about the same time.

Dr. Chiadini, of Forli, stated that while cancer frequently occurred in the parishes of Romiti, Villagrappa, Villanova and Castiglione of Forli, it was unknown in the parish of San Varano, or, at any rate, during the last fifteen years not one case had been seen or heard of there.

Similar inequalities in the topographical incidence of cancer have been noticed throughout the world and have been reported frequently, yet they have not received the attention they deserve. To my mind, they strongly support the parasitic theory and, if properly investigated by competent men, should lead inevitably to the elucidation of the ætiology of cancer.

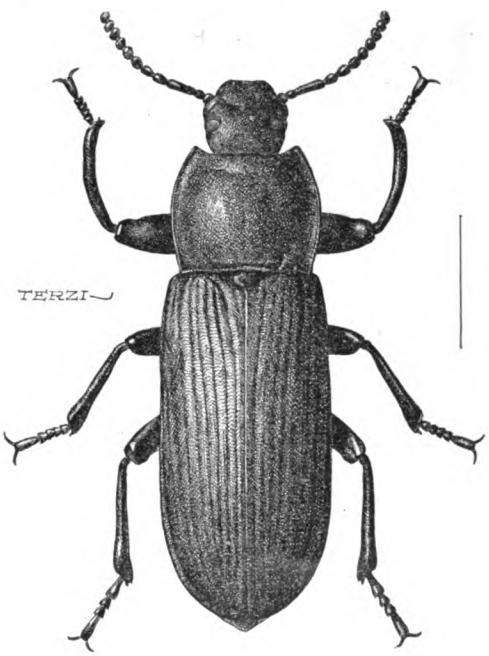
I gave examples also of the "cancer-house" so persistently ignored, yet repeatedly cited. I described two such houses shown to me by the local health officers. One was at Cotignola, a small town of about 7,000 inhabitants, on the River Senio. It was situated in Via Farini and bore the number 44. Five cases of cancer had occurred in this house in different families which had inhabited it within a short period. I examined the house very carefully; it was old and somewhat dilapidated, but well built, spacious, amply ventilated and clean. Having discovered evidence of the presence of cockroaches in two of the rooms on the ground floor, I asked permission to inspect the adjoining building. This granted, I found that the two rooms mentioned backed an old bakery oven. On inquiry, the proprietress of the bakery declared her oven-room so badly infested by cockroaches that, notwithstanding repeated endeavours at eradication, she had not been able to make the least impression on the swarming insects. Rats were seen frequently in the courtyard and mice in the bakery.

The second example was that of Predappio, a hill village of about 3,000 inhabitants, placed on the road

which, following the upper course of the River Rabbi, leads from Forli into Tuscany. Here, in Via Mulino, I saw two contiguous houses where five cases of cancer had occurred. One belonged to the family Capacci, the other adjoined a mill and was inhabited by the miller Francesco Zoli. In the former two cases of cancer had occurred, one of the breast, the other of the stomach, while in the latter the miller had lost father, mother and grandfather from cancer of the stomach. This house was full of sacks of grain and flour. Both buildings were infested by mice, rats, cockroaches and other household pests attracted by meal.

Another observation of importance relates to the organ or part of the body affected. In Romagna, cancer was a disease essentially of the upper part of the alimentary tract (œsophagus, stomach, pharynx, buccal cavity, tongue) and more especially of the cardiac portion of the stomach. This fact, revealed by the figures of site incidence, kindly supplied by the health officers and by the directors of the hospitals of Ravenna, Bologna, Faenza and Forli, was confirmed by my own observations and by the experience of Dr. Utili, radiographer to the Faenza hospital, who particularly insisted on the location of cancer at either the cardiac orifice or lesser curvature, and produced convincing radiographs in proof of his contention.

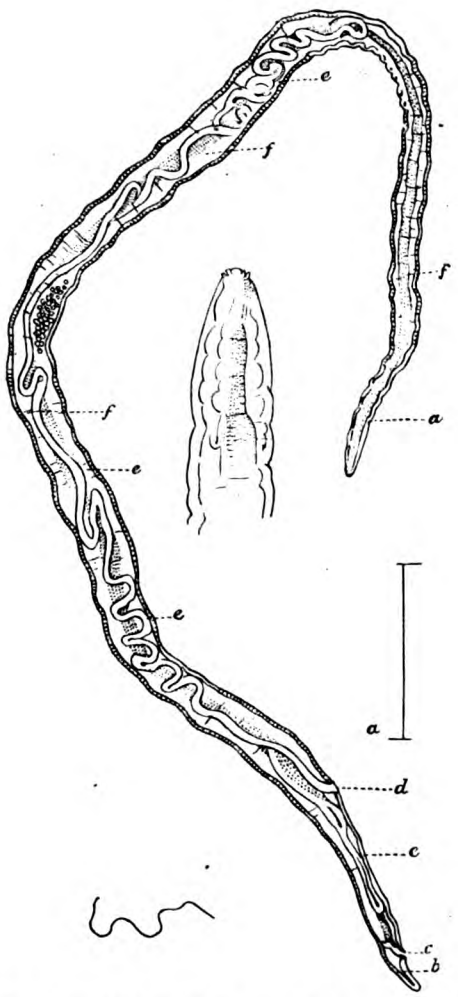
The inspection of farmhouses and dwellings in which cases of cancer had occurred revealed invariably infestation by the common cockroach (*Blatta orientalis*). These insects, as a rule were found in the meal-ark, an indispensable article of furniture present in all farmhouses. Besides cockroaches, I found in the meal-flour Meal-beetles (*Tenebrio molitor* and *T. obscurus*), Meal-moths (*Asopia farinalis*) and Meal-mites (*Aleurobius farinæ* and *Tyrogliphus longior*). In the stables adjoining the living rooms of farmhouses, beneath the alfalfa fodder-heaps, always I found Cellar-beetles (*Blaps gages* and *B. gibba*) as well as wood-lice (*Porcellio*), whilst mice, field-mice and rats everywhere abounded.



The observations made in Italy in 1923, proved:—
(1) The striking inequality of the geographical and and topographical distribution of cancer.

(2) The extraordinary frequency of the disease in the upper portion of the alimentary tract, especially the œsophagus and the cardiac end of the stomach.

(3) The constant presence of rats, mice, cockroaches, cellar-beetles and meal-worms in houses presenting one or more cancer cases.



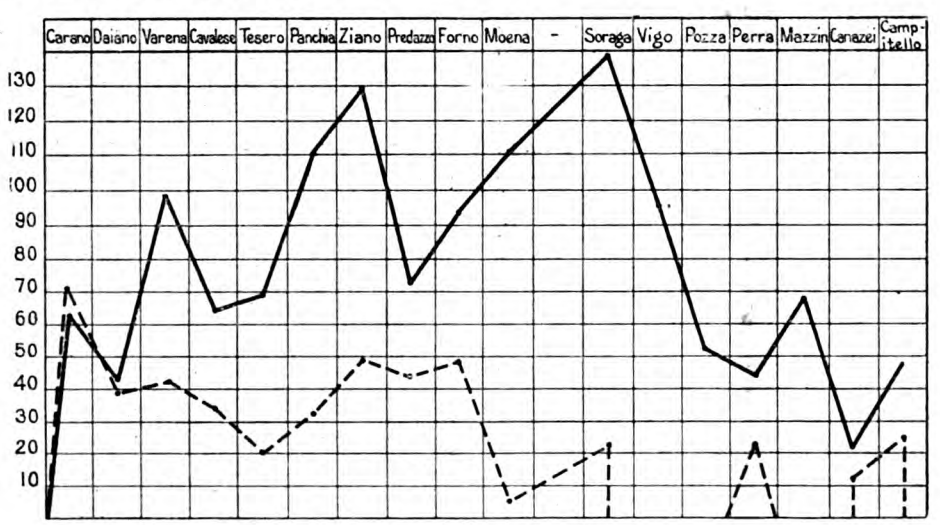
These facts led me to wonder whether a possible infestation with Gongylonema might not explain at least some of the cancer cases met with in Romagna. Professor Fibiger's researches and experiments on the part played by a Gongylonema in bringing about gastric carcinoma in rats are well known. But my Italian researches lasted less than three weeks and when the Gongylonema idea began to take shape in my mind I was back in England, so I turned to literature and found that in 1916 an immature form of Gongylonema had been found in a man by Professor Henry Ward, of Urbana (Illinois). Further, I found that as many as four cases of Gongylonema infection in man had been recorded from the United States of America by Ward, Stiles and Ransom. All these were cases of immature forms found in the region of the lips. But there were no like records from the old world. Checked, I hunted up all references to undetermined or wrongly placed nematodes found in the lip and upper portion of the alimentary tract of man. This brought me Pane's *Filaria labialis*.

Professor Carlo Pane, of Naples, as long ago as 1864 had described under this name a nematode, found beneath the epithelial covering of the upper lip in a Neapolitan medical student. His description showed at once that the worm could not be a filaria because its vulva opened at the posterior instead of the

Tenebrio obscurus Fab.
The dark Meal-Beetle,

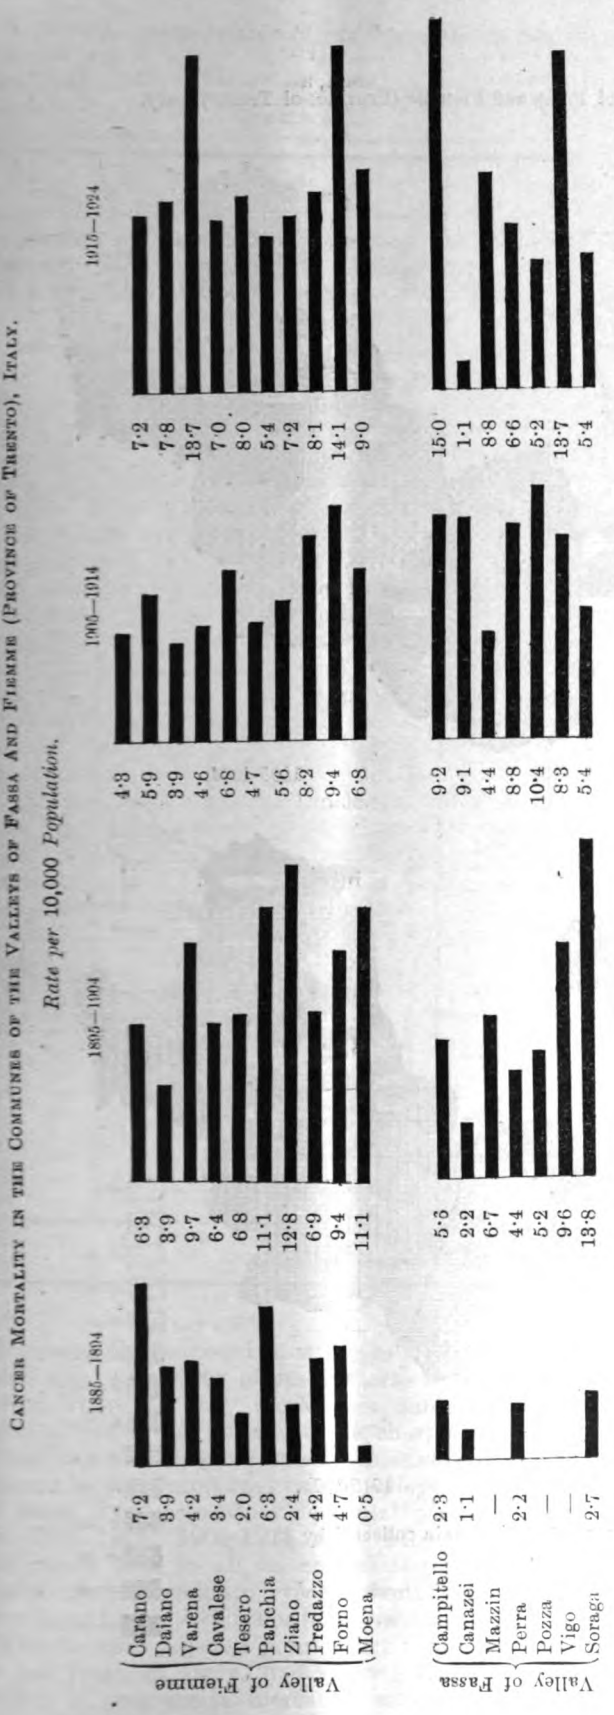
anterior extremity. Pane's description was insufficient to lead to identification, but happily, his paper was illustrated by an accurate picture of the worm drawn by the eminent Italian naturalist Paolo Panceri. The drawing is that of a gongylonema without doubt. Thus was established in Italy also, after a lapse of sixty years, the presence of Gonylonema in man. Professor Ward, on receipt of my paper, at once kindly wrote: "I was intensely interested in your explanation of the case of Pane. You have offered the most likely solution of his problematic *Filaria labialis*. The drawings by Panceri, which I had not seen, leave very little doubt in my mind that your interpretation is correct." But, no doubt the Saint Thomases of our day might quibble about the inadequacy of a drawing as scientific evidence; therefore, I decided to go back to Italy to look for Gongylonema in man, or at least in the domestic

Pane's "*Filaria labialis*," a *Gongylonema*, probably *G. pulchrum*. From the original drawing by Paolo Panceri, 1864.



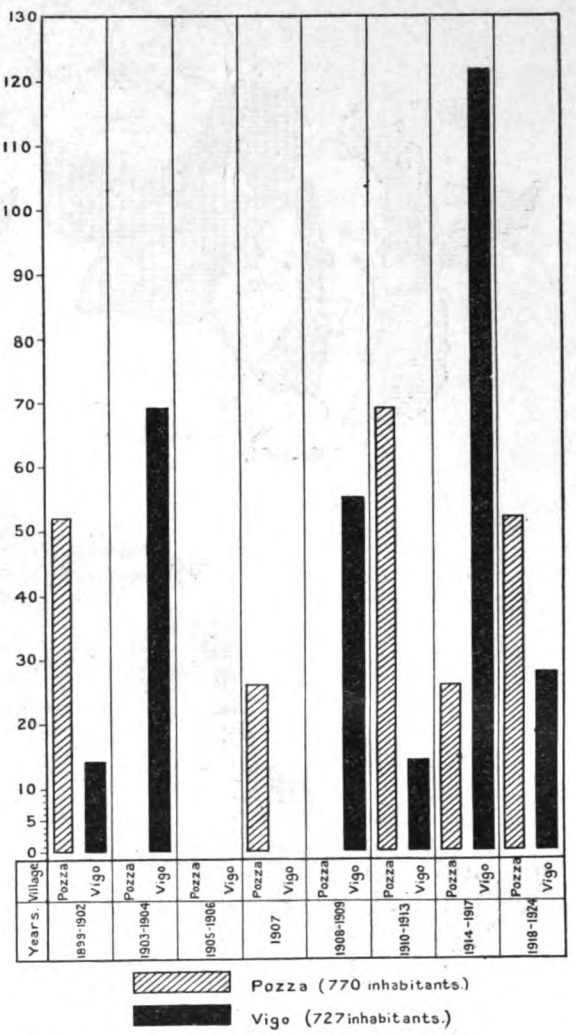
animals living in close touch with him. This I did a few weeks ago with Dr. Baylis who will tell you how we found Gongylonema, and abundantly, in the sheep, goats, oxen and swine of the Trentino and Romagna.

My recent epidemiological researches in Italy were carried out chiefly in the Trentino where I found strong support and valuable help in my friend, Dr. Antonio Ciurcentlar, recently chief medical officer of the Province; who accompanied me in all my excursions, save one to the district of Bolzano, where I went with Dr. Weiss, the present chief medical officer of the Trentino.



Of course I can mention only a few of the observations and these very briefly.

Whilst at Rovereto, on October 8, we met Dr. Mezzena who for twenty-five years had been district medical officer of Cavalese, a district comprising the two charming valleys of Fiemme and Fassa. Dr. Mezzena told us he had noticed that cancer was far more prevalent in the villages placed along the middle portion of the Fiemme valley. Indeed, with regard to frequency of incidence, the disease described a curve which, beginning to rise about Drina, Carano and Varena, reached a maximum between Cavalese and Predazzo, to decline rapidly at about the junction of the Fiemme valley with that of Fassa. The disease was practically unknown then in the Fassa valley beyond Mœna and Vigo. He could not say whether these conditions still prevailed now because he had left the district of Cavalese fifteen years ago.



Six days later, we went to Cavalese and there were met by the district medical officer, Dr. Luigi Cosco Mazzuca, a bright, intelligent, well read Calabrian. He told us that, as stated by Dr. Mezzena, cancer was still very common in the Fiemme valley. Never elsewhere had he seen so many cases. The disease now seemed to be especially rife at Castello, Molina, Carano, Daiano, Varena, Cavalese, it continued with like frequency along Tesero, Ziano, Panchia and

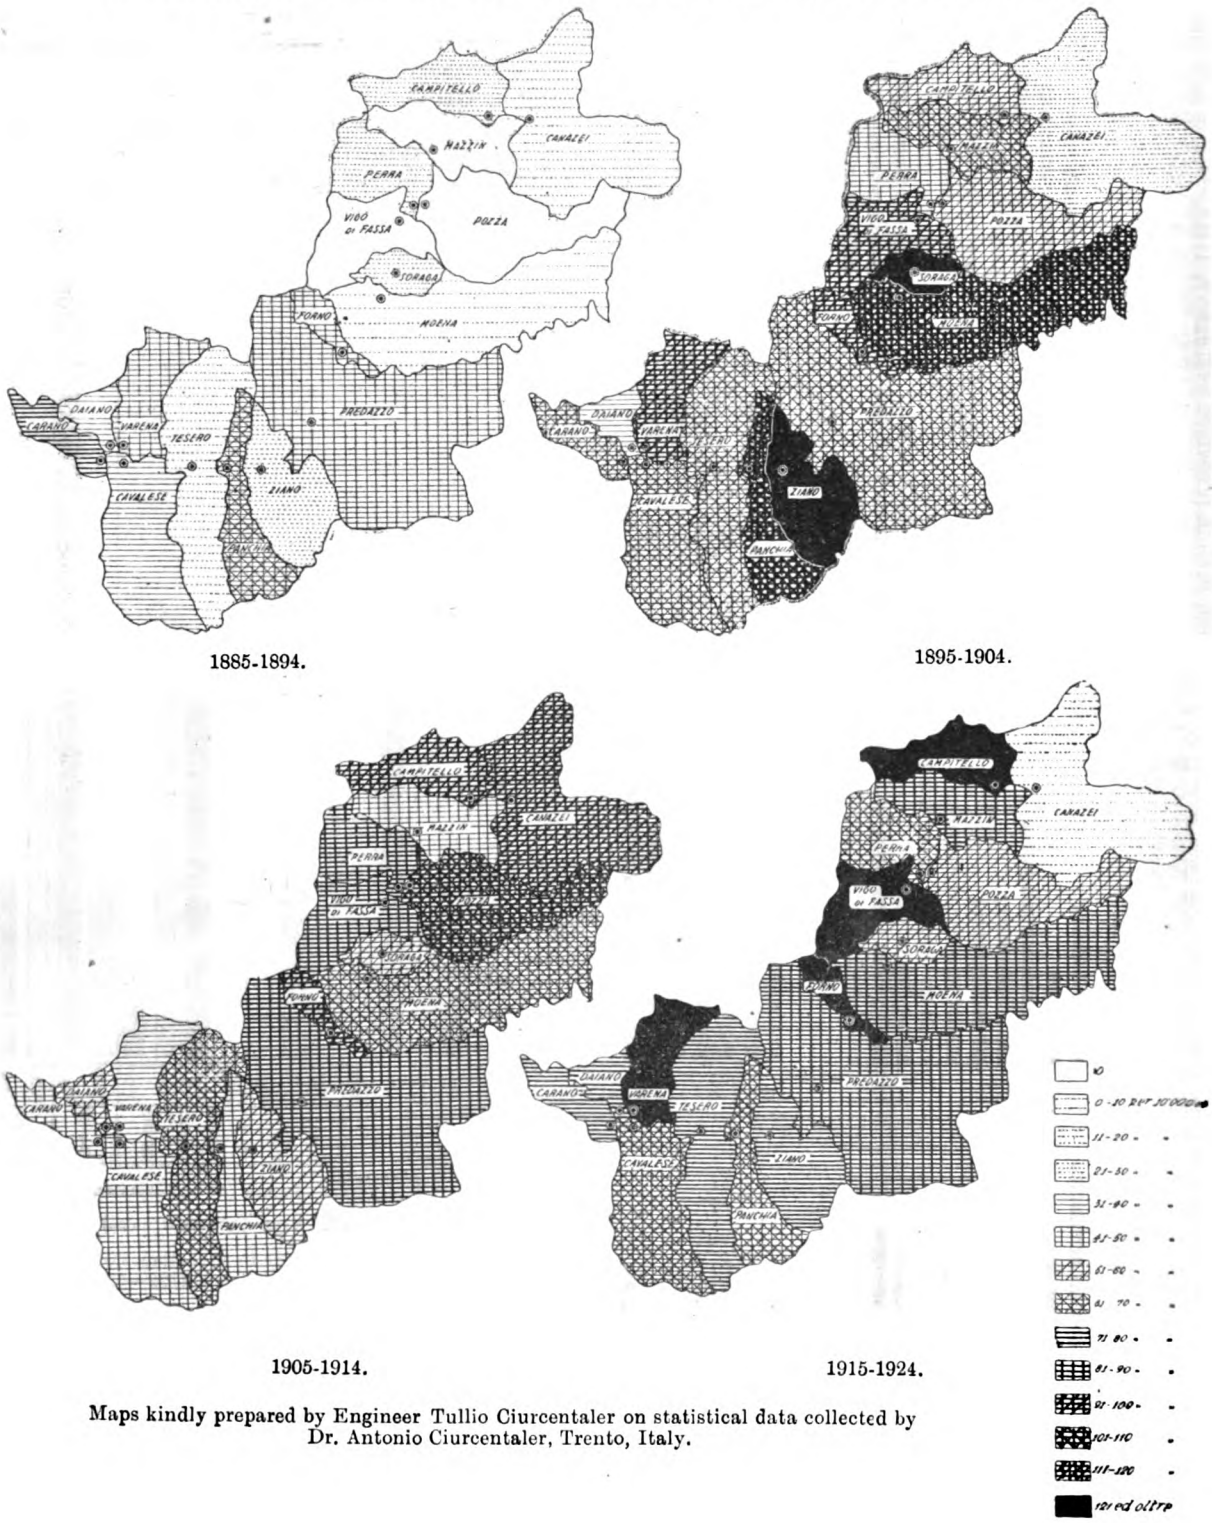
Predazzo, thence becoming less marked, but, contrary to Dr. Mezzena's earlier observations, cancer had now appeared also in the Fassa valley where it seemed to be extending and increasing. When Dr. Mazzuca first came to this district, not only was he greatly impressed by the number of cases, but was surprised to find so little cancer of the lip in a cancer-region where men were inveterate pipe smokers. With regard to site-incidence, cancer here was pre-eminently a disease of the stomach and more especially of the cardiac portion. In one single day he had been able to diagnose no less



Alternating Cancer Mortality in the villages of Pozza and Vigo in the valley of Fassa, 1899—1924.

than three of the latter cases. Notwithstanding numerous instances of pyloric ulcer, he was surprised to find so few of pyloric cancer, a form frequently met with in other parts of Italy. In women he had seen uterine cancer, but rarely cancer of the breast.

The examination of the death registers of this district, kindly undertaken by Dr. Ciurcentaler who commenced with the year 1885, previous to Dr. Mezzena's tenure of office, yielded very interesting data.

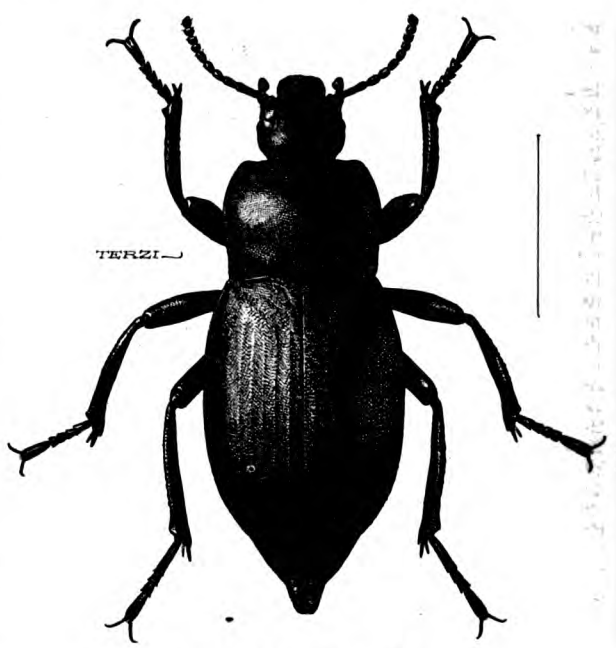
It showed that cancer is distributed very unequally, that it may spread to places hitherto immune, and that its frequency may increase or diminish in the course of years. A glance at the charts and maps representing the distribution and relative prevalence of cancer in the Communes of the valleys of Fiemme and Fassa during the four decennial periods 1885-1894, 1895-1904, 1905-1914 and 1915-1924 shows most clearly that in all its epidemiological features —distribution, prevalence, yearly fluctuations, &c.— cancer is strikingly like other infective diseases.

In my London paper, I pointed out that Professors Foa and Testi, in Italy, had noticed that notwithstanding its progressive increase, cancer exhibits in its incidence notable fluctuations from year to year. The chart on p. 51 shows a remarkable alternation in the incidence of cancer in the two neighbouring villages of Pozza and Vigo. These two villages are hardly a mile apart and have an almost equal number of inhabitants. Similar alternations in neighbouring villages have been repeatedly noticed in the case of typhoid fever, diphtheria and pneumonia.

There are other epidemiological facts to which I should like to draw your attention, such as seasonal incidence for instance, but, so far, my information is not definite enough. Drs. Samuel and W. Soltau Fenwick in their book on "Cancer and other Tumours of the Stomach," London, 1902, say "we are strongly

of opinion that carcinoma obeys certain laws of epidemiology, like enteric fever, acute rheumatism and other infective diseases, and is, consequently, more rife at certain seasons than others." They point out that the usual duration of gastric cancer varies from nine to twelve months, that in 60 per cent. of cases it commences between September and February, and that in over 60 per cent of cases death takes place between June and November. Long before, both Virchow and d'Espine had noticed that persons affected with malignant disease die more frequently in the summer than in the winter.



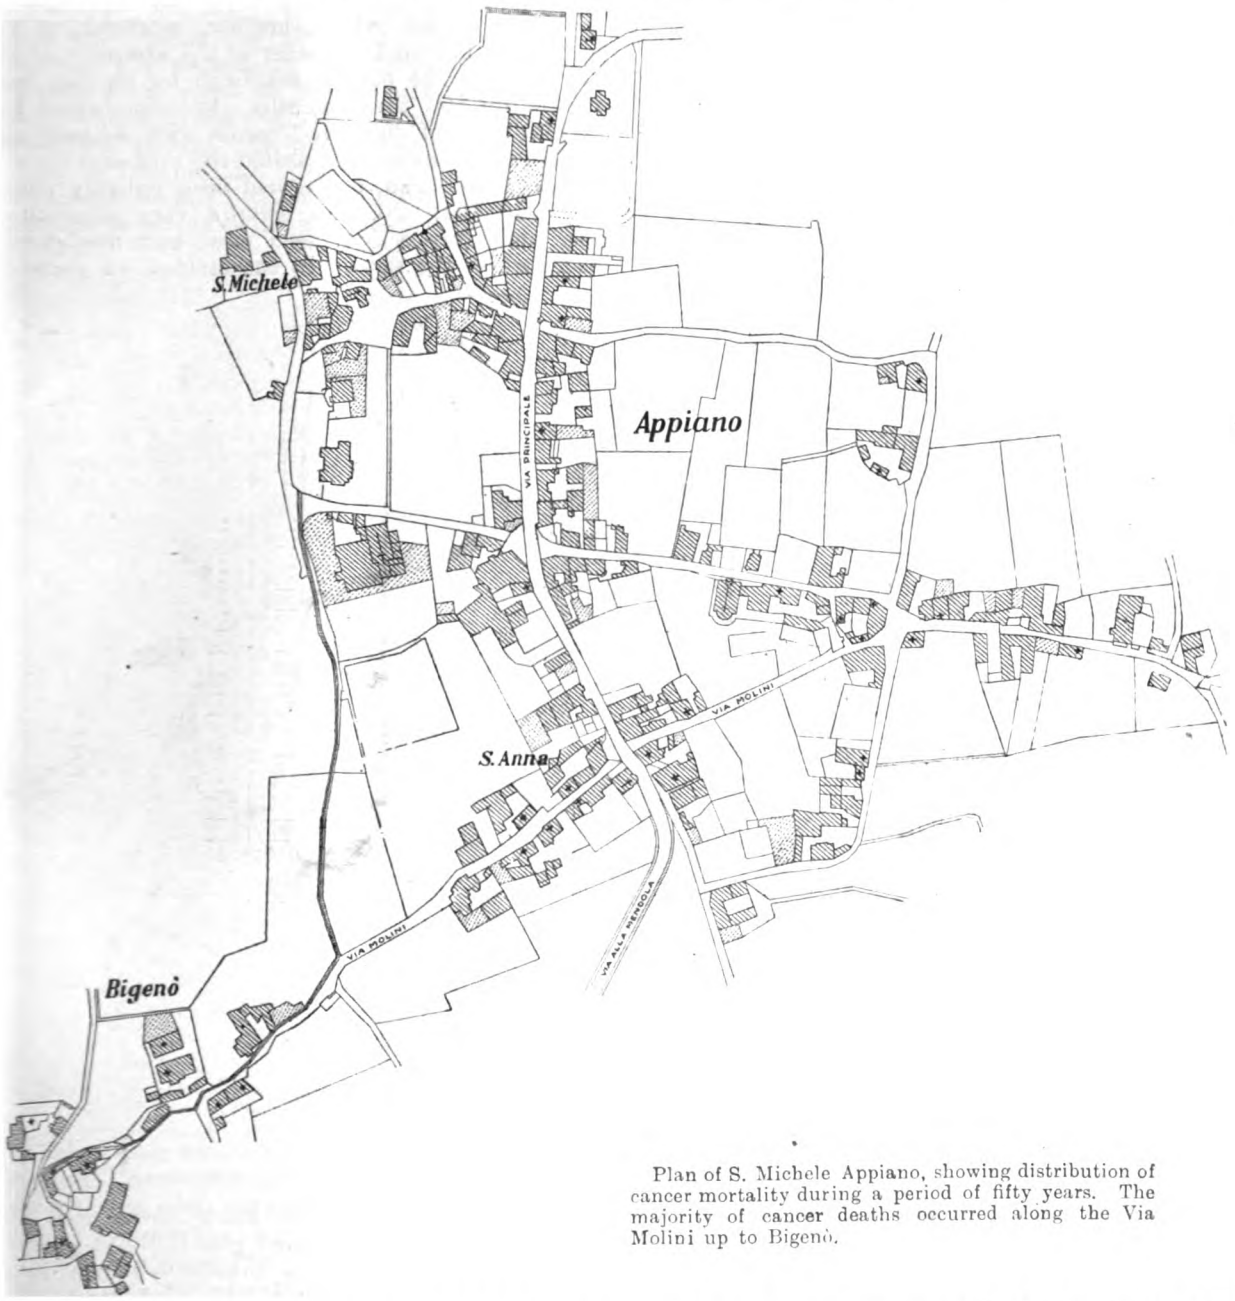
As regards the site incidence of cancer, in the valleys of Fassa and Fiemme we find everywhere a great prevalence of gastric and œsophageal cases. Mammary cancer is rare. In certain communes, such as Tesero, Ziano, Predazzo, cancer of the uterus is somewhat common; in others, such as Daiano, Panchia, Forno, Campitello, it has never occurred during the forty years under consideration.

The thickly wooded valley of Fiemme, prosperous on account of its timber wealth, is inhabited by a strong, healthy, sober, hard-working population. The Fassa valley, more alpine in nature, has poorer, less stable inhabitants. The food of these people differs greatly from that of the Icelanders. Here milk, butter and cheese also abound, because cattle and goats are kept in large numbers, but fish and meat enter far less into the ordinary diet, whilst vegetables and fruit, so scarce in Iceland, here form the bulk of the food. The most common are cabbage and sauerkraut, tomatoes, eggplant, vegetable-marrow, pumpkin, onions, carrots, peas, beans, cauliflower, spinach, lettuce, endive, celery, mushrooms, apples, pears, plums, cherries, figs, grapes, mulberries, peaches, muskmelons, walnuts, filberts, chestnuts. Cereals largely compose the daily ration, especially rice, macaroni and Indian corn, of which they make a mush well known under the name of polenta. On account of their great daily use of polenta, the people of this part of Italy have been nicknamed "polenta-eaters," but Dr. Probizer, of Rovereto, proudly reminded me that the "polenta-eaters" had tunnelled the Alps. Rye bread is practically unknown, whilst white leavened bread is in universal use. Pork is often eaten, especially in sausage form, and wine is the common table drink. Dr. Hepperger chief surgeon in the hospital of Bolzano looked upon wine as the principal cause of cancer and said the disease seemed to be more prevalent in the wine-producing districts.

At Cembra, a cluster of white houses amid chestnut groves, we met Dr. Arturo Vielmeti, district medical officer, who had practised in the valley for about fifteen years. He told us that cancer is exceedingly prevalent there. Nine out of ten were gastric cases and the growth was located most frequently in the cardiac portion. Cancer of womb or breast was very rare. He remembered only one mammary case which was operated, but soon afterwards the patient had died from spinal metastasis, which had caused painful paraplegia. Seven months before, a miller had succumbed to gastric carcinoma and, in the previous year, at Valda, Dr. Vielmeti had attended two cases in the same house, both of whom had died of gastric carcinoma with metastases, one in liver, the other in pleura. He told us we should find at Grumes a small inn where cockroaches were so numerous that often, in broad daylight, he had seen them saucily scamper over the table on which he was writing his prescriptions. The husband of the proprietress had died, not long ago, of gastric carcinoma at the age of thirty-eight.

Passing through Grumes, we stopped at the "Nuova Italia" inn where the small greyish-yellow cockroaches (*Blattella germanica*) abounded. They swarmed around the cooking stove whereon seethed a savoury and appetizing stew.

At Pergine, Dr. Quirino Morelli, who had practised for over twenty-eight years in the district, told us that he had seen cases more or less in every part, chiefly in the Fersina Valley and more especially at Sant 'Orsola and Fierozzo, less at Palù and none at



Blaps lethifera Marsh ♂

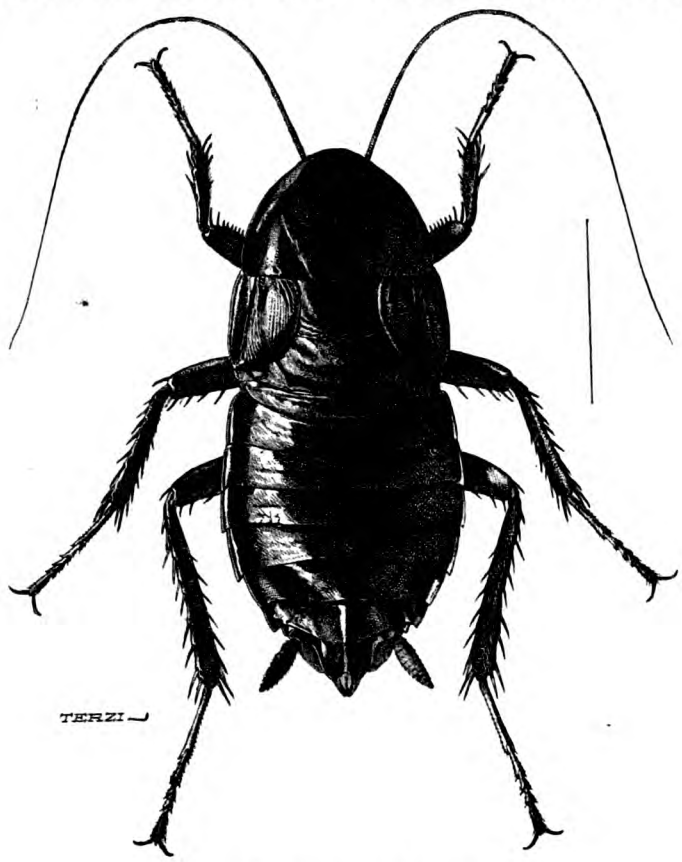
Frassilongo proper, but, curiously enough, several at Rovida which is a "frazione" or tiny dependency of the village of Frassilongo. At Portolo of Canezza, he had known a man and wife who had died of cancer, both on the same day. The man, Giacomo Roner, had died at home of cancer of the stomach, whilst his wife, Monica, succumbed to cancer of the thyroid at the Levico hospital. Both had been ailing for about ten months. The wife had had a small nodular goitre for over thirty years. In her case the cancerous degeneration of the goitre had begun suddenly in April, 1924. She had complained of violent pains about the thyroid region and, more recently, of difficulty of deglutition and respiration.

We drove to Portolo and visited the Roner's house. It was well built and clean, the walls had been distempered quite recently. The Roner family now consisted of three youths and five maidens. One of

the boys had been operated upon for appendicitis. The others seemed well and robust, save one of the girls who was somewhat anæmic. They told us that at one time cockroaches (which they called Sbovi) infested the house, but that now they seldom saw any. They often found "worms" (Tenebrio) in the meal-chest. Whilst we were examining the kitchen, an affrighted mouse scuttled across the room.

We visited the cellars which were full of barrels, containing the new wine and of great heaps of potatoes. There were no cockroaches here, but beneath a great stack of dried leaves and rubbish, against the stable and pig-sty wall, on raking the damp soil, we found numerous cellar-beetles of two kinds (*Blaps lethifera* and *B. mucronata*) together with their larvæ; the soft, fat, incurved maggots of a Cetonia also, as well as innumerable wood-lice (*Oniscus*, *Armadillidium*) which rolled themselves most obligingly into pills. They were once, may-be still are, deemed a "remedy" for cancer.

Plan of S. Michele Appiano, showing distribution of cancer mortality during a period of fifty years. The majority of cancer deaths occurred along the Via Molini up to Bigenò.



The case just mentioned of husband and wife dying of cancer both on the same day, is not the only one to my knowledge, but if death does not strike down wedded patients often at the same hour, the cases of simultaneous cancer in husband and wife, "cancer à deux" as it has been termed in France, are only too common: medical literature abounds in such. This fact often has been adduced as a proof of contagion,

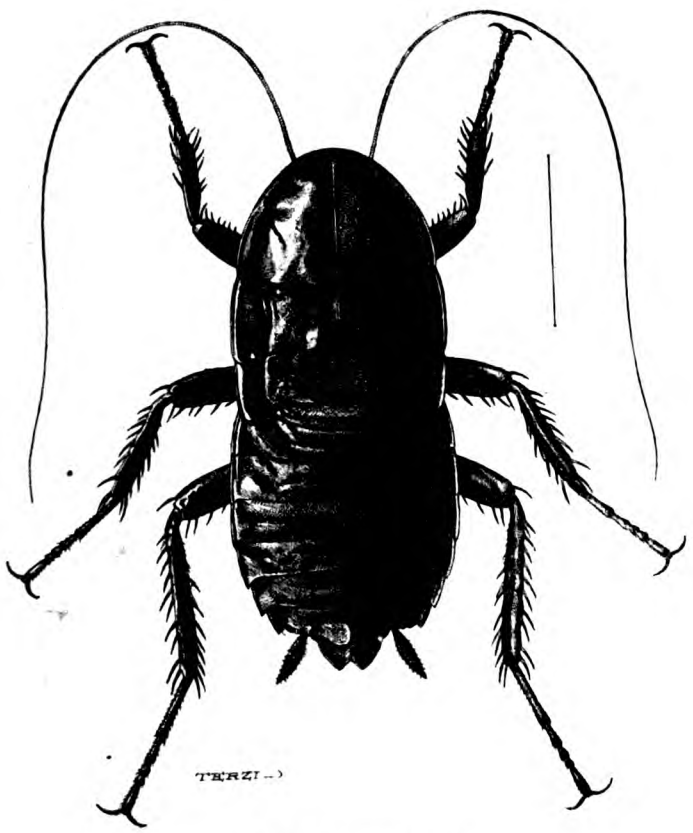
but erroneously, since many other facts prove, in the most unmistakable way, the non-contagiousness of cancer. The whole epidemiology of cancer, such as I know and interpret it, clearly shows that we have before us an endemic infectious disease transmitted by intermediary agents closely linked with the dwelling or with other local conditions. We see it attack husband and wife, parent and offspring, servants and domestic animals all living beneath the same roof. We see it strike, either several generations inhabiting the same house, or several families succeeding one another in the same dwelling.

At Strigno, Dr. Lino Floriani, for the last twenty years district medical officer, told us that cancer was scarce in his district. He had seen epithelioma of the thyroid, but cancer was rare, whilst, on the other hand, goitre was very prevalent. We were in a goitrous region; in the schools no less than 50 per cent. of the girls and 40 to 45 per cent. of the boys were goitrous. He had seen goitre in animals and had even removed it from dogs by operation. He remembered a woman, aged 63, who had died of carcinoma of the stomach in 1920 after about one year's illness; she had lived in a miller's house where, besides the mill, there was a bakery. Not long after her death, the husband began to complain of gastric disorders and subsequently developed a malignant growth which seemed to involve the greater part of his stomach.

At Levico we had a talk with Dr. Luigi Depretis, who told us that practising in the district of Rimini in Romagna, he had noticed that cancer was especially common amongst millers there, but the reason why he could not explain. The millers, necessarily, lived along streams.

Dr. Guido Rippa, at Scurelle near Strigno, took us to see a case of carcinoma of the cardia in a miller 69 years of age whose brother, working in the same mill, had died of cancer of the stomach at the age of 35. The patient examined by us had been ill for the last three months; he complained less of pain than of digestive troubles such as feeling of weight after meals. We visited the mill and found it exceptionally clean, but it had been entirely rebuilt after the war. *Blatta orientalis*, very common at one time, was seldom seen now, but meal-worms occurred in the flour. In the stables we found no Blaps, but the mill-people knew them well and assured us that they occurred plentifully in summer.

Blatta orientalis Fol. ♀



Leaving the mill, we went opposite to see the house of a woman, aged 50, who had died recently of cancer of the pylorus. In this case there had been no premonitory signs. Indeed, until two days before death, the patient had felt no need of going to a doctor, then suddenly hæmatemesis occurred and I was told that she had vomited no less than six pints of pure blood.

At San Michele d'Appiano, near Bolzano, where we motored with Dr. Zieglauer, district medical officer of Bolzano, Dr. Weirorther told us that the great majority

of cancer cases seen by him in San Michele, had occurred in houses situated along the Mühlbach, or Mill-torrent, a stream once open, which now has been canalized and covered. Six to ten years back all these houses had furnished cases of cancer of the alimentary tract, more especially the œsophagus and the stomach. Fifteen or more years ago there were several mills along the Mühlbach, now only one remained. We walked up Via Mulino to a cluster of houses at a place on the mountain side called Piganò (Bigenò by the Germans) where several cases had occurred of late. Dr. Weirorther remembered at least six in this locality. The mill still standing was a very small one and little meal was kept there. The miller, his wife and child were the only occupants, they looked pale and sickly, but there was no history of cancer. The woman assured us that there were no cockroaches in the building and, indeed, we were unable to find any.

Almost opposite the mill were two houses, both of which had furnished cancer cases. One of these was inhabited by a grocer whose shop, on the ground floor, contained oil, candles, sugar and sacks of rice, maize meal, wheat flour and other goods. The house was infested by mice and by two kinds of cockroaches: Schwaben (*Blatta orientalis*) and Russen (*Blattella germanica*). Two cancer cases had occurred in this house. The house adjoining also had yielded one or two cases, but we were unable to examine it.

Considering the great interest of this observation—cancer limited almost entirely to one single street of a village—I begged Dr. Ciurcentaler to visit San Michele d'Appiano in order to verify Dr. Weirorther's assertions and our own observations, also to obtain definite official confirmation thereof. This very morning Professor Calmette has handed me Dr. Ciurcentaler's answer addressed to me here. In it he informs me that San Michele d'Appiano has a population of 1,957 inhabitants; that during the last forty years thirty-four deaths from cancer have been registered, that twenty-six of these occurred in the Via Mulino and at Bigenò along the Mühlbach. Bigenò has 235 inhabitants from among which eight deaths from cancer were registered, that is to say, nearly one quarter of the total number of the cancer deaths. Of all mentioned cases eighteen occurred in men, sixteen in women. With regard to site-incidence eighteen were stomach, three œsophagus, one tongue, one intestine, one larynx, one thyroid, one breast, one uterus, five, organ not specified. Thus you see that the official data, most carefully collected by Dr. Ciurcentaler, fully confirm Dr. Weirorther's statements that most cases had occurred along the mill torrent.

Blatta orientalis nymph.

From San Michele we drove on to Caldaro, a district famous for its fruit crops, passing many an orchard ablaze with apples of deep red and tender green. I knew the loveliness of the apple blossom, but I had no idea that the fruiting branch could appeal so strongly to one's sense of beauty.

At Caldaro, whilst lunching at the "Moonshine Inn" we were joined by the local health officer,

Dr. Carl Konzert, who led us to the Via Goldglass to see a carpenter who had cancer of the cardia. The disease had started about three months before with pyrosis, soon followed by dysphagia and regurgitation of food. In the patient's house we found the two kinds of cockroach (*Blatta orientalis* and *Blattella germanica*) which in this region are usually found side by side though not fraternizing.

On leaving the poor, starved, careworn carpenter, we went to inspect a house in "frazione" Mezzavilla where, some years ago, Dr. Konzert had attended a grain-chandler, aged 32, who had cancer of the tonsils. In the adjoining house another man of 60 had died of cancer of the larynx and in a house opposite, a butcher had died likewise from precisely the same condition—cancer of the larynx.

Frequently, in the course of my researches, I have had the opportunity of observing in neighbouring houses, or in a single house inhabited by different families, several cases of cancer, in all, or nearly all, of which the neoplasm occupied either the stomach, or the liver, or the breast, uterus, œsophagus, or maybe the larynx, as in the example just mentioned. Medical literature affords many such examples of homotypic transmission which have been brought forward in support of the hereditary theory of cancer. I wish to point out that they have another, a true and far more important, value—an epidemiological one. At first sight the homotypic transmission of cancer in successive generations of a same family might lead one to consider the theory of hereditary transmission plausible, but how can one apply this same theory to the exactly similar pathological conditions occurring at the same time in persons of different stock inhabiting the same house, or in total strangers occupying neighbouring houses?

It seems to me that the question of the hereditary transmission of cancer is exactly on a par with that of tuberculosis. Both diseases, according to circumstances, may manifest themselves in grandparent and grandchild, or in uncle and nephew, often leaving the direct child or parent immune and we see both diseases appear in the descendants, either in the same or in different organs. In tuberculosis, cases of homotypic transmission in the same family have been looked upon, not only as evidence of hereditary transmission of the disease, but, further, as indicating the transmission of a particular susceptibility or predisposition of the organ affected (lung or kidney, as the case might be). But I believe, and laboratory experiments bear me out, that the selection of the organ has little to do with the host, but is made by the parasite, because, thank God, it is not a greater predisposition to the disease, but a greater resistance against it, that we inherit. Disease in the parent tends to produce immunity in the child. It is certainly the parasite which, accustomed to a certain organ, makes invariably for that same organ in its successive transmissions to new hosts. The whole science of parasitology teems with proof of this. To my mind, therefore, it is by infection that we must explain the very striking fact of the homotypic transmission of cancer to persons of different stock inhabiting the same house or the immediate neighbourhood of a cancer focus.

The hereditary theory of cancer, like that of tuberculosis or leprosy, is a dying theory which Miss Sly has endeavoured to resuscitate by means of data certainly exact and carefully collected, but ignoring important factors.[1] For my part, I do not understand this strange tendency to invoke heredity at all costs, to explain the genesis of diseases the true cause of which has, hitherto, escaped us. We all remember that even echinococcosis, filarial elephantiasis and scabies were at one time seriously believed to be hereditary diseases!

Now, let me lay before you a remarkable observation which I owe to the great interest Dr. Ciurcentaler has taken in my cancer researches. When I left the Trentino, this able, learned and experienced colleague promised that he would endeavour to continue and extend the work we had begun together in his province.

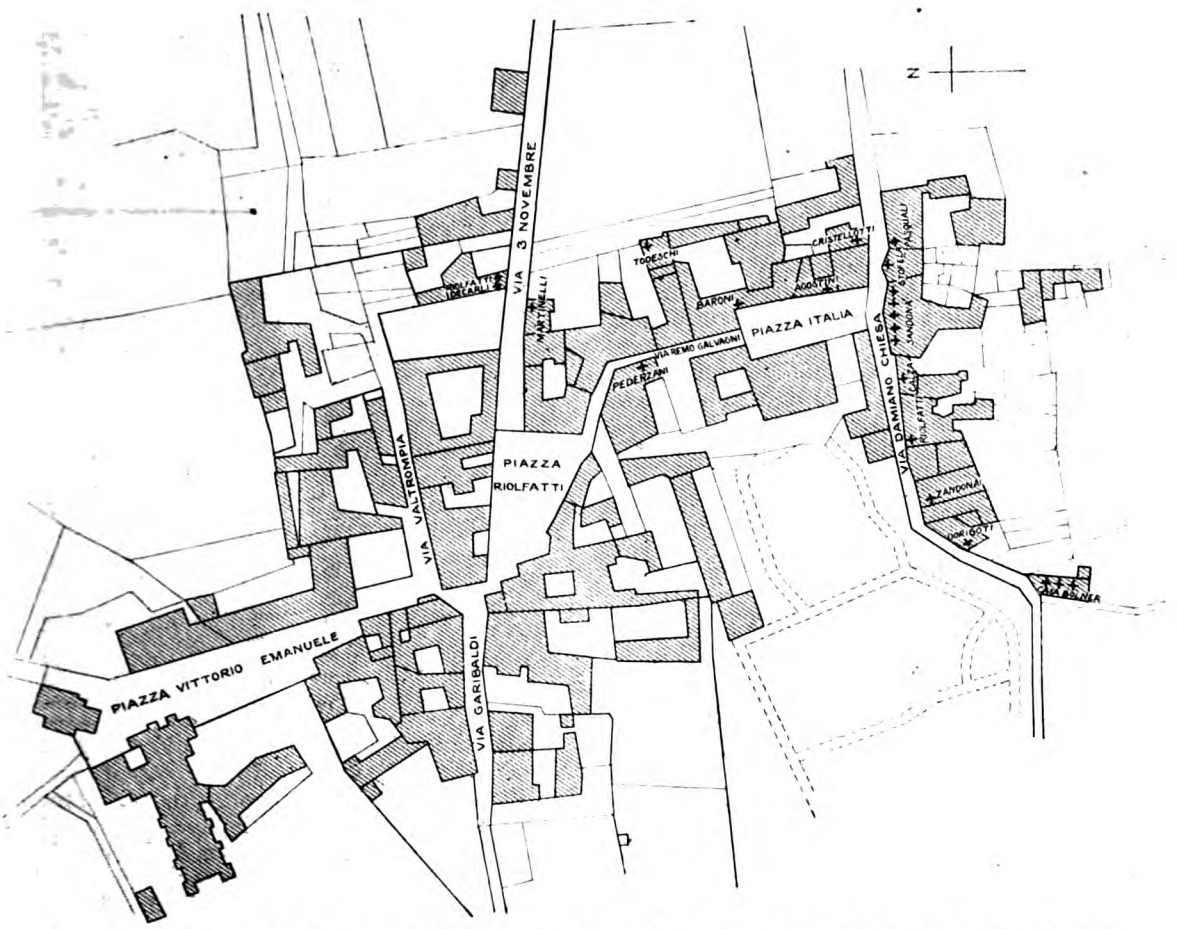
On November 21 last, he wrote: "I have discovered in Villa Lagarina important epidemiological facts which confirm in every way your theory.

"Villa Lagarina has a population of 680 inhabitants, the majority well-to-do farmers. Charmingly situated on a gentle slope, near Mount Stivo, in the valley of the Adige, with its well-built houses, clean streets and pleasant squares, it has the appearance of a small pleasure town. Certainly, enchased in verdure, gleaming in the sunshine, it is a perfect gem.

"Well, the local physician, Dr. Scrinzi, to whom I explained your views concerning cancer, recalling the past experience of over forty years during which he has practised in Villa Lagarina, pointed out that, strange to relate, of the whole village, one street alone—Via Damiano Chiesa—had been smitten almost exclusively!

"Availing myself of this surprising statement, at once I instituted the most careful inquiries and, in the first place, I personally examined the local death registers, jotting down all deaths due to cancer during the last fifty years. The data thus collected gave me the fullest official confirmation of Dr. Scrinzi's statement. I can say that even during the ten years prior to the period of his practice, I could find hardly any cancer death occurring outside the street indicated by him.

"Then I procured a plan of the village from the Government Map Office in Trento, had it enlarged four times the diameter and marked with a cross each single case of death from cancer exactly where it had occurred. The list and map which I send you herewith tell their own tale. Finally, I visited and examined each marked house, collecting all vermin (*blattæ*, *blaps*, &c.), found in rooms as well as stables and sent the material to Dr. Baylis at the British Museum, as per your instructions.



"Of the twenty-two cases marked on the plan, you will notice that no less than fifteen occurred in Via Damiano Chiesa and two in the adjoining Piazza

[1] In *Journ. of Cancer Research*, July, 1924, Sly states that in spite of constant efforts to rule out all vermin and parasites, there have been periods when the stock has shown both tapeworms and nematodes.

Italia, whilst the remaining five occurred not far off, three in Via Tre Novembre and two in Via Remo Galvagni. Thus, seventeen of the twenty-two cases occurred in fifteen families the members of which, together with those of other immune families, formed the population of Via Damiano Chiesa and Piazza Italia, numbering in all 121 persons. In the family B. there occurred three cases and in the family S. no less than five, all women. Two of the cancer deaths which occurred in Via Damiano Chiesa were of persons who had come from abroad: one, a war refugee named Stofella, who came to Villa Lagarina in perfect health and remained so during the four subsequent years; the other, Pasquali, a native who had been abroad practically all his life, returning home in advanced age, when he soon contracted cancer and died.

"Of the twenty-two cases twelve occurred in males, ten in females. With regard to site incidence, no less than seventeen, or over 77 per cent., were gastric carcinomata, ten in males, seven in females. There were besides two cases of oral cancer in men and two of the breast, with one of the uterus in women. The youngest case was that of woman 38 years of age, the oldest that of a woman aged 81. The average age-incidence being 65½."

In examining the plan of Villa Lagarina just received from Dr. Ciurcentaler, you will notice that all the crosses marked in Via Damiano Chiesa, save one, are on the right side of the road, this singularity is no doubt due to the paucity of inhabitable buildings on the left side. However, I take the opportunity of drawing your attention to the fact that similar peculiarities in the topographical distribution of cancer have been noticed already on several occasions. Thus, Dr. Mason has shown that in the district of Leamington,

Plan of Villa Lagarina in the Valley of the Adige (Trentino), Italy, showing cancer mortality, during a period of fifty years, restricted almost exclusively to one street—the Via Damiano Chiesa.

in England, cancer was quite common in houses situated in certain rows or upon one side of a row, while in other streets it was conspicuous by its absence. He stated that about 17 per cent. of these cancer houses were placed at the end or at the corner of a street, were of old construction, and were built upon a porous subsoil. I have no doubt that from a careful study of these peculiarities of distribution will emerge the data enabling us to grasp the ætiology of cancer. It is by such data of topographical distribution that, in the spring of 1903,

without having been to Africa or having seen a specimen of the fly. I was able to incriminate the dusky tsetse-fly (*Glossina palpalis*) as the carrier of sleeping sickness, and maintain, against Manson himself, that the Gambia fever trypanosome, discovered by Castellani in the cerebrospinal fluid of sleeping sickness cases, was the true cause of the disease. Meanwhile, allow me to remind you that the peculiar limitation of cancer to certain restricted areas, to certain streets, to one single street, one side only of a street. or to a single house or apartment, are strikingly paralleled in the epidemiology of yellow fever, leprosy and plague. They seemed indeed mysterious at one time, those streets, those houses, those ground-floor rooms, where the dreaded "Yellow Jack" struck down his victims. They are thoroughly explained to-day by the peculiar distribution and habits of the silver-striped tiger-mosquito—the *Aedes calopus*—which inoculates the germs of yellow fever.

The several observations which I have laid before you, show clearly, I believe, that cancer has a very unequal geographical and topographical distribution. Whilst excessively prevalent in certain localities, it is rare, or totally absent in others adjoining. Sometimes, as I have just stated, it may strike a village only, or a single street or house. When it is limited to one village, we have the so-called "cancer village," when restricted to a single house, the "cancer house." In the third edition of his book on "The Cancer Problem," Green mentions one of these fatal houses in his own district which "had ultimately to be pulled down owing to the great number of deaths from cancer which occurred in it." I myself have examined several cancer houses, villages and districts; of others I have been told or I have read in literature. They are well established realities.

Have not the pathologist and the "food expert" too lightly brushed aside facts opposing their theories? Hypotheses fail, not facts. No, the striking inequalities in the distribution and prevalence of cancer, repeatedly observed in all parts of the world, cannot be put aside with scoffs or by juggling with figures; they are obviously due to peculiar local circumstances which we are beginning now to understand.

"Let us hope," said the Director of the Imperial Cancer Research Fund in London not long ago, "let us hope that the dangers of 'cancer-houses' will cease alike to alarm the public and divert the energies of investigators from fruitful lines of inquiry." May I, in turn, venture to express the hope that investigators will cease to worry mice, for a time at least, and turn their energies instead to researches far more fruitful on real cancer in those places where it attacks man most severely?

No less striking than the great inequality in geographical and topographical distribution of cancer is the diversity of its repartition by organ or part of body in different countries and localities. Some of these differences are well known, such are the rarity of cancer of the female breast in Japan compared with its great frequency in England; the extraordinary frequency of penile cancer in certain parts of Asia contrasting with its rarity in Europe and America; the great prevalence of primitive hepatic cancer in certain coast districts of Asia and its rarity in Europe; the commonness of cancer of the stomach in Europe, its rarity in Asia.

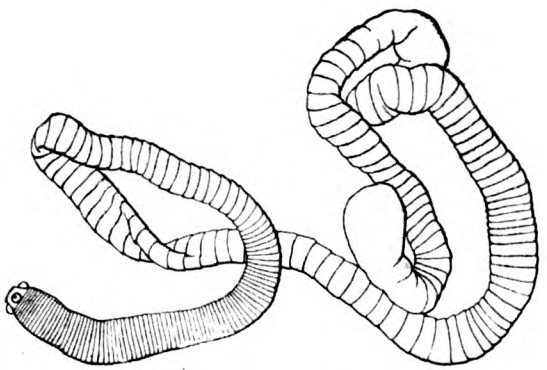
Differences in site-incidence just as striking are found in the various animal species; such are the great frequency of mammary cancer in she-cat and bitch, its extreme rarity in the cow; the very common occurrence of cutaneous epithelioma in the dog, its scarcity in stallion and bull; finally, the great rarity of cancer of the alimentary tract in animals as compared with its frequency in man.

How explain by means of non-parasitic theories these striking dissemblances which cancer exhibits in its distribution in different countries and places; in its repartition in different organs and parts of the body? Can we explain them satisfactorily by food theories such as the use of mustard, salt, wine, cider, roast pork, white bread, water-cress or tomato? Shall we succeed better, do you think, with arsenic, phosphorus, tobacco, coal, tar, radium or the sun's rays? Some *savants* have suggested the erect attitude of man, incestuous intercourse between some of our body cells, embryonic remains, anarchic tissue-cells, endocrine disturbances, moral and physical sufferings, lack or excess of vitamines, arthritism, melancholia, heredity, civilization, constipation; can any of these theories give us the all fulfilling answer we are seeking? Or must we turn to food preservatives, soot, paraffin, burns or blows? Can we reconcile any of these theories with the facts of distribution, site incidence and yearly fluctuation—in a word, with the natural history of the disease?

The results of my researches allow me to claim, without fear, that the name of Cancer must be written large on the tablets of parasitology. Therefore, I range myself by the side of Professor Borrel, a great and indefatigable cancer student, a member of this Institute, who turned us into the right path when he pointed out that the larval form of the thick-necked tapeworm of the cat could bring about the development of a sarcoma in the liver of rats.

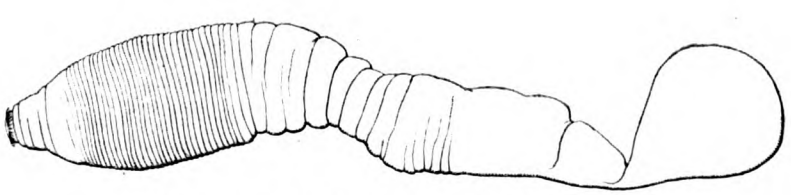
The *Tænia crassicollis* or rather *T. tæniæformis* was first mentioned and figured by the physician, naturalist and poet, Francesco Redi, in his famous work on "Observations on living animals which are found within living animals," published in 1684.

Having found in the omentum of the Wau-wau, or Silvery Gibbon of Java (*Hylobates leuciscus*), the larval form of a new species of cestode presenting the features characteristic of *T. tæniæformis*, I considered it expedient to propose the creation of a new genus which might include my new species together with *T. tæniæformis*, *T. laticollis* and other tapeworms presenting a massive rostellum, the quasi-absence of neck and a strobilate larval form. For this new genus I adopted the name *Reditænia* in honour of the great Italian naturalist, while for the new species I proposed the name of *R. borreli* in homage to Borrel for the new direction he had given to cancer research.



A few years later, Professor Johannes Fibiger, of

Reditænia tæniæformis as delineated by Francesco Redi in his famous "Observations on living animals which are found within living animals," Florence, 1684.

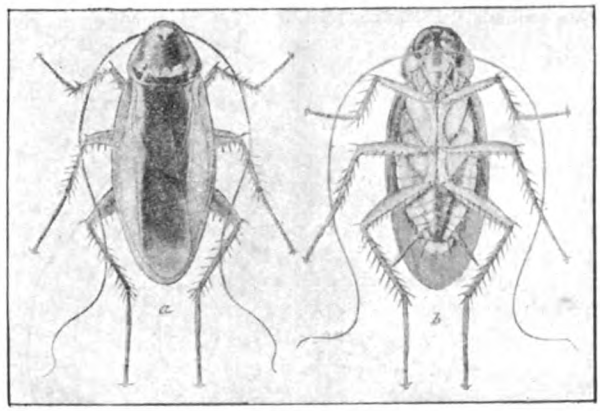


Professer A. Borrel, Director of the Bacteriological Institute of Strasbourg. A great cancer student.

Larval form of *Reditænia tæniæformis* Batsch, 1786, usually spoken of as *Cysticercus fasciolaris*.

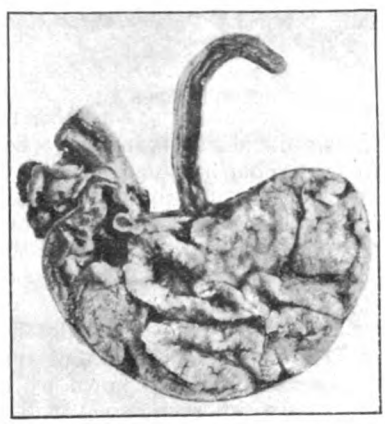
Here, then, are two malignant neoplasms, differing in nature and site-incidence, both developed in the rat and both brought about by the agency of helminthes belonging to two different classes. The rat contracts the hepatic sarcoma by eating food contaminated by the excrement of cats containing the eggs of *Reditænia tæniæformis* and it acquires the gastric carcinoma by devouring cockroaches or other insects (*Blaps*, *Tenebrio*, *Aphodius*) harbouring the larvæ of *Gongylonema*. Two different kinds of tumour may be found in the same rat, as shown by Eiken.

One can artificially reproduce at will these two neoplasms, feeding to rats aliments containing the

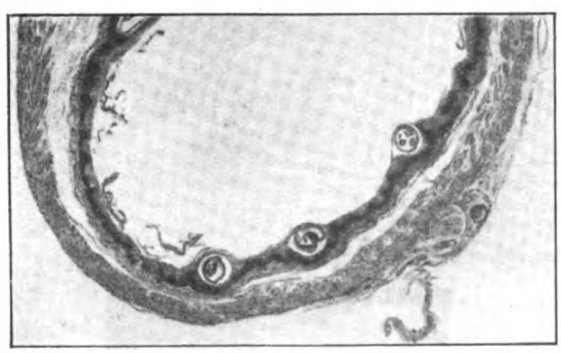


Larval form of *Reditænia borreli* Sambon, 1924.

Copenhagen, made known his remarkable researches on a carcinoma of the stomach of the rat produced by the agency of a roundworm—a *Gongylonema*. The larvæ of this worm he found coiled up spirally, just like trichinella larvæ, among the striated muscles of the Kakerlak or American cockroach (*Periplaneta americana*) infesting a Danish sugar refinery and which had been imported with raw sugar from the Danish West Indies.

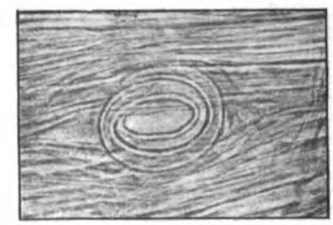


Gongylonema neoplasticum, natural size. (After Fibiger.)



relative parasites: the larvæ of the gongylonema, if one desires to obtain the gastric carcinoma; the ova of the tapeworm if one wishes to reproduce the hepatic sarcoma. It is thus that Bullock and Curtis,

American cockroach, *Periplaneta americana* (*L*).
a dorsal aspect. *b* ventral aspect.



Carcinoma in stomach of rat infested by *Gongylonema*. (After Fibiger.)

Transverse section of rat's œsophagus showing *Gongylonema* in situ. (After Fibiger.)

in New York, have been able to raise more than a thousand liver sarcomata in rats. Professor Brumpt, who has just returned from the United States of America, has been kind enough to bring us here two preserved rats bearing hepatic sarcomata artificially obtained by experimental cysticercosis in the George Crocker Research Fund laboratory. Could anything be more convincing of the part which may be played by parasitism in the genesis of cancer? I am grateful to my friend Professor Brumpt for his kind thought in showing us these two remarkable specimens.

In my London paper, I pointed out that there were several forms of cancer in man, the organ-incidence and geographical distribution of which found an easy and natural interpretation in the parasitism of certain helminthes. I mentioned *Schistosoma hæmatobium*, long suspected of playing a part in the production of cancer of the urinary bladder in Egypt, and *S. mansoni*

Larva of *Gongylonema* encysted in musculature of cockroach (After Fibiger.)

Eggs of *Gongylonema*. (After Fibiger.)

which likewise, in the same country, seems to be an important factor in the genesis of rectal carcinoma. I remarked that the spined ova of these parasites often were found in the neoplasms to which they gave rise, the terminal spined ova of *S. hæmatobium* in cancer of the bladder, those with a lateral spine, characteristic of *S. mansoni*, in rectal cancer. This latter species I established in 1907, separating it from Bilharz's species with which it had been confounded and, basing myself again on epidemiological and parasitological facts, I stated, without fear of error, as is evident from my controversy on the subject with the late Professor Looss, that further researches would prove that the larval forms of the two blood-

flukes in question would be found in the liver of fresh-water snails while for each species of schistosoma would be found a specifically different intermediary host. Professor Leiper's researches in Egypt proved fully the exactness of these provisions which were not "prophecies" as some authors have called them, but the outcome simply of carefully collated epidemiological and parasitological data, open to all.

I recalled that already in 1901 Askanazy had pointed out a tiny reddish, lanceolate fluke, the *Opisthorchis felineus*, as capable of inducing cancer of the liver in man. This trematode worm, discovered in 1884 by Rivolta in cat and dog in Italy, has been

Opisthorchis felineus (Rivolta) 1885.

found since in France, Hungary, Eastern Prussia, Holland, Sweden, Russia, Siberia and Japan, not only in cat and dog, but also in fox, glutton and man. Man and animal become infested by eating raw fish, because the cercaria of this trematode encysts in the musculature and skin of several species of cyprinoid fishes, such as the roach (*Luciscus rutilus*) and the ide (*Idus idus*) which inhabit both salt and fresh waters.

Askanazy has described the lesions produced by this fluke: the congestion of the liver, the proliferation of the epithelium of the obstructed and dilated biliary canaliculi, the appearance of newly formed bile-capillaries, the proliferation of the connective tissue, the hypertrophy of the glands, the production of adenomatous and papillomatous formations as well as the cirrhosis and cancerous degeneration clearly determined by parasitic irritation. But, that which certainly demonstrates the cancer-producing agency of this tiny trematode is an epidemiological observation which has all the distinctiveness of a purposely made laboratory experiment.

It had been pointed out that cancer of the liver or gall-bladder was common among the fisherman of the Baltic shores and more especially among those of the Kurische Haff, a vast lagoon in East Prussia, between Königsberg and Memel. Dr. Rindfleisch's researches elicited the fact that the fishermen of this region were in the habit of eating raw fish during their fishing cruises, hence they were heavily infested by *Opisthorchis felineus;* their biliary ducts were crammed with hundreds and thousands of the tiny flukes. Possibly this same trematode will be found to be responsible for another small focus of primary hepatic cancer near Kolozsvar in Hungary.

Verdun and Bruyant in Tonquin found *O. felineus* in man, associated with the Chinese liver fluke (*Clonorchis sinensis*), a larger trematode also inhabiting the biliary ducts of man and certain fish-eating mammals such as the dog, cat, badger and marten. *Clonorchis sinensis*, like *Opistorchis felineus*, has, for second intermediary hosts, certain fishes, such as *Pseudorasbora parva, Leucogobio güntheri, Acheilognathus lanceolata* and *Carassius auratus* or "gold-fish," in the skin and flesh of which it lies in ambush. *C. sinensis* is widely spread among the coast-inhabitants of China, India, Indo-China and Japan and it is on account of this peculiar coastal distribution—an important epidemiological fact—that, already in 1908, Professor Ward was able to incriminate fish as the probable cause of infestation.

These two flukes are joined in China and Japan by a third trematode, the *Schistosoma japonicum*, a blood-fluke which gives rise to a grave biliary cirrhosis, long known in Japan by the name of Katayama disease from the district of Katayama where it is very prevalent and best known. According to Professor Katsurada, this bilharziosis is very common in the central provinces (Bingo, Yamanashi, Hiroshima) of Japan and especially at Saga in the Island of Kyushu. Now, from a totally different source, I learn that, in this very island of Kyushu, primary cancer of the liver is three times more frequent than in the rest of Japan. Is not this striking? Does not the coincidence with preportionate frequency of liver-fluke and liver-cancer in the same areas indicate a probable relationship of cause and effect?

The three last trematodes mentioned produce, everyone of them, biliary cirrhosis which, indeed, may be looked upon as a "pre-cancerous condition," since obviously it favours the development of hepatic carcinoma. In Japan, in China, in India (especially Madras), the connection between cirrhosis and primary hepatic cancer is well known.

I mentioned *Trichinella spiralis*, a small nematode encysted among the muscle-fibres, found by Hilton, in 1832, in a man aged 70, who had died from cancer of the penis. Hilton took the parasites for tiny cysticerci, but, three years later, James Paget, then only a student at St. Bartholmew's hospital in London, found again the encysted trichinellas in the body of an Italian, recognising that they were small cylindrical worms coiled up spirally. Wormland, demonstrator of anatomy in the same hospital, believing them to be earthy deposits only, brought a fragment of affected muscle to Professor Owen who studied the organisation of the worm and gave it the name of *Trichina spiralis*. The generic name *Trichina* being already in use for an insect, Professor Railliet changed it into that of *Trichinella*. Since Hilton's case, trichinosis and cancer frequently have been found together while the trichinella has been cited as being able to induce cancer. Quite recently Dr. Brown of Blackpool informed me of a case of cancer of the tongue in which the neoplasm had developed around a small calcified worm, possibly a trichinella.

I mentioned also *Thelazia rhodesi*, found in 1818 by Rhodes (a veterinary of Plaisance), in the excretory ducts of the lachrymal glands and beneath the eyelids of cattle. This worm, to my mind, would explain very well a peculiar localization of cancer in bovines—the epithelioma of the lachrymal caruncle. Of a total of 2,514,000 bovines slaughtered at the Chicago abattoirs, Loeb and Jobson, limiting their

investigations to external cancers, found forty-nine cases, but it is worthy of notice in this connection that all these cancers were epitheliomas of the lachrymal caruncle!

Passing to Acarines, I recalled Borrel's numerous researches on cancer of the hair follicles and of the sebaceous and mammary glands, brought about by the parasitism of *Demodex folliculorum* and other ectodermic acarines. In nascent epitheliomas removed by biotomy Borrel always found *Demodex* in the follicles undergoing cancerous degeneration. He demonstrated them likewise in great numbers in the nipple in several carcinomata of the female breast.

Case of elephantiasis in Hindu girl. Drawing by Mr. A. Terz from a photograph taken by Dr. Sambon in George Town (British Guiana).

Having found *Demodex* very numerous in large comedones on the scrotum and penis of a syphilitic chimney sweep, I wondered whether Borrel's observations might not give us the reason of the frequency of scrotal cancer in chimney-sweeps, seeing that, owing to constant dusting of their genital region with soot comedones are prone to form, while these accumulations of sebaceous matter are favourable breeding grounds for the small vermiform acarine.

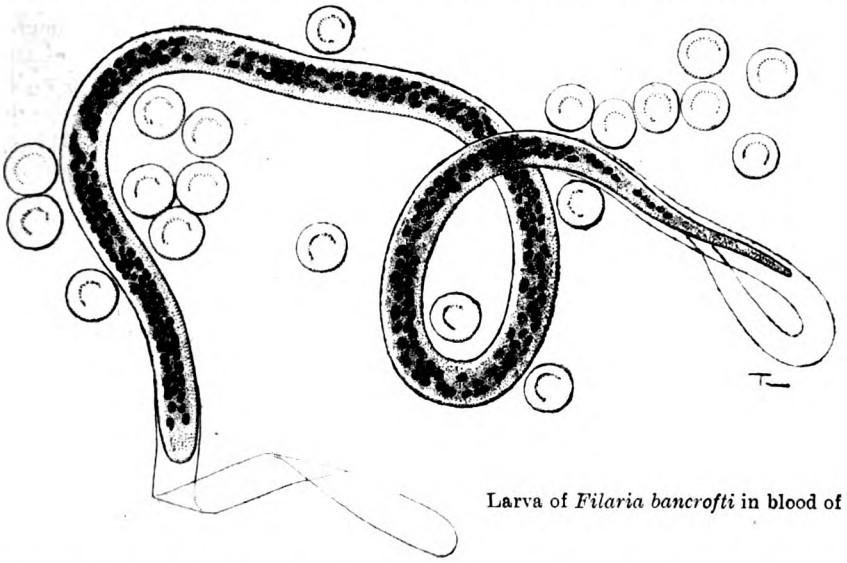
Finally, in order fully to explain the part played by helminthes in the production of cancer, I gave a sketch of our present knowledge of the causes which bring about elephantiasis. This disease, which is very common in certain tropical regions, was, not long ago, believed to be hereditary, contagious, due to malaria or produced by certain foods such as pork, stockfish, wild duck or the bright orange-coloured fruit of the fragrant kaldera (*Pandanus odoratissimus*).

I pointed out that, with us, as in tropical countries, elephantiasis is always the result of repeated attacks of streptococcic lymphangitis in an œdematous region with lymphatic and vein dilatation caused by obstruction of diverse origin (local tuberculosis, tertiary syphilis, helminthiasis). In northern countries, elephantiasis is a somewhat rare disease, but in certain warm countries it prevails endemically with varying frequency. This tropical form has received the name of filarial elephantiasis, because a filaria (*Filaria bancrofti*) discovered by Demarquay in 1863, plays a part of the greatest import in its ætiology. The close relation of cause to effect which exists in tropical countries between elephantiasis and filariasis is proved very clearly by:

(1) The geographical and topographical distribution of elephantiasis exactly coincident with that of filarial endemicity.

(2) The frequency of the disease everywhere proportionate to that of filarial infestation.

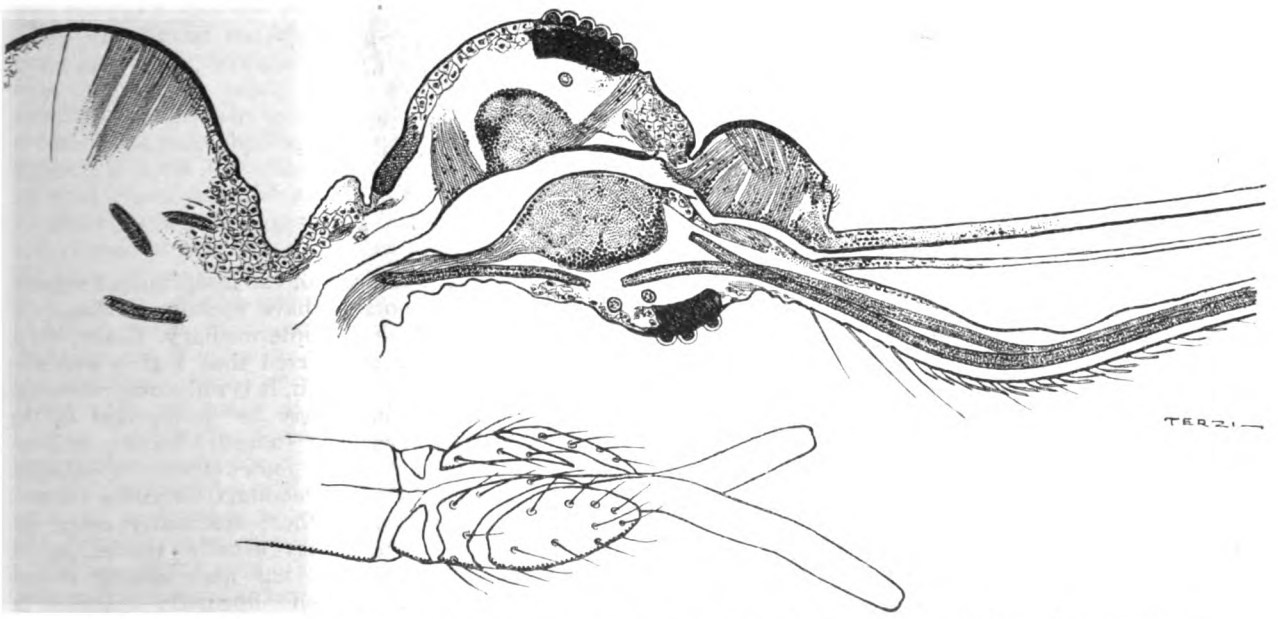
(3) The concurrent presence of other filarial manifestations such as varicose groin-glands, lymph scrotum, chylocele, chyluria and filarial abscess in patients suffering from elephantiasis.



(4) The frequent onset of elephantiasis of the leg following the surgical removal of lymph scrotum.

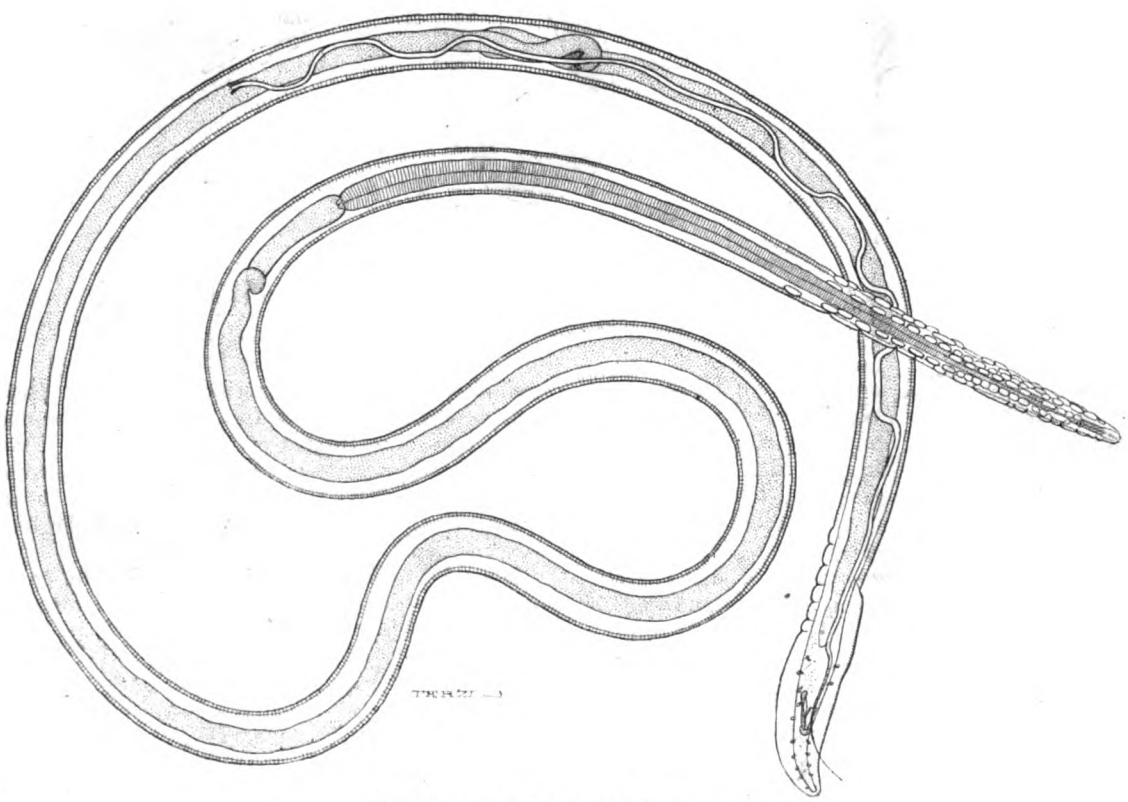
I recalled the part played by mosquitoes (several species of *Culex*, *Aëdes*, *Anopheles* and *Tæniorhynchus*) in the transmission of filariasis, rôle demonstrated by Manson in 1877, but the final details of which were not worked out until 1900. I showed how the young filariæ, leaving the massive wing-propelling thoracic muscles, actively migrate to the mouth parts of their intermediary insect host, pierce the delicate membranes at the base of the hypopharynx (Sambon), or between the two stretched out labellæ at the extremity of the labium (Dutton), whilst blood is being imbibed, and drop on to the punctured part; how they creep over the skin, picking up surface bacteria and make their way through the epidermis, finally reaching the connective tissue and the lymphatic vessels of their definitive host. I mentioned how, not infrequently, numbers of them, coiled up in inextricable tangles, might obstruct lymphatic vessels and, acting as porters of bacterial infection, introduce into the lymph stream micro-organisms which finally kill them—hence the reason why microfilariæ seldom are found in the blood of elephantoid cases.

There can be no doubt that streptococcic lymphangitis is the real, essential cause of elephantiasis, whether nostras or tropical, but in warm countries, a filaria is the agent which almost invariably gives rise to it. Indeed, it is *Filaria bancrofti* which determines the variable frequency and unequal distribution of the disease, limited, in each country, to those localities or



"stations" that are the separate, overlapping, or coincident habitats of the several mosquitoes which may foster it and transmit it. Prominent among these are: *Culex fatigans* in China, *Aëdes togoi* in Japan, *A. variegatus* and *C. fatigans* in Fiji, *Anopheles rossi* in India, *A. costalis* in West Africa and *Tæniorhynchus africanus* throughout Tropical Africa.

Similar to the rôle of the filaria in elephantiasis is, no doubt, that of gongylonema in cancer. Like the filaria, so the gongylonema is not the direct essential cause of the disease it gives rise to, but it probably is, in certain localities, an etiological factor of considerable importance. Like the filaria, so the gongylonema has its own particular intermediary hosts belonging to different insect genera such as *Blatta*, *Blaps*, *Tenebrio*, *Aphodius*, and *Onthophagus*. The gongylonema, known to be a cancer-producing agent in the rat, seems an equally likely factor in the incidence of cancer among human beings in certain regions such as the Romagna and the Trentino. Here the disease affects principally the upper portion of the alimentary tract and more especially the buccal cavity, the tongue, the œsophagus, the larynx and the cardia, and here again cockroaches, meal-beetles and cellar-beetles are an ever present vermin in the old houses in which such cancer cases occur. These observations so clearly designative of a relationship between worm and neoplasm, are strengthened by the fact that gongylonema is present and common in the majority of the domestic animals of these regions. Professor Fibiger's researches and experiments have proved that gongylonema plays a definite part in the production of gastric carcinoma in rats. Why should it be otherwise in man?



Larva of *Filaria bancrofti* in blood of man.

During the few weeks I could devote to cancer research in Italy, I was unable to demonstrate the

Filaria bancrofti. Two specimens actively migrating through labium of *Culex fatigans*. (From ction prepared by Dr. G. C. Low.)

presence of *Gongylonema* in man, because I had only two opportunities of seeing autopsies performed and that was at Bologna, by courtesy of Professor Franchini. But the presence of *Gongylonema* in man is certain. This Spiruroid has been found, not only recently, on several occasions, in the United States of America (Arkansas, Florida, Georgia, Louisiana) but also in Italy by Professor Pane in 1864. Though fully aware that some parasitologists may consider my interpretation of Pane'e *Filaria labialis* as unsatisfactory, I not only hold that it is correct, but am convinced that the *Gongylonema*, though no doubt accidental, is no rare parasite of man in Italy. That it should have escaped medical observation is but a twice told tale; we see only that for which we look. surgeon of the Trentino, Dr. Piero Cavallo, a capable, learned and charming person who was keenly interested in our researches, told me that *Gongylonema* had been found at Rome in oxen imported from Sardinia. *Gongylonema* is a parasite of cattle as cosmopolitan in distribution as are its hosts and everywhere more or less abundant. Parasitologists have noted its presence in the five continents. Its favourite habitat is the œsophagus, but it may be found in the lip, the buccal cavity, the tongue, the larynx, the liver, the cardiac portion of the stomach in carnivores and omnivores and in the rumen of ruminants. Lingard saw it in the œsophagus and in the tunica intima of the posterior aorta in the Brahmin Bull of the plains of India. It is found as a rule, in sinuous galleries

Gongylonema pulchrum (Molin, 1857). ♂

One could cite the examples of *Hymenolepis nana*, *Fasciolopsis buski*, *Agchylostoma duodenale*, *Linguatula serrata*, *Nocardia bovis* and many others. No one saw the *Treponema pallidum* before Schaudinn pointed it out; no one saw *Trypanosoma gambiense* in sleeping sickness until Castellani found it, yea, not even the members of the Portuguese Commission who had it in their slides, as they discovered afterwards. Stranger still is the fact that *Gongylonema*, so common in Italian sheep, oxen and hogs, should have escaped detection by the abattoir veterinarians. They had not seen it, they had not looked for it; the œsophagus is inspected so seldom. But the chief veterinary within the epithelial layer of the œsophageal mucosa.

For obvious reasons, I have spoken at length of *Gongylonema* and of its intermediary hosts, but I should not like it to be inferred that I give exclusive importance to it for, in truth, it is only one of several animal parasites which may be concerned in the complex etiology of cancer. Indeed, I have mentioned others, such as *Demodex folliculorum*, *Trichinella spiralis*, *Schistosoma hæmatobium*, *Clonorchis sinensis*, *Opisthorchis felineus*, but there are many more, not only among the helminthes usually recognized as natural parasites of man, but also among chance parasites' parasites which normally develop in

animals, though at times they may accidently spend their life in man. Thus *Metastrongylus apri*, a parasite of the hog, was found in 1845 by Jortsits in the lungs of a child of six, at Kolozsvar (Transylvania). This parasite is capable of giving rise to neoplasms; Vulpain found it associated with epithelial tumours in the lung of a pig seven months old, sacrificed for physiological studies. The large common fluke of sheep and cattle, *Fasciola hepatica*, also is found occasionally in man. Like *Opisthorchis felineus*, it may give rise to biliary adenomas. Less known is the *Physaloptera*, discovered by Turner in the small intestine of Transvaal negroes and described by Leiper, in 1908, under the name of *Physaloptera mordens*. An Oriental species, called *P. tumefaciens*, produces, as shown by Professor Brumpt, large adenomatous formations in the stomach of its normal host, the crab-eating macaque (*Macacus cynomolgus*), which has the habit, peculiar in a monkey, of feeding largely on crabs, insects and mollusks. Quite recently, a liver parasite of the rat, *Hepaticola hepatica*, has been found by Dive, Lafrenais and MacArthur in the liver of a British soldier aged twenty, in India. The liver was crammed with the characteristic lemon-shaped eggs bearing a plug at each pole. Dr. Baylis will tell you how we found this parasite in every rat we caught at the Bologna abattoir.

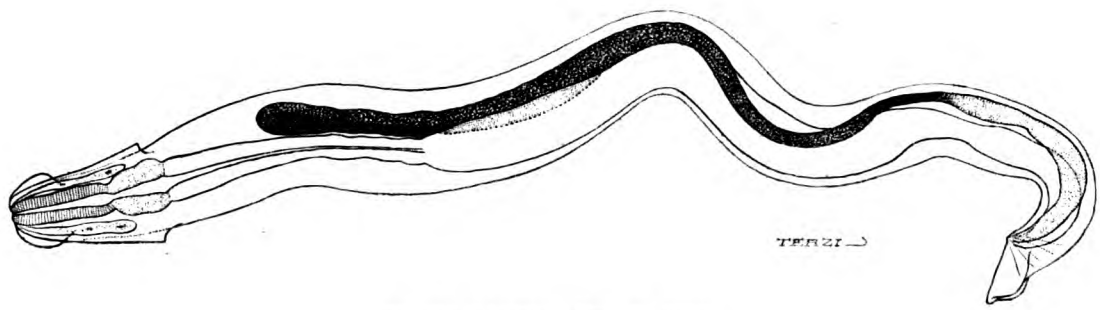
One might go on almost indefinitely, but I must restrict my remarks to the so-called erratic worms, that is to say those worms that are found in parts of the body other than that in which they habitually abide. Thus the common liver fluke *Fasciola hepatica* may be found in the pancreas, in the lung, or in cutaneous nodules. *Oxyuris vermicularis*, a parasite of the cæcum and colon, may be found in the nasal fossæ, buccal cavity, the œsophagus, the urinary bladder, the vulva, the vagina, the uterus and even the ovaries, or the abdominal cavity, free, deeply embedded or encysted. *Ascaris lumbricoides*, a parasite of the small intestine, may be found in the œsophagus, the liver, the pancreas, the peritoneal cavity.

But we should not confound erratic worms with young forms migrating through the body during their invasion. In a paper on "The part played by metazoan parasites in tropical pathology," an abstract of which was published in the JOURNAL OF TROPICAL MEDICINE AND HYGIENE, June 15, 1908, I pointed out that our intestinal parasites did not slide down the gullet, as was believed then, but, piercing the skin or the mucous membrane, reached their final habitats, travelling by way of the blood-vessels and lymphatics or through cellular-tissue routes. I gave several examples, such as those of *Ascaris lumbricoides*, *Agchylostoma duodenale*, *Syngamus trachealis*, *Heterakis papillosa*, based on observations and researches I was able to make at the prosectorium of the London Zoological Society. My views have been confirmed in each case.

I am inclined to give some importance to erratic parasites, and more especially to *Trichinella spiralis* and *Oxyuris vermicularis*. These worms may play one of two parts in the ætiology of cancer, either as porters of bacterial infection, like *Filaria bancrofti* in the case of elephantiasis, or else as irritants like any foreign body. In either case their importance is obvious, because if they do play any part in the causation of cancer, and the facts adduced strongly suggest it, then we have in this knowledge a sure means for the eradication of cancer, in so far, at least, as it is brought about by the agency of parasitic worms. The majority of these worms have necessary intermediary hosts (insects, snails, fish) which it may be possible to control, or they ambush in food which may be rendered harmless by proper cooking.

As our knowledge begins to close round the causation of cancer, many old theories, many wrongly interpreted observations become comprehensible. Thus, the eating of pork long has been incriminated as a cause of cancer; the flesh of the hog itself may be harmless, but in it often lurk some of the more fatal zoöparasites of man; hence the exceedingly wise Mosaic prohibition of its use as human food. Among these parasites, *Trichinella spiralis* is, without doubt, the most fearful, not only for the deadly epidemics of trichinosis to which it may give rise, but for the part it may play in the causation of cancer and more especially cancer of the breast. Mammary cancer often has been observed in association with trichinosis; I need but mention the observations of Klopsch, Langenbeck, Babes.

Uncooked vegetables, repeatedly incriminated, may well be responsible in like manner. Behla's observations at Luckau, in Germany, are well known. Sir John Bland-Sutton in his lectures on "Cancer clinically considered" (London, 1909), talking of uncooked vegetables in relation to the origin of cancer, says: "Indeed I feel so strongly on this matter that for many years I have avoided eating all sorts of uncooked vegetables." It is common knowledge that the eggs of pinworms and eelworms may reach us through eating uncooked vegetables.



Whatever be the rôle of parasitic worms, the actual essential cause of cancer is some ubiquitous micro-organism, probably a filter-passer, as the researches of Rous and his fellow workers seem to indicate, but this parasite, apparently, is unable to thrive except in tissues of low or lowered resistance. We see it therefore affect embryonic residues, pigmentary moles, burn scars, goitrous thyroids, breast adenomas, the margin of gastric ulcers, the lesions of dysentery, syphilis and tuberculosis, as well as those caused by the irritation of foreign bodies or by the parasitism of helminths.

Finally, apart from the parasitological observations and considerations submitted, I venture to believe that this rapid survey of cancer conditions in certain districts of Iceland and Italy proves the usefulness of intensive scientific research in limited areas of different countries where the disease is most prevalent and indicates the uselessness, even the misguiding effect, of statistics, such as are compiled in central official bureaux by mixing and blending data of very different import and value, gathered from innumerable localities and losing, in the confusion resultant, precious facts—dissolving, as it were, pearls in vinegar. But, inscrutable as the ancient Oracles, the Health Boards of our day will continue to scribble figures

as if it were possible to stay the phalanges of Death by the exorcism of numbers, or by some mystic word such as:

I

The local mice had yielded a considerable percentage of cancerous growths, those from Mayence not one. Borrel looked for the condition which might explain this difference, and found that the local mice were infested with a "filaria-like" worm, which was absent from the Mayence mice. He gave me slides with shreds of mouse skin containing the worms, and I found that there were two kinds of nematode worms. One is an *Oxyuris*, the *O. tetraptera*, first described by Nitzsch, in 1821, under the name of *Ascaris tetraptera*. [This oxyurid is found in the large intestine of the house-mouse (*Mus musculus*), the long-tailed field-mouse (*Apodemus sylvaticus*), the common hamster (*Cricetus frumentarius*) and the jerboa (*Jaculus jaculus* and *J. sagitta*)]. The other is a new species, and, I believe, a new genus, though, prob-

Oxyuris tetraptera (Nitzch, 1821).

After the Paris Lecture.

The day after my address at the Institut Pasteur, Professor Borrel invited me to go with him to Strasburg, where he could show me all his preparations, the work of many years on cancer. Professor Calmette also urging me to go, I accepted, and we left by the night train to spend the next day in Strasburg. Most interesting, instructive and delightful was the day spent in Borrel's laboratory in the superb bacteriological institute built by the Germans not long before the war. I examined numerous sections of all kinds of tumours in which the connection between parasite and neoplasm was unmistakable. Some were sections of skin epitheliomas with *Demodex folliculorum* embedded in the growth, others sarcomas of the liver or kidneys of rats with the nascent neoplasm, no larger than a pin's head, budding out, as it were, from the capsule of *Cysticercus fasciolaris*, others again, sections of horse testicle with either *Setaria equina* or *Strongylus equinus* as the exciting cause of the growth.

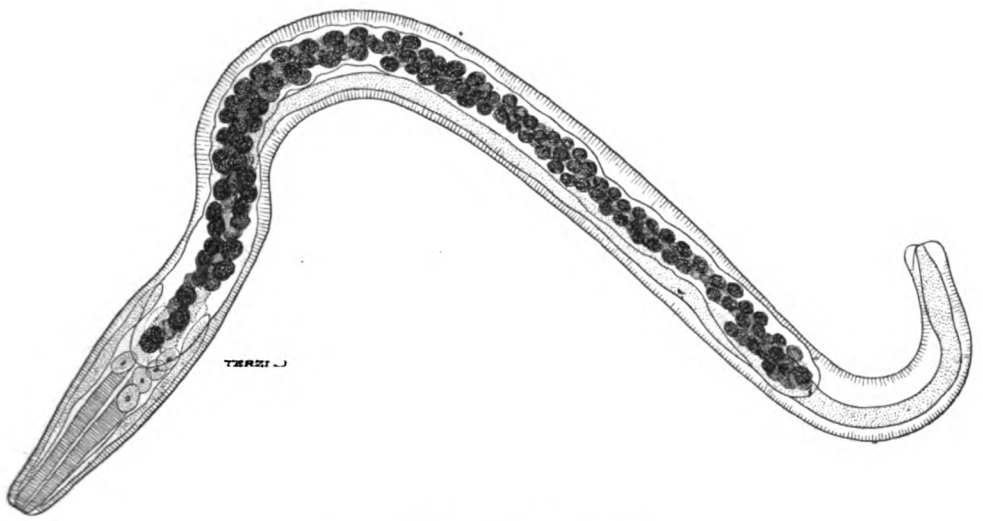
Borrel showed me the centuries of white and piebald mice he was using for his tarring experiments. The actual tarring was the work of an Alsatian maiden, in whose hand a rose would have seemed more appropriate than a mouse, with an ugly sore on its sooty, depilated back. One of the tarred mice had developed a huge horny excrescence which seemed likely to outgrow that of the famous widow Dimanche. There were two sets of mice, one of Strasburg mice, the other of mice from Mayence. ably, seen by Redi (1684), long ago in the inguinal glands of the common mouse.

The material at my disposal consists of seven females (several broken) all in poor condition and embedded in the balsam-smeared reticular layer of the skin. Yet I venture to submit a short preliminary description and some drawings of this interesting nematode:

Genus *Muspicea* gen. n.
Species *Muspicea borreli*, sp. n. (Type sp.)
Host—the Common Mouse (*Mus musculus*)
Location—Sub-cutaneous connective, inguinal glands.
Locality—Strasbourg.

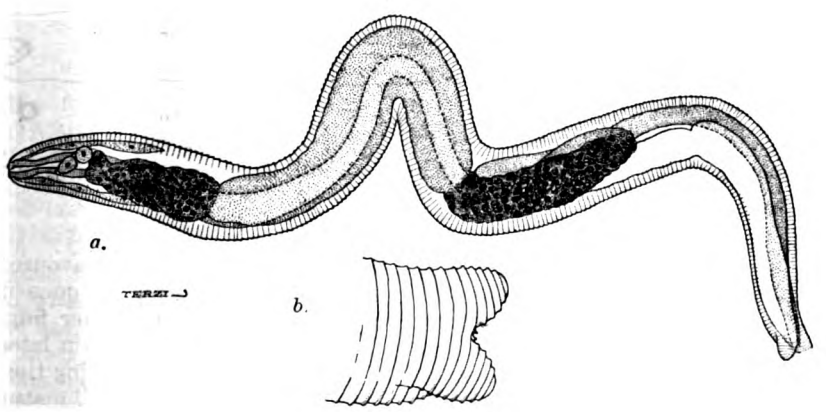
Specific diagnosis.—Body short and stout, somewhat spindle-shaped, but thicker at the anterior end, attenuated posteriorly and terminating (in the female at least) in a bilobed tail; lobes strikingly mammilloid. Cuticle transversely striated, striations prominent, interval between them about 10 microns. Mouth simple, œsophagus followed, apparently, by slight subspherical bulb. Intestine straight, thin-walled, of almost uniform diameter. Anus opens between tail lobes. Large nucleated cells, probably representing glandular structures, about œsophagus. Viviparous.

Female 2·87-3·40 mm. long, 110-160 microns thick at broadest anterior portion, 50-75 microns at narrowest portion near tail. Tail lobes about 20 microns long. Uterus apparently a continuous tube, in all probability consisting of two opposed branches. In one immature form there appear to be two ovaries situated at opposite ends of uterus, in later stages the



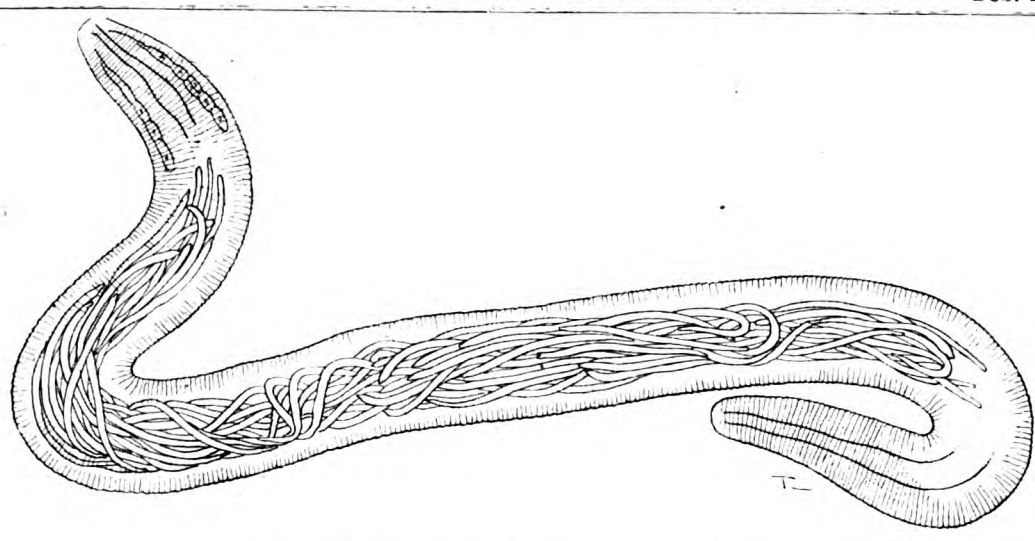
ovaries cannot be made out and the large sack-like uterus is filled with either undeveloped subspherical eggs, or fully developed embryos. The vagina probably opens about the middle of the body, but it cannot be made out clearly in specimens at hand.

Larva—270 microns long, 18 microns thick at broadest posterior end of body. Tail bilobed, lobes nipple-like. Anterior to tail-end a large papilla-like projection on each side of the body. Œsophagus with slight œsophageal bulb. Intestine straight. Mouth with, apparently, six papillæ.



In the new Pasteur Museum, annexe of the Bacteriological Institute, I further had the opportunity of examining several specimens of crown-gall in plants inoculated with the *Bacterium tumefaciens* of Erwin Smith. What a striking thing is this plant-neoplasm, so like animal cancer in its appearance, mode of growth, permeation, metastases and deadliness!

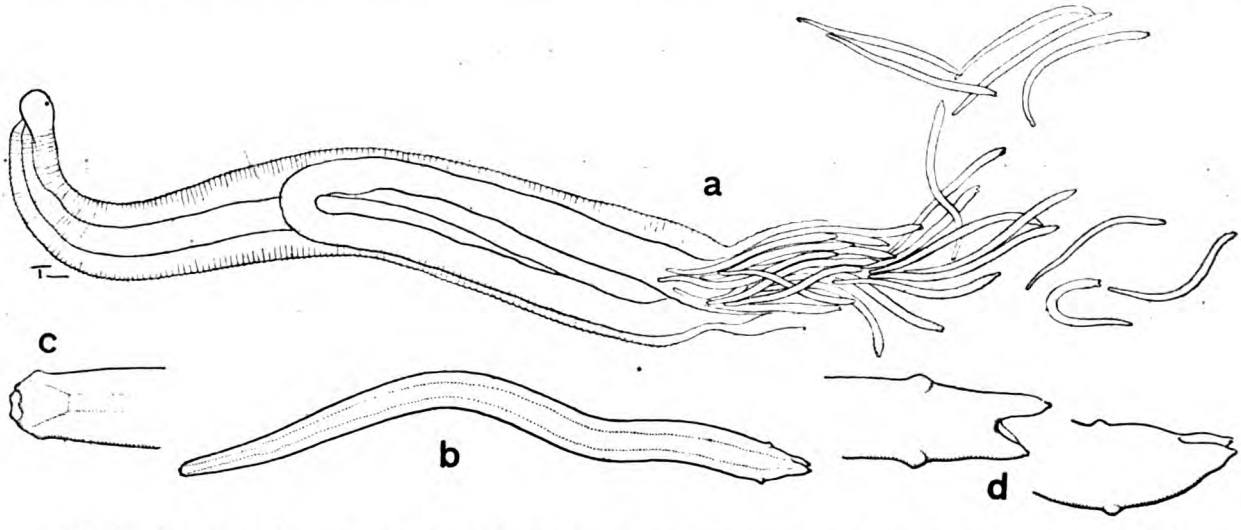
ALESSANDRINI'S GONGLYONEMA.



A few days ago, the well-known natural history artist, Mr. A. Terzi, who had been drawing for me the exquisite pictures of insects illustrating this paper, brought me a reprint of an article by Professor Giulio Alessandrini, of Rome, on a case of Gongylonema infection in man. This paper, published in 1914, had not only escaped my notice, but also that of other parasitologists, such as Baylis, in this country,

Muspicea borreli Sambon, 1925.
Young female.

Muspicea borreli Sambon, 1925
a, immature form. *b*. posterior extremity.

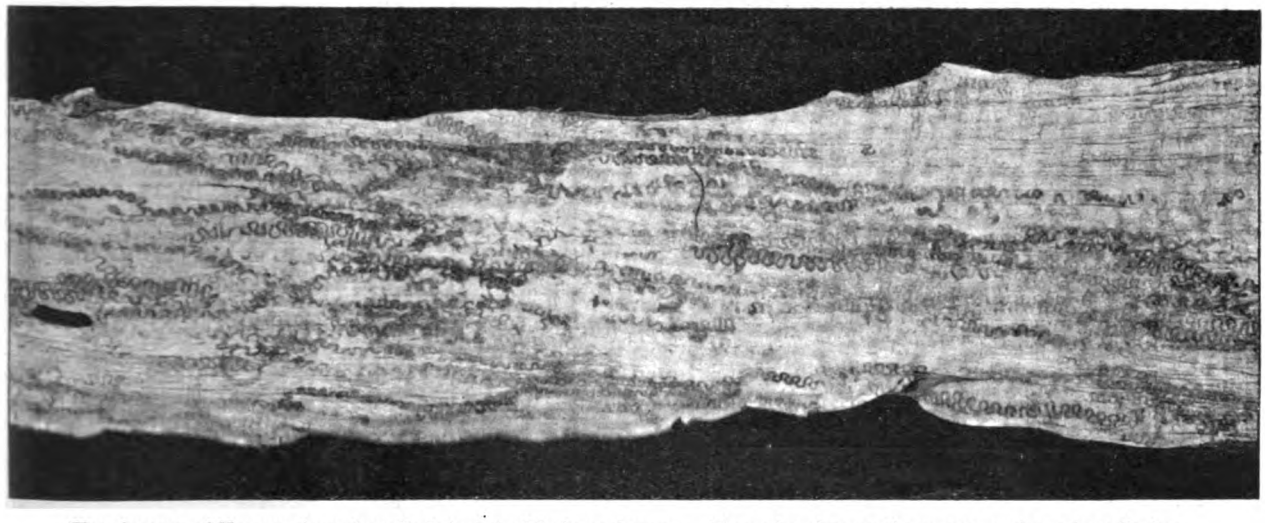


Muspicea borreli Sambon 1925. Fully mature female.

Hassall, Ransom, Stiles, Ward, in the United States of America. Indeed it is not even mentioned in the American index-catalogue of medical and veterinary zoology.

In one way, I regret this oversight; it seems almost unpardonable, especially as Professor Alessandrini's paper was published in the *Bulletin* of the Royal Medical Academy of Rome (year xxxx, part IV). On the other hand, had I known of Alessandrini's paper, I should not have discovered Pane's earlier finding, nor might I have returned to Italy last summer, where so much interesting material was collected.

Professor Alessandrini describes the finding of no less than six worms of the genus Gongylonema in a young woman 18 years of age from Saracinesco, a hill village on the river Aniene, between Tivoli and Mandela (Rome). The worms occupied sinuous galleries which they had made beneath the epithelium of the buccal cavity, some at the root of the tongue, others near the frenulum. Whenever the parasites protruded from their galleries, the patient felt the unpleasant sensation of having something like a hair in her mouth and endeavoured to draw out the worm, but the latter at once made resistance, and usually, slipping out of her fingers, withdrew within its gallery to protrude again later.



Muspicea borreli, Sambon 1925, *a*, broken body of mature female with larvæ escaping: *b*, *larva*: *c*, anterior extremity of larva; *d*, posterior extremity of larva.

Of the six worms infesting the patient Alessandrini was able to secure three, all mature females, the others had been thrown away. Unfortunately, Professor Alessandrini gives neither measurements nor exact description of the interesting worms he had the opportunity of examining. He says: "The species

found by me as a parasite of man although approximating to that of the hog (*Gongylonema pulchrum*) cannot be considered the same. It differs from it especially on account of its greater length, its greater slenderness and because the scutes on the anterior portion of the body occupy a space twice as long; the eggs also are smaller and relatively more elongate. I propose therefore to consider it a new specie and call it *Gongylonema subtile*."

In a previous paper, Alessandrini mentioned the finding of *Gongylonema* in sheep of the Roman Campagna and in cattle imported from Sardinia, findings of which I had been informed by Dr. Piero Cavallo in Trento. No doubt Alessandrini has preserved the Gongylonema worms he found in man and, seeing the importance they have acquired, will furnish a more detailed description accompanied by exact measurements. Dr. Baylis's paper should be very helpful. He, having examined a large amount of material, is inclined to look upon the names of certain species described from various hosts as synonymous.

Œsophagus of Faenza sheep heavily infested with *Gongylonema*. The paler sinuous lines represent empty galleries. (Photograph by Dr. L. W. Sambon.)

ON *GONGYLONEMA* COLLECTED IN ITALY DURING OCTOBER, 1924, WITH SOME OBSERVATIONS ON THE GENUS.

By H. A. Baylis, M.A., D.Sc.

Department of Zoology, British Museum (Natural History).

(Published by permission of the Trustees of the British Museum.)

The material collected in Northern Italy during the writer's expedition with Dr. L. W. Sambon in the autumn of last year has not all been completely worked out, but the most important point was to determine what were the species of *Gongylonema* met with in the region. Owing to lack of time and facilities for the detailed study of material during the expedition, this had to be left until our return to England. We were under the impression that we had obtained four species of *Gongylonema* from the various animals examined, but, as will be explained, this number has now been reduced to one.

In the first place, we found in the walls of the stomach of a wild rat, captured in the public slaughter-house at Bologna, some slender worms which seemed likely to be *G. neoplasticum* Fibiger and Ditlevsen. Microscopic examination, however, at once showed that they were not *Gongylonema* at all. They appear to be examples of *Hepaticola hepatica* (Bancroft) in an unusual situation. In the liver of the same rat (and indeed of almost all the rats examined) there were masses of the eggs of this worm, and these agree very closely with those of the worms found in the stomach.

Again, in a number of fowls the walls of the crop were found to be invaded by very slender worms which, from the naked-eye appearances, were thought to be in all probability *G. ingluvicola* Ransom. They prove, however, to be a species of *Capillaria* which has not as yet been determined. In these two cases, therefore, we have Nematodes whose habitat and mode of life are similar to those of *Gongylonema*, and which, without the aid of the microscope, may readily be mistaken for it. It seems possible that, if pathological effects may result from the presence of *Gongylonema*, similar effects might be produced by *Hepaticola* and *Capillaria*. In this connection it is of some interest to recall that a case of *Hepaticola* in the human liver has recently been recorded by Dive, Lafrenais and MacArthur.[1] Another worm of somewhat similar habits and naked-eye appearance is *Onchocerca armillata*, which furrows in the internal coat of the aorta of cattle, and causes the formation of nodules or tumours.

G. scutatum was found in great abundance in sheep, goats and cattle in the region investigated. At

[1] *Journ. Roy. Army Med. Corps*, xliii, pp. 1-4 (1924).

TABLE I.—MEASUREMENTS OF *GONGYLONEMA SCUTATUM* (ORIGINAL)

The figures given in this table refer to the largest male and female in each set of specimens.
The measurements in all the tables are in millimetres.

Faenza, for example, where we examined a large number of sheep, we saw only one which was free from infection with this worm. On comparing the existing descriptions of *G. scutatum*, the curious fact came to light that, while authors dealing with European material described the long left spicule of the male as 16 to 17 mm. long, Seurat, studying Algerian specimens, gave it as only 8·5 to 9·5 mm. The writer had the good fortune, through the kindness of Professor Henry, of the École Nationale Vétérinaire at Alfort, to be able to examine specimens from a sheep and a goat from Algeria, and to compare them with the Italian specimens. Curiously enough, it was found that in these Algerian specimens also the length of the left spicule averaged about 8 mm., and they thus agreed closely with those described by Seurat. It seemed possible that the Algerian forms might represent a local race or even a species distinct from the European *G. scutatum*. However, no other important difference could be found between different sets of material from various parts of the world (Table I). The length of the left spicule was found to vary between 5 mm. in a specimen from an Indian buffalo[1] and 23 mm. in a specimen from a North American ox.

Whether these differences have any fixed local distribution, or whether the length of the left spicule is equally variable in all localities, is a point that can only be settled by the examination of long series of specimens. For the present it seems preferable to adopt the latter supposition. Moreover, it must be admitted that we do not yet know to what extent the spicules of Nematodes continue to grow in length during the life of the individual. It is commonly assumed that, once they have become chitinized, the spicules cease to grow. This, however, is no more than an assumption, and a good deal of evidence might be adduced which points in the other direction. The proximal, or "root," end of the spicules very frequently has an unfinished appearance, as if the process of chitinization were not yet complete. It seems not at all improbable that the process is a gradual one, going on indefinitely as long as the spicule continues to increase in length, and this, for all that is known, may be for a considerable time after the worm has completed its last moult.

We may now pass on to consider the specimens obtained from pigs in Italy. Unfortunately, we obtained only two female examples of *Gongylonema*, which were found in two different pigs. The reason for the scarcity of material, as we only discovered when it was too late, was, no doubt, that all the pigs which we examined had been fed on waste products from a cheese factory, and not allowed to forage for themselves, so that they had had few opportunities of ingesting the intermediate hosts of *Gongylonema*. These two specimens, however, were compared with others from a wild boar from Algeria, determined by Professor Railliet as *G. pulchrum* Molin. Careful series of measurements were made (Table II), as the result of which it seems almost certain that the species found in swine, both domestic and wild, in Europe and North Africa, is identical with the *G. scutatum* of ruminants. The only constant difference is the smaller average size of the worms from the pig and wild boar. Mere total dimensions, as is now generally recognized, are of little importance among Nematodes. We know that in many cases (as for instance, has been shown by Ransom for *Syngamus trachealis*) Nematodes tend to grow larger in those hosts to which they are better adapted. It is not unlikely therefore, that the ruminants are the animals in which *G. scutatum* has been longest established, and in which it finds its requirements best fulfilled, and that the small size of the *Gongylonema* of swine is merely the result of imperfect interadaptation between the parasite and its host. Specimens of *Gongylonema*, attributed to *G. pulchrum*, are occasionally found in horses and donkeys, and these are likewise undersized, probably for the same reason.

The view has recently been taken by American helminthologists that the *Gongylonema* of the pig in the United States differs from that of European pigs. It was described by Chapin in 1922 as a distinct species, *G. ransomi*. On comparing the measurements given by Chapin[1] (see Table II) with those observed in European and African specimens, it is found that, once more, there is a general agreement. In fact, the only character mentioned by Chapin as distinguishing *ransomi* and *pulchrum* is the greater length of the left spicule in the American form. But, as we have seen, there is good reason for believing that this feature is so variable as to be unworthy of consideration, by itself, as a specific character.

On morphological grounds, therefore, the writer is led to the conclusion that there is not sufficient justification for separating *G. pulchrum* or *G. ransomi* from *G. scutatum*. This view will, doubtless, meet with opposition from those who believe that these forms represent physiologically distinct species or subspecies. But (while the existence of "host-races" or local races is quite possible), unless and until it can be experimentally proved, by those in a position to undertake such investigations, that the form found in one host cannot be transmitted to another host, there appears to be no alternative but to regard all these forms as belonging to one and the same species. It is even possible that certain other supposed species may fall likewise into synonymy.

Through the kindness of Professor Johannes Fibiger, of Copenhagen, the writer has had the opportunity of examining a certain number of specimens of *G. neoplasticum* Fibiger and Ditlevsen, the form believed to be instrumental in the production of cancer in rats. According to its original description,[2] this form differs from *G. pulchrum* chiefly, if not solely, in the length of the left spicule of the male, which is given as only 0·528 mm. The material available for the writer's

[1] Since the preparation of this paper, specimens from buffaloes domesticated in Italy have been received through the courtesy of Dr. Cesare Cappelli of Bologna. The left spicule, in two males, measured 15·8 mm. and 16·8 mm. respectively.

* This column includes the figures given by Neumann (*Mém. Soc. Zool. France*, vii, 463-473 (1894)), and by Seurat (*Compt. Rend. Soc. Biol.*, Paris, lxxix, 717-742 (1916)), as

study included only five males, all of which came from two rats. In these specimens the length of the left spicule varied between 0·59 mm. and 0·67 mm. It is true that this size is extremely small as compared with that found in the other forms considered in this paper, but it is not unlikely that the study of a large amount of material would reveal greater variation. The male worms available are all very small (7·4—11·1 mm. in length), and this fact may be of some importance.

Careful search has been made for some other morphological character in either sex that would enable *G. neoplasticum* to be definitely separated from the forms found in other hosts, but the results, so far, have been entirely negative. In every character studied the amount of individual variation is so great that the specimens from the rat usually fall between the extremes met with in specimens from other sources. The number and arrangement of the cuticular bosses on the anterior end of the worm are very variable, and prove unreliable as a diagnostic character. The number of caudal papillæ in the male is also variable. In all the specimens from rats in which they could be made out, the number of preanal papillæ appears to be four pairs, as described by Fibiger and Ditlevsen. But Seurat[1] has shown that great variation in this respect occurs in *G. scutatum*, where the number of preanal papillæ on either side may vary between two and eight, and the two sides are frequently asymmetrical.

Cervical papillæ were stated by the describers to be absent in *G. neoplasticum*. This, however, is not the case, as has already been observed by Seurat. Though very inconspicuous, these papillæ are present in the same position as in *G. scutatum*. The form of the spicules and accessory piece (or gubernaculum) is the same in all cases. At first sight it seemed likely that the left spicule might present some difference in shape as well as in length, but it appears that the figure given by Fibiger and Ditlevsen[2] of the tip of this organ is somewhat misleading. It has a rounded tip, as in the figure, but the shaft of the spicule only is shown, the transparent alæ, which make up the greater part of the width, having been omitted. Hence the terminal chitinoid cap of the spicule does not form a knob conspicuously wider than the rest of the spicule, but is similar to that of *G. scutatum*. The tail of the female sometimes appears more pointed in *G. neoplasticum* than in *G. scutatum*, but even this difference is not constant. The eggs show the same amount of variation in shape and size.

In Table III the writer's measurements for *G. neoplasticum* are compared with those given by previous authors. In Table IV the measurements of *G. neoplasticum* are compared with those of *G. scutatum*, *G. pulchrum* and *G. ransomi*, the data given by all authors being combined and only the extremes given. While some of the absolute measurements appear very different, on the whole they form series quite compatible with the ordinary individual variation which may be found within any single species when a sufficiently large number of specimens is studied. It was found that an attempt to express certain of the more important measurements as fractions of the total length indicated no constant ratios, and the amount of variation is so great that this method appears quite unreliable.

It is, therefore, a very difficult question whether *G. neoplasticum* should be considered a distinct species or not. It appears to depend upon the importance to be attached to a single character, limited to the male sex, viz., the length of the left spicule. Many helminthologists would, doubtless, consider this quite sufficient to constitute a "good" species. The writer feels, however, that in view of the amount of variation possible in the forms from other hosts, and until a much larger number of males of *G. neoplasticum* has been examined, the evidence is rather strongly in favour of specific identity. This view does not, of course, exclude the possibility of the existence of a "host-race," or even an incipient species, confined to rodents. As in the other cases previously discussed, the question calls for careful experimental investigation by those able to undertake it.

As regards the nomenclature of the species from domestic animals, if *G. scutatum* (Müller, 1869) is identical with *G. pulchrum* Molin, 1857, it is evident that the latter name has priority. Molin[1] described three other species of *Gongylonema* at the same time as *G. pulchrum*, but only one of these (*G. minimum*) seems certainly to be distinct from it, while the other two (*G. filiforme* and *G. spirale*) have never been redescribed since Molin's paper appeared. There is nothing in the very brief diagnoses of these forms to indicate that they are distinct species, except their hosts, though it cannot be assumed, without further proof, that they are synonyms. In the circumstances, therefore, the most reasonable course appears to be to adopt *pulchrum* as the name of the species from swine, sheep, goats, cattle, and equine animals, with *scutatum* and *ransomi* as synonyms. To this synonymy *neoplasticum* may perhaps have to be added.

In conclusion, if, as has been suggested, all these species are identical, the fact has very interesting and important bearings upon human pathology. On several occasions immature specimens of *Gongylonema* have been found in man in America, and Professor H. B. Ward has suggested that they may belong to the species found in pigs. Further, the worm described from man in Italy by Pane, which Sambon refers, with great probability, to *Gongylonema*, bears a very close resemblance to *G. pulchrum*. It is, therefore, highly probable that, when further examples of the human parasite are discovered and carefully examined, they will prove to belong to the species which we found so abundantly among the domestic animals in Italy. In that case, these domestic animals—sheep, goats, cattle and pigs—will have to be considered as important reservoirs of the parasite, and, if Dr. Sambon's theory receives confirmation, as factors in the spread of carcinoma.

In addition to those gentlemen whose valuable assistance in the matter of material has been acknowledged elsewhere, the writer has great pleasure in expressing his indebtedness to Mr. Frank Ware, F.R.C.V.S., of the Royal Veterinary College, for the loan of various specimens from zebu and buffaloes from India.

SOME NOTES ON THE INSECT INTERMEDIATE HOSTS OF GONGYLONEMA.

By K. G. Blair, B.Sc., F.E.S.

(*By permission of the Trustees of the British Museum.*)

In view of the extremely probable connection between *Gongylonema* and certain forms of cancer a knowledge as detailed and accurate as possible of the life-history of *Gongylonema* is an obvious desideratum. Whether this connection be direct or indirect is immaterial; if we can eliminate *Gongylonema* we can, if not eliminate, at any rate control to a very appreciable extent the incidence of this dread disease, at least of that form of it that follows the ravages of *Gongylonema*.

But if we are to eliminate *Gongylonema* the first essential is to discover any weak points in its developmental phases, points in which it is most susceptible to attack, so that effort may be concentrated upon that period of its life history when attack will be most effective.

Actual records of the association of *Gongylonema* with insects, though not very numerous, and not always correlated with certainty with the mature form and vertebrate host of the worm, clearly indicate that the intervention of an insect host at some period of its life history is essential to the proper development of the worm.

Encysted *Gongylonema* larvæ have been found within the body cavity of many genera of coprophagous beetles, e.g., *Ateuchus*, *Chironitis*, *Onthophagus*, *Gymnopleurus* and *Geotrupes* in Algeria and *Onthophagus* and *Aphodius* in America and in the body cavity of different species of *Blaps*, a genus of tenebrionid beetles. Under experimental conditions encysted larvæ have also been found in the mealworm, the larvæ of another genus of tenebrionid beetles, and in the musculature of different species cockroaches, *Blattella germanica*, *Blatta orientalis* and *Periplaneta americana*.

A brief review of these recorded insect hosts and of their habits may prove suggestive.

Dung Beetles (Fam. Scarabæidæ.)

Ateuchus (or *Scarabæus*) *sacer* L is the well-known sacred beetle, the source of inspiration of the scarab of ancient Egyptian sculpture. Its economy has of recent years been re-investigated and made accessible to the public by the writings of the great French naturalist and observer, the late Jean Henri Fabre. The beetle is a lover of darkness, yet for part of its work the hot sunshine is essential. From the droppings of some large animal such as the cow, horse or camel, he cuts out a mass of dung which he works into a large ball very much larger than himself. This he proceeds to roll about in the sunshine till the outside becomes case-hardened, i.e., baked into a hard shell with which are incorporated grains of sand picked up in the rolling process. When the ball is sufficiently baked it is buried in the earth, the beetle accompanying it. Frequently, this ball is destined merely as a food store for its owner, the beetle now proceeding to gorge and gorge until the food store is exhausted, when he emerges again to collect another one. But in the case of the female beetle some of the balls are prepared not for her own delectation, but for the nourishment of her progeny, an egg being deposited in each and the resulting larvæ feeding upon the contents till only the hard, sand-encrusted shell is left. In this chamber it undergoes its further transformations to emerge in due time as the adult beetle. Dr. Sambon has already discussed the probable reasons for the sanctification of this insect by the Egyptians.[1]

Gymnopleurus, *Onthophagus*, *Chironitis* and *Geotrupes*, all members of the same family, behave in essentially the same way except that the rolling process in the preparation of the food-mass is omitted, a hole being excavated immediately beneath the patch of dung selected and the dung carried down. Frequently, the adult

[1] Not only did the Ancients control the plague by pitting against the plague-carrying rat all its natural enemies—the cat, the ichneumon, the kestrel, the snake, but they availed themselves of like methods in several other cases. Ancient Egypt offers two striking examples: the control of hookworm disease or endemic anæmia by the Dung-Chafer or Sacred Scarab (*Ateuchus sacer*) and that of endemic hæmaturia, or bilharzia disease by the Sacred Ibis (*Ibis æthiopica*).

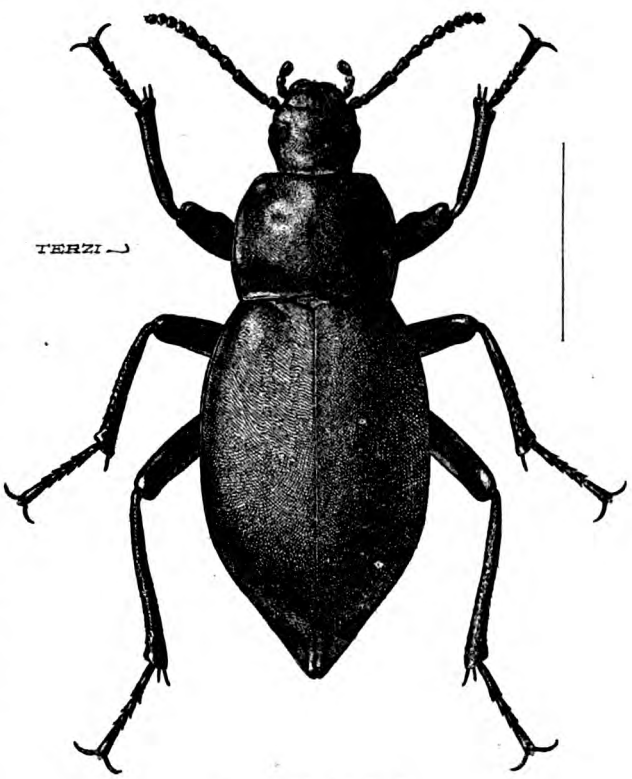
Hookworm disease was well known to the ancient Egyptians. According to Scheuthauer and Joachim, the famous papyrus Ebers (1550 B.C.) rightly ascribed the disease to an intestinal worm—the Heltu worm; and von Oefele has pointed out that a connection between the disease and the carrying and handling of sand was fully recognized.

The important part played by the Dung-Chafer in the theogony of Egypt is well known. This coprophagus beetle is represented in all monuments from the Delta to the very heart of Nubia, carved of all dimensions out of every possible material, but no doubt you will own that all the theories hitherto advanced to explain its sacredness are very fanciful.

Some years ago I suggested that the extraordinary veneration paid to the Dung-Chafer found an easy, natural and satisfactory explanation in the prevention of hookworm disease. In 1900, whilst carrying out my malaria experiment in the Roman Campagna, I had the opportunity of studying the habits of the sacred dung-beetle and I was struck by the rapidity with which excreta, scarcely dropped, were cut up, rolled into pellets, and buried deeply in the sandy soil. It would be impossible to find a more rapid and efficient method of fecal disposal. I understood then why the scarab had been consecrated and looked upon as a tutelary god. It destroyed the larvæ of the hookworm and thus prevented one of the most fearful plagues of Egypt.

The ancient Egyptian habit of wearing a scarab or scarab-shaped amulet over the heart region, of which every mummy we unwrap gives proof, surely suggests protection against the anæmia-causing hookworm disease and explains the words of the Berlin medical papyrus "Even the amulet maker knows the circulation of the blood." [L. W. Sambon] See this Journal, September, 1, 1908.

beetle is content to feed in the original mass of dung, and only the food supply for the progeny is carried underground. These beetles are usually nocturnal in habits, remaining in the dung or in the earth beneath it during the day, coming up to work or flying in search of pastures new as night falls. *Geotrupes* is familiar to all as the "shard-borne beetle" of Shakespeare, while the passing hum of the door-beetle as he "wheels his droning flight" (Gray) is a characteristic sound of a calm summer evening.



The species of *Aphodius*, generally speaking, are smaller than the dung beetles hitherto considered, and as a rule deposit their eggs in the mass of dung in which the larvæ develop. Some of them are strongly selective in their choice of pabulum, confining their attentions to the dung of particular animals, e.g., cow, sheep, deer, rabbit and so on, while others are much more catholic in their tastes. Many species fly readily in the sunshine and some of them occur at times in enormous numbers.

The larvæ of all these beetles are soft, whitish grubs, with hard brown heads and strong jaws; they lie with the posterior part of the body curled beneath the front portion, and, living as they do, completely surrounded by their food material, their powers of locomotion are very feeble. Their transformations are completed usually in the cavity they have created in the course of their feeding as larvæ, and even the mature beetle remains here for some time while its integuments acquire their full hardness before it is able to break forth from its prison.

Cellar Beetles (Fam. Tenebrionidæ.)

Blaps is a genus of ground-dwelling beetles, black, usually of large or very large size. The elytra or wing-covers are usually produced behind to form a tail-like process, in some species very long, in others scarcely indicated; these processes are nearly always longer in the male than in the female. Wings beneath the wing-covers are wanting, the insects being thus incapable of flight, so that their distribution is more circumscribed, than that of the dung beetle, and when they do occur they are usually found in more or less limited colonies. In England we have two fairly common species, *B. mucronata* Latr. and *B. lethifera* Marsh. The former, popularly known as the cellar-beetle, occurs not uncommonly in cellars and basements even in London. Its life is very imperfectly known, but it is probable that the larva lives mainly on the dung of rats and mice beneath the floors or possibly on fungoid growths that may develop in such situations. *B. lethifera* with us is more usually found in stables and outhouses, the larva probably feeding like that of *B. mucronata* or in accumulations of dung left in odd corners and never properly cleared out. Both these species were found in or about dwelling-houses by Dr. Sambon in Italy, together with two other species that do not occur in this country, viz.: *B. gages* L. and *B. gibba* Cast.

In order to ascertain to which species of *Blaps* any given specimen belongs it is essential to determine the sex. With a single individual this is not always easy except by examination of the genital armature. But when a number are collected from one spot, and presumably all of one species, the sexes can be fairly readily separated by the longer "tails" of the males, by their longer and more slender legs and antennæ, by their more parallel form, and, in many species, by the presence on the underside of a pad of yellow hairs between the first and second segments of the abdomen.

Blaps gibba Cast. ♂

The four species above-mentioned may be separated as follows:—

(1) Tail parallel sided, the tips separated by a distinct notch; size large (40 mm. or nearly); ♂ with ventral hair-pad, tails long (3 to 4 mm.); ♀ with tail about 1 mm. *gages* L.
Tail convergent behind, tips adjacent; size smaller (25 mm. or less) 2.
(2) ♂ with hair-pad; thorax distinctly transverse, the sides rounded, convergent behind the middle 3.
♂ without hair-pad; prothorax small, not much wider than long, or than half the width of the elytra, its sides nearly parallel behind with posterior angles rectangular *mucronata* Latr.
(3) Thorax distinctly narrower than elytra (about ⅔ as wide), upper surface more finely and smoothly punctured; joints 4 to 7 of antennæ fully twice as long as wide (♂) *gibba* Cast.
Thorax nearly as wide as elytra, upper surface more coarsely, elytra asperately, punctured; joints 4 to 7 of antennæ scarcely 1½ times as long as wide *lethifera* Marsh.

The genus is widely distributed in the southern palæarctic region, the species being most numerous in S.W. Asia, thence spreading westwards along both shores of the Mediterranean, a few species penetrating into Central Europe or beyond, while eastwards it reaches Japan.

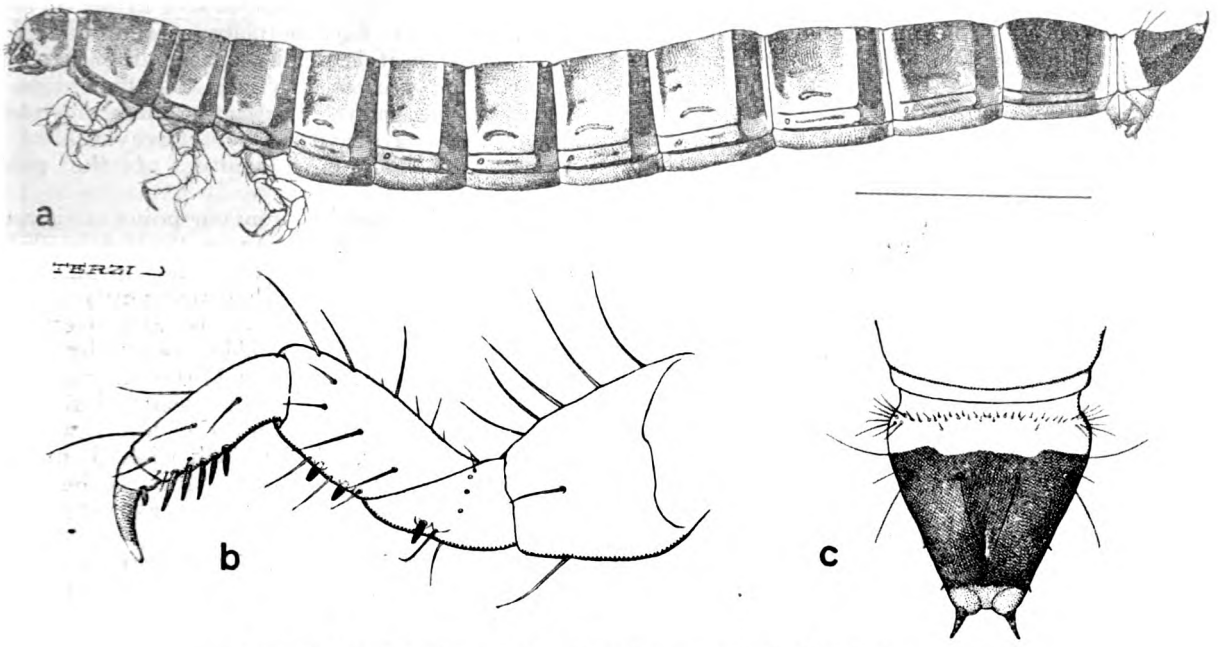
The larvæ are subcylindrical, moderately hard-shelled grubs of a yellowish colour with a considerable resemblance to the better-known "wire-worms" (larvæ of the skip-jack beetles or Elateridæ). From these they may be distinguished, *inter alia*, by having the first pair of legs, i.e., those immediately behind the head, larger and stronger than the two pairs behind them, by the head being rounder, not so depressed, with the mouth parts free and rather soft in texture, while in the Elateridæ the labium and bases of the maxillæ are strongly chitinized and fused together to form a solid tripartite plate occupying the buccal cavity of the head beneath.

The terminal segment in *Blaps* is flattened above, subtriangular with the apex produced into a small upcurved point; the sides are arcuate, provided with a series of upstanding spinules just within the margin. They are subterranean in habit, and can burrow readily, even through hard sun-baked earth.

The food, both of larvæ and adults, of the Tenebrionidæ was probably originally decaying vegetable matter. Certain genera have acquired importance from an economic standpoint, by developing the habit of eating off the seedlings of growing crops, while others have become dung feeders. Many species appear to have profited by the gregarious habits of man, and many species, especially of *Blaps*, but also of the not distantly allied genera *Akis*, *Ocnera* and *Pimelia* thrive on the outskirts of towns and villages, whilst some, yet more domesticated, invade the dwellings of man and of his cattle.

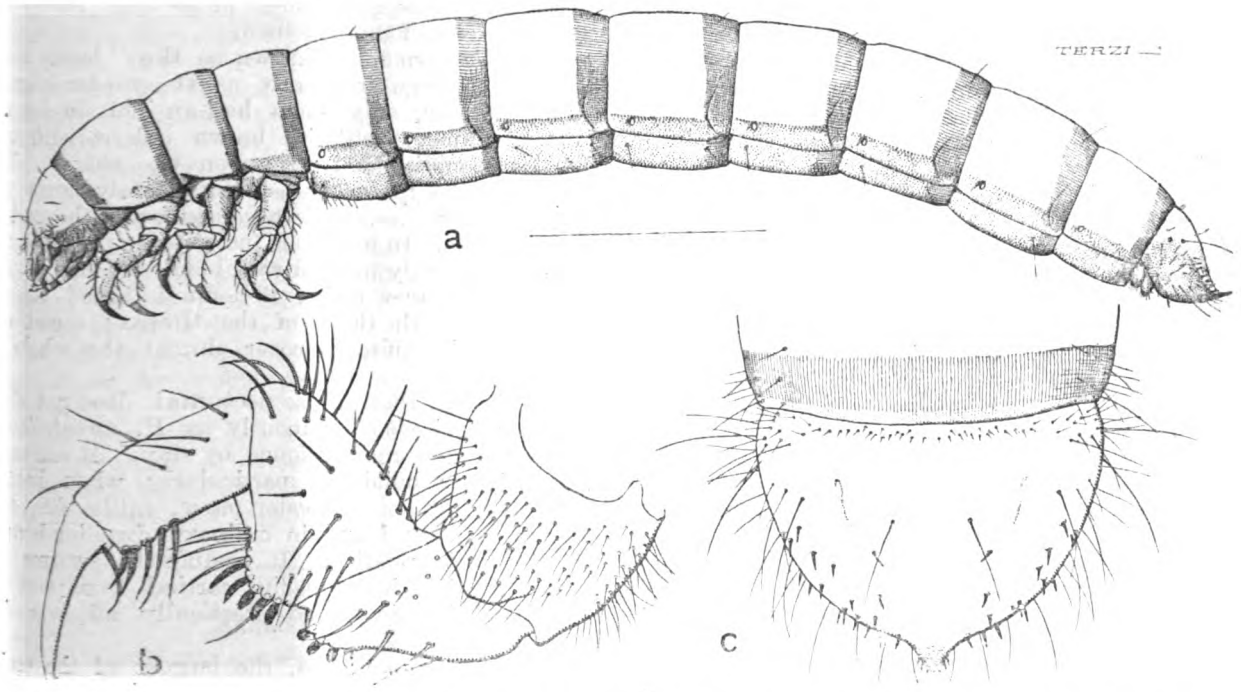
The adult beetles, on account of their lack of wings, are unable to travel far or quickly in search of food. Unlike the true dung beetles, they are poorly equipped for digging and quite unable to lay up a store of food for their progeny. They dislike the light and hide away by day under stones, under vegetation or rubbish and come out to feed at dusk.

With regard to *Blaps* it is interesting to find that it has always been looked upon with suspicion of harm. The French call it "*Présage mort, Porte-malheur, Sorcière de la mort*"; in Sweden it is regarded as the messenger of pestilence and death; in Germany it is known as the "Totenkäfer," while we call it the churchyard beetle as well as the cellar beetle.



Meal-Worm Beetles.

Tenebrio, another genus of the same family, *Tenebrionidæ*, includes in Europe two common species, *T. molitor* L. and *T. obscurus* F., both found in houses. The beetles themselves are narrower, more parallel-sided than *Blaps*, more depressed, with shorter, more feeble legs, and of a deep mahogany-red, almost chocolate colour. *T. molitor* is not quite so long and narrow as *T. obscurus*, and more or less shiny, whereas the latter is so closely punctured as to appear quite dull and opaque. Their larvæ are the well-known meal-worms occurring everywhere in granaries and bakehouses, and even in ordinary dwelling-houses. They are very similar to the larvæ of *Blaps*, but more slender, with the last segment of the abdomen more conical and terminated by a pair of small spiniform projections.



Hence, as regards the known beetle hosts of *Gongylonema*, it is evident that they fall into two categories, viz.: dung feeders and meal feeders. In these insects the *Gongylonema* passes the early stages of the development, presumably after the host has ingested an egg that has been passed out of the alimentary canal of the mammalian host of the mature worm. As regards the dung feeders this egg might be swallowed either in the larval or the adult stage of the beetle host, both stages being dung feeders, though it is possible that the age of the host may be more definitely restricted if the proper development of the worm is to ensue. Having hatched from the egg the larva burrows through the wall of the gut and encysts either in the body cavity or in the musculature of the insect (possibly the situation varies with the species of *Gongylonema*) when transference to a vertebrate host becomes necessary before development can be completed. In the case of small mammals, rats, mice, hedgehogs, &c., and of domestic fowls, this transference presents no difficulty, as the beetle is eaten by the new host, the cyst-wall dissolved, and the worm liberated. In the case of sheep and cattle, too, if the host be one of the smaller dung beetles, e.g., an *Aphodius*, it is readily conceivable that it may be eaten accidentally with grass, though with the larger beetles, *Ateuchus*, *Blaps*, &c., this is less likely. It is still possible that the beetle may be crushed or trodden upon and the encysted worm with the body-contents of the beetle smeared upon the grass or fodder and swallowed by the next comer.

For infection to be contracted by man it is obviously necessary that the encysted worm should be swallowed alive, a state of things that, owing to the nature of man's food, can only occur occasionally or accidentally. It is by no means uncommon for *Tenebrio*, *Blatta*, and particularly some of the smaller "flour" beetles, *Gnathocerus*, *Tribolium*, *Anobium paniceum*, &c., to be found in bread, but normally any encysted *Gongylonema* in such insects would be killed in the process of cooking. If, however, the cooking be incomplete and hasty, as is only too frequently the case, especially in more primitive communities, it is quite conceivable that the encysted worms may survive the operation and resume activity after being swallowed with the food.

In the case of *Tenebrio* it is not so obvious how the egg of *Gongylonema* comes to be swallowed by the beetle larva. The meal-worms in the flour-bin would scarcely be likely to come in contact with human fæces, and thus are not likely to swallow

Larva of *Tenebrio obscurus* Fab. *b* foreleg, *c* terminal abdominal segment.

Larva of *Blaps* sp. incerta. *b* foreleg of larva of *Blaps lethifera*, *c* posterior extremity of *Blaps* sp. inc. seen from above

the eggs from a human source. It is more likely that the eggs so swallowed were passed in the fæces from a rat, mouse, or, possibly, domestic fowl, and these fæces may have been desiccated and disseminated in the course of time. After encysting it may (or may not) be immaterial to the *Gongylonema* whether the meal-worm be eaten by another rat, or, after surviving an attempt at cooking, be eaten by man.

Very probably the investigation of other meal-feeding larvæ, e.g., the beetles mentioned above, as well as lepidopterous larvæ of the genera *Ephestia*, *Pyralis* and *Aglossa*, for larval Nematodes would yield results of value.

Cockroaches.

These insects are broad and flat, usually with two pairs of wings, the upper pair stiff and corneous, protecting the folded under pair. They thus bear some little resemblance to beetles, indeed, the common domestic cockroach, *Blatta orientalis*, is perhaps more familiar under the designation "black-beetle." With the beetles, however, they have, systematically speaking, no relationship whatever; from them they may be recognized by having the head depressed ventrally, completely concealed when at rest beneath the carapace of the prothorax; by the very long and slender antennæ, composed of a large number of joints (in beetles there are normally eleven, sometimes less), by the characteristic neuration of the upper wings, which overlap to some extent instead of meeting in a straight line down the middle of the back as they do in beetles, and by the fan-like folding of the lower wings. These wing characters are not always available as in this group of insects the wings are frequently undeveloped, especially in the female. In *B. orientalis*, for example, the wings in the male are small, not nearly covering the body, while in the female they are reduced to mere rudiments.

In their development also the cockroaches differ widely from the beetles, having what is termed an "incomplete" metamorphosis. That is to say, there is no caterpillar-like or grub-like larval stage, succeeded by a resting pupal or chrysalis stage during which no food is taken, and on the assumption of which the form of the limbs of the adult first becomes externally recognizable, but the young cockroach on hatching from the egg has the long-legged, flattened, active form of the parent insect, differing from it only in its pale colour and in the complete lack of even the rudiments of wings. These organs are developed gradually as external lobes of the second and third thoracic segments, increasing in size with successive moults, until at the last moult, when maturity is reached, their full development, at least in such species as possess fully-developed wings, is attained.

The cockroaches are very general feeders, passing indiscriminately from garbage to material intended for human consumption, whether animal or vegetable in nature, whether cooked or raw, and this habit, in conjunction with the partiality evinced by certain species for human habitations, makes them dangerous agents in the contamination of human food. It is indeed only too common to find them, either in fragments or intact, in bread, soup, or other food actually served up on the table, so that it is readily conceivable that where the cooking process has been insufficient to kill *Gongylonema*, encysted either in their musculature or in the body cavity, the conveyance of the parasite to man is a matter of the greatest facility.

The principal species, from our point of view, are: *B. orientalis* L., the common "black-beetle" of our kitchens. These insects are nocturnal in habits and lovers of warmth. They frequently swarm in incredible numbers in kitchens and rooms kept constantly heated, but hide away by day in crevices, particularly around the kitchen range, so that they are seldom seen, but if the room be entered after dark the floor, walls, furniture, everything, will be black with them. Even by day their presence may frequently be detected by the disgusting, though not very strong, odour that they emit.

This species is dark mahogany-red in colour, so dark indeed as almost to appear black, and nearly an inch in length. The males may be at once recognized by the possession of wings, which cover one half to two-thirds of the abdomen. In the female the wings are mere lobes and leave the abdomen fully exposed. They may frequently be observed carrying the egg capsule projecting from the posterior end of the abdomen.

Blattella germanica, known as the "lesser cockroach," or very frequently as the croton-bug, is much smaller, only about half-an-inch in length, and of a pale, yellowish brown colour with two blackish longtitudinal stripes on the thorax. The wings in the mature insect completely cover the abdomen, in fact, project considerably beyond it in both sexes. In immature individuals the abdomen is rather strongly marked with black or dark brown, arranged in two rather ill-defined broad streaks continuous with those of the thorax; sometimes these streaks unite to cover almost the whole of the abdomen.

This insect, though also nocturnal, does not shun the light quite so assiduously as *B. orientalis*, so that it is more readily found by day. It seems to affect larger buildings, particularly when heated with a system of hot-water pipes, mills, &c., and is not so often found in ordinary dwelling-houses as its larger relative. It frequently swarms on ships, so that it is readily carried from port to port, and is now found practically all over the world.

Periplaneta americana, the largest of the cockroaches mentioned, is nearly one-and-a-half inches in length; of reddish brown colour, not so dark as *B. orientalis*, and the wings completely cover and extend beyond the abdomen. This species also is frequently found on ship-board, and is thus widely distributed in seaport towns.

Possible Insect Hosts of *Gongylonema* in Iceland.

The very limited insect fauna of these regions must obviously narrow down our search for possible hosts of *Gongylonema*. Of such hosts hitherto recorded from other parts of the world the beetles are represented only by the genera *Aphodius* and *Blaps*. *Aphodius lapponum* Gyll. is not uncommon in sheep's dung, while *A. alpinus* Scop. and *A. foetidus* F. have also been recorded, possibly in error for the first-named. This species might be expected therefore to serve as host for the early stages of a *Gongylonema* affecting sheep, goats or reindeer.

There are no published records of any species of *Blaps* or of *Tenebrio* occurring in Iceland, but Dr. Sambon informs me that specimens of *Blaps mucronata* locally captured and of *B. gages* are preserved in the Reykjavik Museum, while it is not improbable that *Tenebrio* may occur in bakehouses.

Blattella germanica was found in some numbers by Dr. Sambon in houses, and on ships in the harbour, while *Periplaneta americana* and *Blatta orientalis* have also been found.

Any of these insects may function as intermediate hosts for a *Gongylonema* occurring in rats and mice, and occasionally securing lodgment in man.

Another semi-domestic insect recently collected by Dr. Sambon and not hitherto recorded from Iceland, though of this also specimens are preserved in the museum, is the carabid beetle, *Pristonychus terricola*, Hbst. This beetle belongs to a family that is strongly predaceous in habit, both in the larval and adult stages. A closely allied species, *Sphodrus leucophthalmus*, L., preys particularly upon *Blaps*, and has been found with it by Dr. Sambon in Italy. What would be the fate of a larval *Gongylonema*, presuming that it were swallowed without injury by one of these predaceous carabidæ, is not certain. There is the possibility that it would have lost the capacity, possessed on its first hatching from the egg, of burrowing through the wall of the intestine in order to seek its proper quarters in the body cavity or musculature, or would perish in the process of digestion.

Seurat, however, has shown that the larvæ of certain Spiruridæ, if ingested, along with their first host, by some small animal which is not their appropriate final host, are capable of re-encystment.

Annotations.

Investigations on the Epidemiology of Hookworm Disease in Colombo. Part I: On the Isolation and Identification of Infective Nematode Larvæ. Part II: Observations on the Viability of the Hookworm Larvæ (L. Fabian Hirst, *Ceylon Journal of Science*, vol i, part i, June 4, 1924).—In part i the available methods for isolating nematode larvæ from soil, sludge and sewage are briefly discussed. Modifications of the Baermann technique for the special purpose of isolating nematode larvæ from gasified sewage effluents and sewage sludges are described. Descriptions are given of three methods for separating infective nematode larvæ from the free-living nematode larvæ found in certain soils. The methods are based upon the reactions of hookworm larvæ to particular environmental stimuli. A new thermotropic reaction of hookworm larvæ is described. In part ii a series of laboratory experiments are described on the length of survival of human hookworm larvæ (*Necator americanus*) in various soils of given composition. In one set of experiments two of these soils were heated sufficiently to destroy nematode larvæ, a shallow layer placed in pans, and mixed with human fæces containing numerous ova. Human hookworm larvæ were recovered after at least 108 days and at most 124 days from the surface of the soil. The numbers of living larvæ were well maintained during the first two months of these experiments, which were carried out under tropical conditions. The length of survival of *N. americanus* larvæ isolated from cultures by Baermann's method was studied in another series of experiments. The larvæ were immersed in various fluids and implanted in pots containing the three soils. Larvæ lived about three months in water and fluid extracts of trench soil. They died out rapidly in salt solution. Cultivated Necator larvæ survived 120 days in the interstices of the unsterilized laterite soil. The human hookworm larvæ died out much more rapidly in soils and fluids maintained at blood heat, than in the same substances at room temperature.

Control of Hookworm Disease in South Alabama (W. G. Smillie, *The Southern Medical Journal*, vol. xvii, No. 7, July, 1924).—Hookworm infection is widely distributed in all ages and classes of people in the sandy coastal plane of South Alabama. Hookworm disease, that is, infection so severe as to be of actual harm to the individual, and so widespread as to be of economic importance to the community, is limited to rural children of school age. It can be almost entirely eradicated from a given country in a single year by mass treatment of the rural school children. This does not require an expensive hookworm campaign, but should be effected through the routine activities of the full-time county health officer and his nurse. The hookworm infection rate will not be reduced by this method of mass treatment. But hookworm infection is never permanently reduced by treatment. Hookworm treatment should be used to control actual hookworm disease. Sanitation should be employed to reduce hookworm infection. Sanitation methods should be begun in conjunction with the hookworm treatment and should be pushed consistently until at least 80 per cent. of the rural homes have sanitary toilets.

Experiments in the Treatment of Hookworm Disease with Carbon-Tetrachlorid and Ascaridol (S. B. Pessoa, *Southern Medical Journal*, vol. xvii, No. 9, September, 1924).—A mixture of carbon tetrachlorid and ascaridol, in a maximum dose of carbon-tetrachlorid, 1 mil, and ascaridol 0·75 mil, removed 94·5 per cent. of the hookworms harboured by a group of twenty patients. A dosage of 0·75 mil of ascaridol, followed in half-an-hour by 1 mil of carbon-tetrachlorid, removed 94·3 per cent. of the hookworms harboured by a group of twenty-eight persons. Carbontetrachlorid is well tolerated by the great majority of persons in doses up to 3 mil, which is the maximum dose used by the author. In some persons the ingestion of this drug, even in small doses (1 mil) produced symptoms attributable to a lesion of the liver. These symptoms may even be those of acute toxic jaundice. Four of the five cases of intoxication which have been noted following of administration of the drug were observed in chronic alcoholics, two of them showed evident signs of hepatic cirrhosis. However, several other alcoholics have been treated who did not show any symptoms of intoxication. No conclusions can be drawn from one case of intoxication in a non-alcoholic patient. Considering that most persons bear the administration of carbon-tetrachlorid well, but that some persons, such as chronic alcoholics, are susceptible to even small doses of this drug, the author thinks it advisable in future experiments to exclude the latter class of persons from treatment with the drug. In suitable cases the carbon-tetrachlorid could be administered in larger doses (2 to 3 mils) with ascaridol in doses of 0·5 mil to 0·75 mil. Such treatment would probably be sufficient to cure. The contra-indicated cases might be treated with chenopodium oil or ascaridol in accordance with the standard method.

Determination of the Resistance of Leukocytes (J. J. Sampson, *Arch. Internal Medicine*, October 15, 1924).—White blood cells recently delivered into the circulation have an increased resistance, excepting, presumably, according to the present criteria of morphology, immature cells such as occur in acute leukemia. In patients who succumb to an infection or intoxication, there is evidence that the increased resistance is less marked than in those patients who are holding the infection or intoxication in check or overcoming it. This partially confirms Mauriac's "Oscillation of Defense," which promises to be an additional factor in arriving at a prognosis in at least some of the acute infectious diseases.

Report of a Fatal Case of Juvenile Diabetic Coma with Insignificant Ketonuria, and with a Large Amount of Acetone in the Spinal Fluid (H. M. Feinblatt, *Arch. Intern. Med.*, October 15, 1924).—In the case of a comatose girl, aged nine years, with the classical symptoms of diabetes mellitus, dating back three weeks, and with a markedly reduced carbon dioxid combining power of the plasma, the urine revealed only a faint trace of acetone and no diacetic acid. Notwithstanding the fact that there was no acetone in the blood, a very large amount of this substance was found in the spinal fluid. Although 110 units of insulin (H. insulin-lily) were administered within a period of twelve hours, there was no reaction at all and the blood sugar level was not in the least affected.

Observations on the Morphology and Life Cycle of Filaria recondita *Grassi* (M. A. Narayan Rao, *Agricultural Research Institute, Pusa. Bulletin*, No. 144, 1923).—Of the numerous dogs brought to the College Hospital, Madras, none was found to harbour microfilaria until December, 1921. Since then seven cases have come under observation, all of them in-patients of the hospital. The microfilaria appeared the same in all cases. Five of the dogs infected were brought to the hospital for other reasons and were kept in contact with the other two cases for periods varying from a fortnight to a month. It is evident, therefore, that the filariasis was acquired after their admission to hospital. The author is of the opinion that the carrier of the disease was culex mosquito.

Abstract.

REPORT OF THE ANKYLOSTOMIASIS INQUIRY IN MADRAS.[1]

By K. S. Mhaskar.

The inquiry was commenced on July 28, 1916, and was closed on January 27, 1923. After studying for a month and a half the methods adopted by Lieut.-Colonel Clayton Lane, I.M.S., in carrying out his ankylostomiasis inquiry in the Darjeeling District, I began work in October, 1916, among the coolies collected at the Nagapatam Emigration Depot. This first portion of the inquiry was completed in March, 1917. The results of the examination of 11,500 coolies showed that 98·6 per cent. of the coolies harbour hookworms.; the infection is endemic; it is universally distributed in the rural areas of the thirteen districts and four States of the southern half of the Presidency. It is slightly less in amount—91·0 per cent.—in the urban areas. The infection is compatible with apparent good health. Sixty and thirty-seven per cent. of the coolies are infected with round-worms and whip-worms respectively. Multiple infections are a common feature.

The chief object of the inquiry at Dindigul and the surrounding villages was to ascertain how far

[1] Abstracted from the *Indian Medical Research Memoirs*, vol. i, No. 1, October, 1924.

propaganda and free medical help can induce the population to adopt sanitary habits; and by endeavouring to rid this area of the infection, to formulate the lines of future field work in the presidency. As no improvement in the sanitary habits of the people was apparent after two years of field campaign and the results were long in coming, the Scientific Advisory Board felt that such a campaign lay outside its scope of research work. This second portion of the inquiry was closed on May 24, 1919. The results of other investigations at Dindigul confirmed the findings of the inquiry at the Negapatam Emigration Depot, and showed that (*a*) the infection is mainly by necators; (*b*) it varies in intensity in the various communities; and (*c*) is on the whole a light one (twenty-two hookworms per person).

The investigations at the Trichinopoly Central Jail were intended to indicate the intensity of the hookworm infection in the districts and the effects of treatment on the general health of the community. Problems in connection with hookworm anthelmintics (in collaboration with Rev. Father J. F. Caius, S.J.) and other problems arising from difficulties experienced in the field were also tackled. After the close of work at Dindigul I was asked to devote myself exclusively to experimental work in this jail. The results of these investigations confirmed the findings of the inquiry at Negapatam Emigration Depot and at Dindigul, showed that the percentage prevalence of *Ankylostomum duodenale* varies between ten and eighty; the highest degree of infection with it, is ten per person in Tanjore district. *A. ceylanicum* infection is absent in southern India. The intensity of hookworm infection varies in the different districts of the presidency; it is highest in Malabar and Tanjore with 103 and 93 hookworms per person respectively; and averages between twenty and forty-one in the districts of Salem, Coimbatore, Trichinopoly, Ramnad, Madura and Tinnevelly. Roundworm and whip-worm infection was found in forty-three and twenty-six per cent. of 6,400 convicts examined. Oxyuris infection was found macroscopically in ninety-nine per cent. of the convicts. Ground-itch and consequent dermatitis are invariably absent. Ankylostomiasis with pronounced anæmia and consequent emaciation is rarely noticed. The presence of occult blood in stools, long after the hookworm infection has been removed, indicates a possible cause of the refractory anæmia of some cases. The hæmoglobin percentage averages 74·0; 91·5 per cent. of the convicts are apparently healthy, the balance of 8·5 per cent. consisting of mild cases of ankylostomiasis. The hæmoglobin percentage bears no clear relationship to the number of hookworms harboured. There is, therefore, no justification for a classification of light, mild and severe infection based on the degree of anæmia. Removal of the infection brings about a gain in body weight. Flies carry with them hookworm ova and larvæ and may thus be the disseminators of the disease. They also carry the round-worm and whip-worm ova. There appears to be some correlation between humidity and intensity of infection—the higher the humidity the greater the infection. The infection is influenced by gross seasonal variations in humidity. Diagnosis of hookworm infection in the host is unreliable if it is based on the presence of occult blood in stools, the degree of anæmia or high œsinophilia percentage. Diagnosis based on the presence of ova and worms in stools is reliable. Of these the first is to be preferred whenever the determination of the degree of the infection is not required. The diagnosis of ova is best made by the "Flotation" method. In the case of post-treatment diagnosis of helminth infections, the diagnosis of ova made after the fourth day of treatment with betanaphthol, thymol, carbon tetrachloride and santonin, is reliable. With chenopodium oil the diagnosis should not be undertaken until the twelfth day of treatment. Hookworm infection is a predisposing factor in bowel complaints and in such generalized infections as influenza. Freedom from infection shortens the period of illness and lessens the average death-rate. Natural elimination of hookworm infection does occur under sanitary conditions; which appreciably lowers the intensity of the infection; such natural elimination is a slow process. It is impossible at present to give an opinion about the duration of life of the hookworm. The variations that occur in the intensity of the infection when the host is kept under sanitary conditions, or when reinfection is influenced by changes in atmospheric humidity, suggest that the duration of life of the worm is probably one that can be counted in months. Natural elimination of hookworm infection (ova and larvæ) in the night-soil occurs within a period of fourteen weeks, and is rapid in every succeeding age-period of the infection. The larvæ do not migrate from the place of development and are commonly found unsheathed in nature. So far as parasitic helminthic infections are concerned, night-soil can safely be used as manure after a period of six months.

The investigations on anthelmintics showed much that was obscure and irrelevant in hookworm treatments.

Current Literature.

THE INDIAN MEDICAL GAZETTE.

Vol. lix, No. 12, December, 1924.

Note on a Herpetomonas Found in the Gut of the Sandfly Phlebotomus Argentipes, *Fed on Kala-azar Patients* (R. Knowles and L. E. Napier).—In ten out of eleven consecutive experiments, female laboratory-bred *P. argentipes*, fed on the parasite-containing blood of kala-azar patients showed typical herpetomonad forms in the fore-gut or mid-gut at the third to the fifth day after the feed. No less than twenty-five out of fifty-six such fed flies showed herpetomonads, and in six instances the infection was a heavy one, although the patient's

blood films had shown only scanty *L. donovani* present. On dissection and examination of 811 control sandflies, including both *P. minutus* and *P. agentipes,* the only natural infections encountered have been once a Rickettsia, three times a Bodo, and once a doubtful spirochæte. Nothing resembling a herpetomonad had been encountered. On dissection and examination of forty-six other control female *P. argentipes* fed upon persons not suffering from kala-azar, no protozoa were found. It is concluded that *L. donovani* passes into its flagellate form in the gut of *P. argentipes* under suitable conditions of atmospheric temperature and humidity. Any further conclusions with regard to the kala-azar transmission problem, however, are at present carefully avoided. What is wanted is further work, which is now in progress, rather than speculation.

Ankylosis of Joints (W. L. Harnett).—Ankylosis of joints are classified into (1) Cases in which the pathological process (disease or injury) started outside the joint; (2) Cases in which the primary process started within the joint, the contracture of surrounding structures being secondary. The comparative rarity of ankylosis as the result of tuberculosis in India is noteworthy. Bony ankylosis and fibrous ankylosis are described and illustrative cases are given.

Canine Leishmaniasis in Bombay (Khan Bahadur C. R. Avari and F. P. Mackie).—A pariah dog was noticed to have a superficial sore near the base of one of its ears. Films were made and leishmania-like parasites were found in fair numbers. The dog was not seen again for some days, and, when caught a week later the small lesion was found to have healed and there only remained a small nodule partly covered by a scab. The nodule was excised and broken up in saline and rubbed into scarifications on the head of a dog and a monkey. No case of leishmanial infection of Indian dogs has been previously recorded, but this case shows that the disease exists in India.

A Note on the Testing of Insulin in India (J. Taylor).—The details of a method used in the standardization of insulin are described. The results of tests of a sample of insulin in tablet form are given, and show that with Indian rabbits a potency approximating to the manufacturers' estimate was obtained. These tests show that although there is a variation in the response of Indian rabbits of mixed breeds, the average result obtained from a series of these rabbits can be relied on. Later, tests have been carried out with further samples of insulin in solution form from English manufacturers which have been found to be of full original potency.

On the Life History of Herpetomonas Muscæ Domesticæ (W. C. Ross and M. Hussain).—The observations carried out show that herpetomonas is a tissue parasite, not an intestinal parasite. The flagellate stage is an ephemeral one, lasting for a period of not more than six hours, and often less. The function of the flagellate stage is one of sexual reproduction. The parasite after entering the fly's intestine in its effective spore stage, penetrates the intestinal wall in the upper part of the intestine, and reaches the loose areolar tissue under the lining membrane of the intestine, in which it divides by fission, multiplies, and grows to maturity. The process of growth in the tissue usually occupys three days, at the end of which period the mature flagellate bores its way back to the lumen of the gut, where a process of sexual conjugation takes place almost at once and cannot usually be observed after a lapse of fifteen minutes after the migration of the parasite. After one or two hours a process of " spore extrusion " takes place, which lasts for about ten minutes. These spores are present in enormous numbers in the lower gut of infected flies, and they have also been observed in N.N.N. cultures from kala-azar cases. The spores undoubtedly constitute the infective stage of the parasite and are resistant to a hostile environment and capable of withstanding exposure. The flagellates themselves have almost all disappeared before reaching the lower gut, and those that remain are almost all degenerate or dead. Fission of flagellates has never been observed during the whole course of these observations.

A Case of Complete Transposition of the Viscera (N. C. Kapur).—A rare case of complete transposition of the viscera is described in a Hindu boy, aged eight years, attending the out-patients' department of the Medical College Hospital for treatment for kala-azar. Palpation of the abdomen revealed a tumor in the right hypochondriac region extending downwards and inwards to about the level of the umbilicus. The liver was felt in the left hypochondrium and was slightly enlarged. He was taken into hospital and X-ray examination showed the heart on the right side of the chest. Skiagrams of the abdomen taken after a bismuth meal showed that the stomach was mainly situated on the right side of the abdomen with its cardiac end under the right cupola of the diaphragm and the duodenale bulb on the left side of the middle line. The cæcum and the ascending colon were found on the left side. The descending and the sigmoid colon were situated on the right side of the abdomen.

Notes on Some Cases of Relapsing Fever (K. V. Raju).—Twenty-nine cases are described of relapsing fever admitted to the Railway Hospital, Hubli, during a local epidemic in August to October 1923. All the patients complained of pains in the back, legs, and all over the body. The disease attacks mostly male adults of the poor and dirty working class. A few cases were seen amongst women, and five cases in children between four and five years old. Many cases could have been mistaken for plague, which was also prevalent at the same time, but were confirmed by diagnosis which showed spirochætes in the blood. The aches and pains persist during the apyrexial period.

Original Communications.

THE INFLUENCE OF CLIMATE AND MALARIA ON YAWS.

By G. C. Ramsay, O.B.E., M.D.Edin., D.T.M.&H.Eng.
Labac Central Hospital, Cachar, Assam.

According to Manson-Bahr in "Manson's Tropical Diseases," "Yaws is practically confined to the tropics and sub-tropics and even there is absent at high altitudes, but owing to its great similarity to syphilis and the extent to which these two diseases overlap, it would appear to be impossible to define its exact limits."

In a description of the diseases of Mongalla Captain Cantlie writes: "The statement that yaws does not occur in the mountains or at a higher level than 800 feet (Castellani and Chalmers, page 1537) is refuted by experience here. Cases are very common from the upland mountainous regions around Torit at levels of 1,000 to 5,000 feet or more above sea level."

My own experience in the Cachar district of Assam is that yaws is more prevalent among the hill tribes than it is among the inhabitants on the plains.

The district of Cachar is a low-lying plain broken up by isolated hillocks and surrounded by ranges of hills varying from 2,000 to 6,000 feet in height.

The climate is characterized by excessive humidity and is markedly oppressive during the monsoon season.

The hottest months are from May to October, with an average mean temperature of about eighty-three degrees, the coldest month being January, with a mean of about sixty-five degrees.

The average rainfall is slightly over 100 inches, with liability to floods from June to October.

The lesions of yaws as seen on the plains and foot-hills during the warm, steamy weather are typically text-book in the primary and secondary stages.

The extra-genital mother yaw, the minute yellow-pointed papular eruption, the furfuraceous desquamation, the warty ring-worm or circinate yaws and the foot lesions (crab yaws) are as typical in Cachar as in other yaw-infected countries.

The effect of climate on these lesions is remarkable: during the cold season on the plains it is a very rare occurrence to see frambœsial patients presenting typical yellow-crusted excrescences, but condylomatous-like lesions in the warm, moist regions of the axilla and between the nates, chronic dermatitis of the hands, desquamating and worm-eaten-like lesions of the soles of the feet and occasionally painful joints all liable to be mistaken as syphilitic are what is usually seen.

As soon as the weather becomes warmer the characteristic yellow-crusted yaws may reappear with, on the advent of the warm, rainy season, the painful plantar lesions.

The same phenomena are evident amongst the surrounding hill tribes, the higher up the hills a yaw-infected person resides the more atypical does his disease become, but when these yaw-infected hill cases come down to reside on the plains or lower ranges of the hills during the warm monsoon season the true nature of their disease is at once apparent by the development of the typical sulphur yellow-crusted excrescence which is the pathognomonic lesion of frambœsia.

The effect of climate giving the lesions of frambœsia a syphilitic appearance is doubtless one of the principal reasons for diagnostic errors in colder latitudes.

Heat and moisture, but principally the former, appear to be the main factors in producing the characteristic lesions of frambœsia, for the cooler the climate the more do yaws and syphilis resemble each other.

It is when we come to the much-debated question of tertiary and quaternary lesions that Cachar apparently differs from yaw-infected regions like Ceylon and Fiji.

In an experience of over 1,000 cases, tertiary lesions, with the exception of chronic dermatitis of the hands and desquamation, exfoliation and pitted worm-eaten-like appearances of the soles of the feet, are comparatively uncommon.

Superadded infection of ulcers with Vincent's bacilli and Schaudinn's spirochætes converting the characteristics of the frambœsial ulcer into those of tropical sloughing phagedæna with occasional serious sequelæ is by no means rare.

Arthritis is seen in about three per cent. of the tertiary cases, the interphalangeal joints of the fingers being most frequently involved, but bone lesions (periostitis) I have only seen in six cases and on two occasions juxta-articular nodules were seen in patients with a history, but no other signs of yaws.

Gangosa, goundou and cases of neuro-frambœsia (?) (Harper, Fiji) have not been seen in this yaw-infected community.

It is a very noticeable fact that in Cachar the tertiary lesions of frambœsia predominate amongst the residents on the cooler slopes of the surrounding hills and not on the warmer malarious plains.

Climate *per se* fails to explain this anomaly, for severe tertiary lesions are, according to Manson-Bahr and Spittel, extremely prevalent in the much warmer climates of Fiji and Ceylon.

When investigating the reasons for the comparative mildness of tertiary syphilis and the absence of para-syphilitic affections in this district, it appeared to me that repeated malarial infection might be the possible explanation, for coolies imported from a non-malarious district usually appear to contract a much more severe type of syphilis than those born and brought up locally.

The question of racial immunity I have carefully considered, but racial immunity apparently varies with the degree of malaria present in a district and the extent to which a person has become immunized by plasmodia.

Theories such as Fournier's and Levaditi and Marie's dermatropic and neurotropic strains of

Spironema pallida fail in my opinion as far as Cachar is concerned, for cases of neuro-syphilis have been contracted in this province by unacclimatized Europeans from apparently dematropic types of Aryan syphilis.

I am well aware that statements are to be found in text-books contrary to my own experience. In the chapter on syphilis in Thomson and Miles' "Manual of Surgery" we read that malarial and other fevers and the conditions attending life in tropical countries from the debility which they cause tend to aggravate and prolong the disease, which then assumes the characters of what has been called malignant syphilis.

I agree if these statements refer to the complications liable to result from superadded secondary sepsis and the organisms of tropical sloughing phagedæna, but as regards severe tertiary lesions (excepting possibly syphilitic aortitis) my experience has been that one sees more in the average out-patient department of an English hospital in a few days than one sees in this district in a year, and my experience is shared not only by those with whom I have discussed this subject in Assam, but in other parts of India.

On searching the literature on frambœsia I was interested to find that my own observations were by no means new, for Powell, in his article on "Yaws in India," which he read before the Dermatological Society of Great Britain and Ireland in 1896, remarks on the effect of pyrexia on frambœsia.

He writes: "One of the most striking characteristics of frambœsia is the disappearance of the eruption during or after a febrile attack. So remarkable is this that the coolies themselves observe it and usually mention the fact when describing the disease to an inquirer. The cases in which malaria is the curative agent are so numerous that I shall only refer to some of the most recent."

He then mentions cases of yaws where frambœsial eruptions subsided after contracting severe remittent fever and again remarks that yaws is most prevalent in gardens where the incidence of malaria is least.

Powell, however, did not confine his belief entirely to malaria, but believed fever due to other causes has also a beneficial effect and in his conclusions on the effect of pyrexia, writes, "The fever to produce satisfactory results should be of some days' duration."

From Powell's observations, from my own investigations from the fact that Fiji is non-malarious, Ceylon (I am informed) very slightly so, from the fact that tertiary yaws in Cachar predominate on the cooler and less malarious hills, it would seem a feasible conclusion that the prevalence and severity of tertiary frambœsial lesions depends upon the absence, incidence and degree of malarial infection in a yaw-infected region.

One naturally asks in what way does malaria protect?

Are antibodies formed by plasmodia against the toxins of spironemata or can these phenomena be explained on the basis of "protein shock therapy?"

"Protein shock" is, I believe the commonly accepted explanation of the Vienna treatment of general paralysis of the insane by plasmodia.

When discussing these observations recently in England, a distinguished London bacteriologist with a tropical experience, made the interesting remark that the rarity of enteric fever amongst indigenous communities in the tropics might possibly be explained on the same basis.

In the meantime I trust that other workers in other yaw-infected regions will publish their unbiased opinions.

THE TREATMENT OF HÆMOGLOBINURIC FEVER WITH CAFFEINE SODIO-BENZOATE.

By A. A. FACIO, M.D.,
AND
M. D. ROJAS, M.D.
United Fruit Company Hospital, Port Limon, Costa Rica, C.A.

IN the symptomatic treatment of hæmoglobinuric fever three prominent conditions must be considered, namely (1) kidney lesions; (2) the cardiac weakness; and (3) the nervous condition. Having in mind these three cardinal points, we have adopted a special line of treatment.

At the present time we are in a position to state that during the past eight months all our hæmoglobinuric fever patients admitted to the hospital, twelve in number, have been successfully cured. It is not our purpose to attribute a specific value to this plan of treatment, but simply to report the result of our experience with these cases. Two of the more severe cases will be fully reported.

There are few conditions in tropical pathology which require greater skill on the part of the physician than the treatment of a case of hæmoglobinuric fever. The basis of the plan of treatment recommended by us consists in the hypodermic administration of caffeine sodio-benzoate. About two years ago one of us was treating a severe case of acute catarrhal jaundice when it was found that cardiac stimulation became necessary, and for this purpose caffeine sodio-benzoate was the stimulant selected. With its administration the circulation of the patient decidedly improved, and what was particularly impressive was the rapidity with which the skin cleared up from its icteroid hue and the bile from the urine. These results appeared on the fourth day following the daily administration of

three grains of caffeine sodio-benzoate hypodermically.

Caffeine sodio-benzoate is an official preparation of the U.S. Pharmacopœia. Physiologically it is not only a general tonic but a cardiac and renal stimulant as well. According to Hare, caffeine increases diuresis by causing dilatation of the renal vessels, particularly in the glomerules, and it further prevents the absorptive action of the tubules. It also exerts a direct stimulating influence on the secretory epithelium of the kidneys. Upon the tissue waste the drug acts as a depressant and therefore conserves tissue.

Recently we have been able to demonstrate experimentally in our laboratory that caffeine sodio-benzoate also possesses anti-hæmolytic properties, which may explain the good results obtained by us in our treatment of hæmoglobinuric fever patients.

The drug is not supposed to supply the normal anti-hæmolytic substance of the blood, if this be at fault in blackwater fever and paroxysmal hæmoglobinuria, but nevertheless it tends to prevent further hæmolysis.

The following technique was used to demonstrate *in vitro* the anti-hæmolytic power of the drug. Eleven separate solutions of caffeine sodio-benzoate were made in isotonic solution of sodium chloride. The degrees of dilution varied in strength from 1 to 20 milligrammes of the drug to each c.c. of sodium chloride solution. Anti-human hæmolytic amboceptor was used in the test, and also complement previously titrated with a 10 per cent. emulsion of human red blood cells. To each test tube was added 1 c.c. of the different strengths of the solution of caffeine sodio-benzoate, 1 unit each of amboceptor and of complement, and 0·1 of the suspension of red blood cells. Sufficient saline solution was then added to make 3 c.c. in each test tube. Two control test tubes were prepared in the same way, omitting only the caffeine sodio-benzoate, and all were incubated in a water bath at 37½° C. for three hours. The results are given in the following table:—

Test tubes	Strength of sol. caff. and sod.-benzoate	Results
1 (Control)	0·000	Total hæmolysis
2	0·001	Medium hæmolysis
3	0·002	,, ,,
4	0·003	,, ,,
5	0·004	,, ,,
6	0·005	,, ,,
7	0·006	Slight ,,
8	0·007	,, ,,
9	0·008	,, ,,
10	0·009	No apparent hæmolysis
11	0·010	,, ,,
12	0·020	No hæmolysis at all
13 (Control)	0·000	Total hæmolysis

It will be noted that tubes 1 and 13 were the controls, and the hæmolysis was complete; tubes 2 to 6 showed medium hæmolysis; tubes 7 to 9 slight hæmolysis; tubes 11 and 12 no hæmolysis. Similar experiments were made with solutions of sodium benzoate and plain caffeine respectively, and the results were the same as those produced by the combination of caffeine sodio-benzoate. It appears, therefore, that both sodio-benzoate and caffeine possess the anti-hæmolytic properties. Clinically we have observed that the combination of these two drugs yields better results than the administration of either one separately, and hence we have adopted for treatment the caffeine sodio-benzoate.

We have a complete record of twelve cases of hæmoglobinuric fever; five of them were true blackwater fever and the remaining seven were probably cases of quinine hæmoglobinuria. The following are reports of two severe cases of blackwater fever which terminated in recovery:—

Case No. 1.—B. A., Costa Rican labourer, 23 years of age, had been suffering off and on with attacks of chills and fever for three months previous to his admission to the hospital. During this time he had been taking 10 grains of quinine sulphate three times daily. He was admitted to the hospital at 4 p.m. on July 7, 1924, when he was suffering with a chill which lasted 45 minutes. He stated that he had had persistent vomiting and had passed bloody urine for the past 14 hours. The skin and sclera were very yellow. The pulse rate, 127 per minute, was soft and irregular, respirations 34, and temperature 104° F. in the axilla. The lungs were negative but the liver and spleen were palpable. Hæmoglobin was 30 per cent. and the red cell count 2,100,000.

An enteroclysis with glucose and sodium bicarbonate was prescribed, and he was given a hypodermic injection of caffeine sodio-benzoate. His nourishment was restricted to iced lemonade. Vomiting was persistent and the stomach contents bile-stained. At 7 p.m. the pulse rate and temperature remained about the same, and he passed 275 c.c. of port wine-coloured urine. He was very restless and a quarter of a grain of morphine was given, after which the vomiting ceased, and the patient rested until 5 a.m. the next morning. At 8 a.m., July 8, temperature was 103° F., pulse 118, and he passed 300 c.c. of dark red urine. Three grains of caffeine sodio-benzoate were given hypodermically and the rectal instillations continued. At 7 p.m. that day his temperature rose to 104½° F. and the pulse rate to 142. He complained of pain in the back and severe headache and no urine had been voided for nine hours. During the night he had had two bile-stained stools. The caffeine sodio-benzoate hypodermically was repeated. At 8 p.m. the temperature dropped to 100° F., and he passed 600 c.c. of yellow clouded urine. His condition gradually improved, and on the morning of the 12th his temperature became normal and the urine was of a dark yellow colour.

The injections of caffeine sodio-benzoate were continued once a day until the 16th, on which date the urine was clear and the icterus of the skin had disappeared. The patient was then ordered quinine hydrochloride by mouth, grains 10, three times daily. He was discharged from the hospital in good condition on July 27.

Case No. 2.—R. G., age 38, Costa Rican labourer, was admitted to the hospital on August

29, 1924, at 8 a.m. He was in such a weakened condition and confused state of mind that no history of the illness could be obtained. The temperature was 103° F. in the axilla, pulse 127, and respirations 27. The skin and conjunctiva were of a deep lemon colour, his breath foul, tongue heavily coated and of a dark yellowish hue. The heart sounds were weak and irregular, the lungs apparently normal, and the spleen could be palpated five fingers breadth below the costal margin. The liver was somewhat enlarged and sensitive on palpation. Hiccough and vomiting were very persistent and the patient's clothing was stained with bloody urine. The blood examination proved negative for parasites, the hæmoglobin showed 20 per cent., and the red cell count 2,250,000. Three grains of caffeine sodio-benzoate were given hypodermically and a cleansing enema ordered, which resulted in a large quantity of hard bile-stained fæcal matter. Rectal instillations with glucose and sodium bicarbonate were begun.

At 11 p.m. that night the patient voided 40 c.c. of black urine. The vomiting and hiccoughs persisted until 3 a.m. the following morning, when the patient fell asleep. In the morning the patient was almost comatose, though the temperature was only 99½° F. An intravenous injection of three grains of caffeine sodio-benzoate was given at 9.45 a.m. The patient then voided 185 c.c. of port-wine coloured urine, his mind cleared, and he complained of thirst and severe headache. Iced lemonade was ordered but was not retained. An ice bag was applied to the abdomen, and subsequently lemonade and white rock water were given and partly retained. On the next day the temperature became normal. At 9 a.m. he voided 500 c.c. of dark red urine, hiccoughs and vomiting had ceased, patient felt hungry and soft diet was ordered. He continued in this condition until September 3, passing dark-coloured urine, and complained occasionally of headaches. On September 4 at 1 p.m. he had a chill, the temperature rose to 104° F., and he voided 250 c.c. of dark red urine. Tertian malaria parasites were found in the blood at this time. The previous treatment was again instituted, and the following day, September 5, at 6 a.m., the temperature became normal and he voided 200 c.c. of clear urine. On this date the patient was ordered quinine hydrochloride, 10 grains three times daily, by mouth, and the hypodermic of three grains of caffeine and sodio-benzoate were continued daily until September 9, at which time the skin had lost its icteroid colour. He was discharged in good condition on September 12.

At the beginning of our observations we gave the caffeine and sodium-benzoate intravenously, but patients always complained of severe headache immediately after the injection, and it was then decided to administer it intramuscularly except in depressed cases with weak circulation, when it was given intravenously.

The following is the routine method we have adopted in treating these cases. This of course may be varied to meet the indications of each individual. No quinine is to be given unless the parasites are found and then only after the patient's urine has become normal. The temperature is controlled by cold sponges and the application of an ice cap to the head. Purgatives are not advisable during the acute attack, and cleansing enemas are to be preferred. These should be followed by an enteroclysis of a solution containing 2 per cent. of sodium bicarbonate and 1 per cent. of glucose, administered very slowly (from 40 to 50 drops per minute). This is kept up for three hours at a time, with equal intervals of rest, until the urine is voided more or less normally as to quantity and quality. Caffeine sodio-benzoate (U.S.P.), grains 3, is given intramuscularly twice daily; the first injection early in the morning and the second at 4 p.m., so that it will interfere with sleep as little as possible. If after the seventh day the patient still remains much jaundiced, the caffeine sodio-benzoate can be continued once daily until the twelfth day.

We have found that vomiting and hiccough could best be controlled by a single hypodermic injection of morphine and atropine, which also acts as a nerve sedative. Thirst is generally controlled by the enteroclysis, but in very severe cases a hypodermoclysis is recommended. During the first three days of the attack the diet is restricted to liquid gelatine, soda water, lemonade, or plain Vichy water. When the vomiting ceases milk may be added to the diet.

THE ÆTIOLOGY OF BLACKWATER FEVER.[1]

By W. M. Hewetson, M.B., D.P.H.
Government Medical Officer, Sinoia, S. Rhodesia.

What, then, do we know of the particular relation of light to hæmoglobin? Space only allows a scanty account.

Chemically.—Since the work of Wilstatter and Stoll was confirmed, it is now established that chlorophyll and hæmoglobin are closely related—their enormous molecules having as a common base the four-pyrrol ring combination—ætio-porphyrin—a remarkable chemical structure containing by weight 372 parts of carbon to 92 of hydrogen and nitrogen. In chlorophyll one atom of magnesium gives it its colour and unique endowment for transforming light into chemical energy. In hæmoglobin an atom of iron likewise endows it with its specific power of absorbing and releasing oxygen, also a primary life endowment for animal organisms.

Evolutionally.—The work of Fulton on "Anima Chlorophyll" [11], together with the evidence from other researches collected by him, shows a very strong probability that hæmoglobin originated from chlorophyll and was gradually adapted in the course of evolution to its specific purpose in the higher

[1] Continued from The Journal of Tropical Medicine and Hygiene, December 15, 1924, pp. 333-336.

orders, and, as we have seen, is at its highest in the mammalia.

Physiologically.—Though diagrams showing the portions of the visible spectrum absorbed by hæmoglobin, oxy and reduced, have been for many years included in the textbooks, no study had up till recently been directed to discovering the effects of light so absorbed. This though we have had from the time when we began to observe frequent ocular and personal demonstration of the effects of different exposures to light upon the skin—an effect which contains an undeniable suggestion. Grotthus's law states that "light must be absorbed in order to produce an effect," so light which is absorbed must produce an effect. To quote Bayliss: "Something must happen to the substance, it may be merely warmed, or other forms of energy—chemical, electrical, and so on—make their appearance."

Light Converted to Heat by Blood Absorption.

It is now accepted that while ultra-violet rays from the sun do not penetrate the skin and reach the blood, the longer visible ones do. Gauvain states that the fact has been discovered by Sonne that "the visible rays which are absorbed by the blood are converted to heat." Accepting this, there is nothing to show that it is the whole story or the end of the story as regards heat. Leonard Hill says: "The luminous rays penetrate and are absorbed by the blood and there changed into heat rays, and *probably also effecting changes of a nature as yet unknown*" [12].

In September, 1923, in recording the temperatures of ten pedigree Friesland cattle in this district preparatory to making the tuberculin test, an interesting point was noted and casually mentioned by a veterinary friend. I asked for the figures and a complete table was submitted to me covering five days, two pre- and three post-test. Six of the animals were kept inside during the first day of the pre-test period, while four were not, but were allowed to graze near the homestead. They were not chased and heated by exercise when brought in for temperaturing, a point I specially inquired about. The temperatures of all were taken at 8 a.m., noon, 3 p.m., 5 p.m., and 8 p.m. on September 9. The noon, 3 p.m., and 5 p.m. temperatures of the two lots differed considerably, that of those exposed to the sun being much higher, and as some alarm was felt they were kept inside the following day, with the result that their temperatures showed no difference to that of the others. The temperatures of September 9, in the lot exposed to the sun, at noon, 3 p.m. and 5 p.m., averaged 103·3, that of those kept inside 100·3.

The extent of the rise in temperature in the sun was hardly credible, and naturally I examined the whole table closely, and it was quite consistent otherwise. How is such a rise in thick-skinned bovines to be explained? Breinl found rectal temperatures in man, on walking in the sun, of over 103° F. We know that the great majority of chemical reactions are accelerated by heat, and that there is for most an optimum temperature. "In chemical action there is both absorption and liberation of heat" (Jago).

My experience of the very marked benefits of hospitalization of patients in this country leads me to attribute this to the exclusion of light—and heat—along with the direct treatment received by quinine, and the rest in bed.

For the last three years I have been preaching the necessity of wearing large tinted spectacles of a greenish yellow colour, because I know from experience how enormously they save my nervous energy. Many people have followed my advice and adopted the habit. With remarkable consistency after a first experience, the remark has been made, entirely spontaneously, "You don't feel the heat of the sun so much when wearing them." Remembering the retinal blood sponge, this is not to be wondered at.

An amateur photographic friend tells me that he has tested these glasses, and found that it took 5½ times as long with one side of such spectacles and six times with the other to take a print compared with the ordinary method. I have not confirmed this, but the difference he makes is striking. Assuming that he is only to some extent correct, it is a fact which is easily verifiable that with a reduction of light the sharpness of definition of objects (with plain coloured glass) is *increased* considerably when wearing them in direct sunlight here.

I mention such facts in order to draw particular attention to the eye route. There is the natural light-curtain, the iris, responding continually and insensibly to light variations. I have been amused often to watch the unconscious reflex screwing of the eyebrows and puckering of the skin round the eye in persons who say the light does not worry them and contrasted it with the effect when wearing these chlorophyll-tinted glasses. They usually admit that they feel they "can open their eyes better" then.

Other Effects of Light Absorption.

In addition to its conversion to heat, however, Bayliss, quoting various workers, shows that "light can be stored by Hb": "Hartridge and Hill calculate from . . . what this amount is, and find that it is very considerable, in fact greater than that of any similar photo-chemical reaction with the exception of that of the chlorophyll system." "They find that the infra-red absorption is considerable in this region, which has great radiation energy."

The words of this great master, who has just passed—Sir William Bayliss—are: "It is perfectly clear that light acting on the skin produces something which must pass into the blood and be carried through the whole body" [13].

If the generalization of the liver cells representing green leaf cells be approximately correct, then looking to the synthesis of carbohydrates by the latter and the activity of light absorption by hæmoglobin, taking a very long shot one might suggest that this

light absorbed may have to do with the glycogenic function of the liver.

This is by the way, however.

Regarding the similarities in principle of the action of various lengths of electro-magnetic rays I must take the work on this point as read, it is impossible to detail it here. If the action of X-rays is indeed comparable but of course in degree infinitely greater and more rapid than that of sunlight, then the remarks by Mottram of the Research Department of the Radium Institute are *apropos*: "Many attempts have been made to detect chemical changes in irradiated tissues and in the various substances of which they are composed; in the vast majority of cases no chemical change has been detected, or only insignificant alterations. In contrast to these negative results, the evidence of physical changes is abundant; I refer more particularly to alterations in colloidal state . . . I refer to alterations in permeability of membranes and to the precipitation of colloidal solutions and suspensions" [28].

Clinical Histories Regarding Light Exposure.

At this point I desire to quote, besides those of onset in my preceding paper on blackwater, some other cases which, borne in mind, form useful pegs for the consideration of light energy acting, either slowly, as a photo-thermal or photo-chemical reaction, and secondly, by means of an intermediary substance with peculiar catalytic-like powers, acting with great rapidity.

The case described as the worst case of blackwater I ever saw, of bronze hue when first seen, was a man, a farmer, of strong physique, about 30 years of age, on the day previous to being taken ill he had been exposed to the November sun (Dec. 21, midsummer), for 14 hours sitting on a maize planter. Extra exposure to sun has occurred in many cases of blackwater just before onset. This case was one of those which first led me definitely to suspect some light reaction. Jackson quotes two remarkable cases in which the blackwater developed on the very day of return to the endemic area; one of these had scarcely reached it. He states that these could be multiplied from the practices of medical officers working in highly malarial (? endemic blackwater) districts.

A remarkable case was that of Mrs. V., who left the Shamva Mine, Southern Rhodesia, for a visit to England. Her stay there lasted four months, during which time she was in good health, but on her arrival in Salisbury after a train journey of four days from Cape Town, *en route* for Shamva, she developed blackwater. (Shamva district is a valley conforming to the type where the malignant tertian parasite is rife, 3,200 feet above sea-level.)

Another case illustrating this was that of T. H., history as follows: Five years in Nyasaland, which is highly malarious; furlough for a year in the Cape, a non-malarious territory as before stated, good health; return to Nyasaland; on the day of arrival blackwater, and death three days later. In these cases the blackwater developed after a prolonged residence in a non-malarious country, as even T. H. had not returned to Nyasaland sufficiently long to allow of an incubation period of blackwater [14].

Such cases, excluding the possibility of being due to a reinfection, as they do, appear to suggest a climatic factor. What influence, climatic and dynamic, it would seem, can that be? It would appear in Jackson's two cases to be an immediate reaction, yet dependent on previous residence also.

It is well known that blackwater occurs in persons from endemic areas on a change of even a short distance, especially if the new locality be cooler to the extent of being bracing only. Cases occur frequently on arrival in England, generally within a week. Manson saw a case occurring 9½ months after leaving Africa, and I have had a verbal report of one occurring 18 months after leaving Mesopotamia. Such cases as these could not be due to a photo-chemical reaction due to "light storage." The erratic onset of blackwater bears some similarity to the onset of hæmatoporphyrinuria in persons who have been taking sulphonal and the delayed jaundice in those exposed to other chemicals (Willcox). "The patients have often taken the drug (sulphonal) for months or years with apparent impunity prior to the development of hæmatoporphyrinuria" (Garrod).

Racial Immunity or Merely Colour.

There is the susceptibility of whites to blackwater and the immunity, not absolute, of negroes. Two cases in negroes have occurred in my experience. One was fatal and I made a post-mortem examination. All the tissues were saffron-tinted and the appearances typical. Mulattoes, Eurasians and Eurafricans, Chinese, Greeks, &c., are subject, though possibly to a less degree than blondes.

We have a check on this "racial immunity" statement. For many years I have wondered why the townsman, or modern cave-dweller, in his office from 9 a.m. till 4 p.m. during the period of strong sun, was immune also, to the same degree almost as the negro. His race and colour of skin are the same as those of his country brother, who, exposed to fierce light, gets blackwater. True, the latter also gets malaria to a greater degree, but the discordance is not of the absolute character which occurs with blackwater.

Towns often swarm with anophelines. Grassi [15] has pointed out recently at Rome two definite incongruities between the incidence of malaria and the opportunities of infection. Why do also the vast majority of attacks of malaria—I am speaking from my own experience—come on between the hours of 11 a.m. and 4 p.m.? The type here is, of course, the subtertian. There are other questions also to be asked, but space forbids. Hess has shown that there is a negro susceptibility to rickets. "In New York the milk for the negro babies was supplied from the same dairies as the milk for the white children, yet the negroes developed rickets out of all proportion to the others" [16]. By means of

experiments on white and black rats and local coverings in the human patients, he showed that the action of light was withheld by black colour.

"Light-Receptors."

Retinal.—Let us turn again to some more general evidence. It can hardly be necessary to call attention to the light-receptors which must be assumed in the retinal function. We have also heat receptors in the skin which quickly warn us of the approach of excess. The functioning of the retina is so automatic that it only warns us of blinding glare—it takes no account which can be sensed of the effect of continuous absorption of light of widely varying intensity. The iris light curtain already mentioned is also automatic, but in such intensities as here it is probably inadequate. The negro's iris is so dark that it is difficult to distinguish it from the pupil. Even plants use only a fraction of direct sunlight, the majority about ten or twelve per cent. only, rising as high as 35 per cent. as a maximum in *Helianthus annus* and the cotton plant [17]. Everyone knows how plants wilt in the hottest hours of the day—the chloroplasts retreat to the side of the cell further from the sun.

Light Receptors—Cutaneous—in Lower Orders and (?) in Man.—Jelly fish, certain fishes, amphibians, and the chameleon reptile possess a "chromatic function" by which they quickly adapt their own colour scheme to that of their surroundings. The skin colour of the human race varies, being broadly darker towards the equator. Exceptions to the rule have been adduced to show that they upset the *à priori* suggestion of protection from the actinic rays. Closer examination, however, of the circumstances upholds the principle if not the first and more crude generality.

In speaking of actinic rays it is true that much the most chemically active are those beyond the visible spectrum—known as ultra-violet—but it must be remembered that the whole range of the spectrum, including the infra-red, is, though to a less degree, chemically active. (See diagrams in textbooks.) At the Royal Society in 1922 "Dr. Trevan gave an account of experiments on colour changes in frogs under the action of light. It was easy to turn a frog from dark black to yellow in the course of a few hours. The frog that had been exposed to light was definitely more susceptible to digitalis than the frog which had been kept in the dark. Frogs which had been kept in the light were more susceptible also to quinine. It was possible that in the mammal there was some such mechanism as that which produced colour changes in the frog; *there might be nervous receptors in the skin as well as in the eye,* which were affected by light, and which influenced in some way the metabolism of the whole animal" [18].

Speaking from clinical experience in England and this country, I had been definitely convinced long before I saw this statement that digitalis has a more potent and appreciable effect here.

Photo-Dynamic Sensitization.

We now pass from a consideration of the general effects of light to that of a special action on living tissues when along with it is exhibited some sensitizing substance in quite insignificant quantity. Such substances belong generally to the class possessing the physical property of fluorescenee, though not all fluorescent substances possess this special sensitizing power.

Experiments by Hertal (confirmed by many others) show that no change occurred in bacteria in half-an-hour when exposed to light waves from near the middle of the spectrum, 518 microns, but when a fluorescent substance such as eosin is added which has its maximum absorption band in this region, the bacteria were dead in seventy—ninety seconds. The eosin had no action in itself.

"Light which has no action in itself on infusoria bacteria and blood produces the effect of ultra-violet light when certain dyestuffs are present." Ultra-violet light of 280 microns killed the bacteria in sixty seconds. Light of 448 microns in which eosin has nc absorption band had no effect on them with the presence of eosin or without. [19].

(The visible spectrum ends at about 400 microns.)

A certain sensitizing substance, or rather a group of such, all related, with widely varying results, has been discovered in the human organism, in the urine and blood, viz., hæmatoporphyrin, but before referring in detail to the available knowledge on this I should like to mention some clinical points about sensitization.

Herpes Labialis *vel* Malariæ.

In malaria there is, especially in the autumn months, when it and blackwater are most rife, a pathognomonic herpetic eruption round the mouth, most generally affecting the upper lip. A layman seeing this on a friend remarks: "You've had fever?" They are commonly known as "fever blisters." It has occurred to me that this might indicate a sensitization to light. A similar eruption occurs in other fevers, though not so marked and constant as in malaria, but in these also some pathologic sensitizing product may be present.

"With the possible exception of pneumonia, herpes is seen more frequently in malaria than in any other disease. Its commonest sites are the lips and nose, but it may appear elsewhere. It is not nearly so common in the negro as in the white. Urticaria and erythema are sometimes observed" [20].

Barber, discussing protein sensitization in its relation to certain skin diseases, remarks: "Herpes catarrhalis is of course a frequent symptom of the common cold, pneumonia and cerebro-spinal meningitis, but may in certain people invariably result from the eating of a certain article of food such as cheese" [21].

Earlier in the same paper Barber quotes McBride and Schorer (*Arch. of Med.*) in a paper on "Erythematous and urticarial eruptions resulting from sensitization to certain foods," who "Make the

interesting observation that animal intestinal parasites are capable of rendering certain foods toxic—for instance, eggs—and that destruction of the parasites may produce immunity to the foods in question." This forms a good example of the oak and mistletoe simile. The protein sensitization explanation of the nature of certain skin eruptions, including some forms of eczema, is accepted, no other factor being called into account, but mark the following: "It is difficult to explain susceptibility towards non-protein drugs such as quinine or towards external irritants on the grounds of anaphylactic sensitization, and yet the accompanying phenomena are often so similar as to suggest that they are closely related" [21].

I have seen the most violent urticaria follow the taking of quinine by mouth. It did not occur on intra-muscular injection. A personal experience I have had in common with many others, and one which we do not repeat, is that on taking five grains about 10 a.m. and exposing oneself to the sun afterwards one quickly becomes groggy in the legs, giddy and may almost collapse. The standard prophylactic is "five grains of quinine *at night*."

The discussion on "cutaneous sensitization" at the 1921 [22] annual meeting opened by Cranston Low ended on the note of the importance of light, and this was before heliotherapy was so widely discussed as it is to-day.

Kenneth Wills mentioned an erythema of old people "in which there was another factor besides cutaneous sensitization—namely, light." Barber agreed with him that light was an important factor in the determination of lupus erythematosus, and described another type in which sensitization came on in adult life: "In all the patients there was marked excess of indican in the urine and in most of them the reaction was intense." He had never found hæmatoporphyrin. Low in reply quoted an article in which was described "fago pyrismus," or buckwheat poisoning. "Animals fed on buckwheat and exposed to light developed acute dermatitis on white parts only, not on black. In buckwheat there was a substance which very closely resembled hæmatoporphyrin."

(To be continued.)

On the Human Liver-Fluke in Korea and a note on the Immediate Hosts of Liver-Fluke in China (Harujiro Kobayashi, *Mitt. der medizinischen Hockschure zu Keijo*, 1924).—In Korea human liver-fluke is a common disease, especially in the southern part of the peninsula. *Lutreola sibiricus* was found to to be a natural host of *Clonorchis sinensis*. The first intermediate host of *C. sinensis*, *Bulimu striatulus japonicus*, is present in various parts of Korea, where liver-fluke disease exists. Several species of cyprinoid fishes in Korea were found to be infested by the encysted larvæ of *C. sinensis*, also a number of fishes of China. Human liver-flukes in Korea are of one species, i.e., *C. sinensis*, as is the case in Japan proper.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—**All literary communications should be addressed to the Editors.**

4.—**All business communications and payments, either of subscriptions or advertisements, should be sent to the Publishers of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE.** Cheques to be crossed The National Provincial Bank Ltd.

5.—**The Subscription, which is Thirty Shillings per annum, may commence at any time, and is payable in advance.**

6.—**Change of address should be promptly notified.**

7.—**Non-receipt of copies of the Journal should be notified to the Publishers.**

8.—**The Journal will be issued about the first and fifteenth of every month.**

TO CORRESPONDENTS.

9.—**Manuscripts if not accepted will be returned.**

10.—**As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.**

11.—**To ensure accuracy in printing it is specially requested that all communications should be written clearly.**

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—**Authors of original communications are entitled to 25 reprints, free of charge.**

14.—**Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.**

15.—**Correspondents should look for replies under the heading "Answers to Correspondents."**

REPRINTS.

Contributors of Original Articles will be supplied with reprints if the order for these, with remittance, is given when MS. is sent in. The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 " "	1	3	3
200 " "	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 " " "	2	6	0
200 " " "	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

A WHITE AUSTRALIA: IS IT A POSSIBILITY?

By SYDNEY J. SKERTCHLEY, J.P.

(*Continued from page* 32.)

CHAPTER VII.

The Anthropology of the Roman Empire.

96. We stated in the last article that the Roman Empire was practically confined to the area in which the Dark Whites were indigenous, and that

while the Dark Whites were incapable of establishing themselves in the home of the Fair Whites, those more vigorous people conquered, and for centuries held the whole of Europe, and the greater part of Roman Africa. Lastly, that over the whole of this great area the Fair Whites either completely died out, or are being steadily replaced by the native Dark Whites. These are such momentous statements and have been so overlooked by historians and politicians, that it will be wise to make the matter perfectly clear.

97. Take the first point. Look at the extent of the Roman Empire as it existed at the beginning of our era. The Eastern dominions in Asia do not concern our immediate object, but they tell the same story, for the Romans never established themselves in the region of the Yellow Race.

98. The northern boundary of the Roman Empire is a line drawn from the Roman wall in Britain south-east to the Rhine, thence down that river to the upper Danube, which stream it follows for a while, and then makes a wide detour northward, so as to embrace the area between the rivers Theiss and Dneister, and the Carpathian Mountains, a compact area now forming part of Hungary, and all of Roumania. This was the portion which became the province of Dacia, and was only held for 164 years, from A.D. 106 to 267. This shows the greatest extent of the Roman sway in Europe.

99. In some respects the Roman Empire was held together much as we now hold India, by force of arms, by the administration of strict and sympathetic justice, and the maintenance of civil rights including above all the rights of property. The parallel must not be strained, for the Roman Empire was an undivided area that had been accreted around Rome, and was in consequence much easier to administer than the scattered dominions of King Edward.

100. Now consider the nature of the army that sustained the power. At its greatest strength it probably never exceeded half a million all told, a number that to-day even the populace of ancient Dacia far outnumbers.

101. It was made up of two divisions, the legions and the auxiliaries; each legion having its attached auxiliary, about equal in number. The legions were, at first, exclusively confined to Roman soldiery, not necessarily of Roman birth, but of Roman citizenship. For our purpose we will assume they were all of the Dark White race.

102. The auxiliaries, on the other hand, were all foreigners, and though many were of the Dark Race the majority were selected from the more hardy and vigorous Fair Whites of the strenuous north. We are expressly told they were preferred, and moreover, some of them were infused into the legions themselves. Mark this difference. We stiffen our Indian army with a few Fair Whites, so did the Romans; but in our case it is the conqueror that stiffens, with the Romans it was the vanquished.

103. The Fair Whites of the Roman army were at first pressed men, soon they became mercenaries, and finally masters. It is hard for those who are unacquainted with the story of the Roman Empire to realize how much it owed its power to the Fair Whites. Not only did they supply troops, but leaders, alike in the field and the Senate, and if they did not actually give a Cæsar to the Empire it was because they preferred not to adopt a title derived from a Roman family, and became kings in their own right.

104. We are apt, too, to overestimate the size of the Empire. We mentally measure it by the magnitude of its deeds, and the supreme value of its civilizing powers. In point of geographical fact, at its widest span it was little more than half the size of Australia—say as large as Queensland and West Australia combined. It was held by forty-six legions, and how powerful were the Fair Whites upon its frontiers is proved by the necessity of maintaining half this number on the Rhine-Danube border.

105. Look again at the map. A very startling fact comes out. The Romans never got anywhere near the motherland of the Fair Whites. It was always the Fair Whites who in their southerly advance fell upon the northern frontier of the Empire. They rolled Rome back; Rome never infringed an inch on the Fair White soil.

106. So powerful did the Fair Whites become, that by about the end of the fifth century all Europe was in their hands, save Greece. The old Roman Empire was no more. Odoacer the Ostrogoth was King of Italy, and the Eastern Empire was Roman only in name, and was hastening to decay.

107. I have shown the areas ruled by the Fair Whites and Dark Whites. It will be seen that the latter have lost everything, save in the extreme south-east. Even North Africa is under a Fair White king. Surely, never in the world's history has there been such a complete overmastering of one race by another—the Dark White has practically gone under. The Fair White kingdoms on foreign soil are the Anglo-Saxons, the Ripuarian and Salian Franks, the Visigoths and Ostrogoths, the Suevi, the Vandals, the Burgundians, the Lombards, and the Gepidæ. Not a single one has lasted; their names are but shadows and over the greater part of the area the blood has faded as completely as the fame.

108. The conclusion is incontrovertible. *The Fair Whites have never been conquered on their own soil (save by themselves); they have been conquerors everywhere else, but have gone down surely and steadily before those ethnic laws which seem to have set a bound to race extension.* "Stat nominis umbra" may be written over half Europe.

Spain and Portugal.

109. The darkness of the Dark Ages fades into twilight at either end, but we shall not be far wrong if we make it begin with the fall of the Roman Empire, A.D. 476, and end with the fall of the Eastern Empire in 1453. Henry of Portugal, surnamed the Navigator, son (let us always remem-

ber) of Queen Philippa, daughter of old John o' Gaunt, had fixed his observatory at Sagres, the westernmost point of the continent, where the deep waters of the Atlantic allow the Australian liners to pass close in and view the fine cliffs of St. Vincent of naval fame. The fall of Rome had caused the closing of learning to Europe, and now half a millennium had passed, and Constantinople—the new Rome—has fallen, too, and has let the flood of learning loose upon the darkness of monkish superstition. Henry has sent his trader-discoverers along the African coasts, the Cape of Good Hope is found, and Columbus is back again with a New World as his reward, and all in the space of a few years. From this epoch modern geography dates. The Dark Whites were to have a fresh trial, but this time their conquests were to be in far lands —it was the era of maritime discovery.

110. This history is so close to us as to need no epitome. But what have been the results; has the darker race been more successful in the warmer regions more akin to his own than in the chill north? Let us take the case of Spain first. Everybody knows the story of Cortez and Pizarro, and the band of Conquistadores who made Spain rich and glorious, who poured the riches of a virgin continent into the coffers of Castille. Let us seek their descendants.

111. Come to California, whose splendid capital, San Francisco, looks out, across Saucalito, through the Golden Gate into the Pacific, first gazed upon by Bilbao. Where is Spain? Fifty years ago, when Dana wrote his famous "Two Years Before the Mast" it was still Spanish, but the Spaniard was a wreck, and the country going fast to decay. Dana scraped hides on the bare ground where now million-dollar buildings stand. In three hundred years the Spaniard had done nothing but build a few missions, and lead the lazy life of a rancher. Thirty years ago I sought in vain to find a Spaniard or a real relic of his presence. I found a fragment of an adobe wall (Indian, not Spanish) where the Mission Dolores preserves its old name, and this was all.

112. Try Mexico. Listen to what my friend, Dr. E. B. Tylor wrote in 1857 or thereabouts. Do not miss the point that the Spaniard never discovered the mineral wealth of California; neither did he in Mexico. The Aztecs had done that for him. So here, with wealth ready to hand, the Spaniard built, or altered to his taste, fine cities, and impressed his language upon the people; and here he is to-day.

113. After illustrating the deplorable state of the Government, he proceeds: "The Indians have been of late years becoming aware that the government of the country is quite rotten and powerless, and that in their own districts at least, the power is very much in their own hands, for the very few scattered whites could offer but slight resistance. The doctrine of 'America for the Americans' is rapidly spreading among them." The learned anthropologist predicted that sooner or later the Spanish rule must cease, and though he saw the difficulties in the way, he thought the United States would be compelled to come on the scene.

114. What has happened is curiously instructive. Mexico is still an autonomous republic, but since the stoppage of a regular supply of fresh blood from Spain, consequent upon their separation in 1824, the Spanish blood has been dying out, and the Indian gathering strength till now it is not the Spaniard but the native who is the real power, and the owner of the principal wealth.

115. The tropical republics, as all know, are a by-word; Venezuela has made herself notorious of late by the culmination of a long innings of rascality. In the West Indies, Spain to-day holds nothing. Of Spanish South America I can say nothing from personal knowledge, but if one takes the summary of my friend, Prof. G. G. Chisholm, the eminent geographor, and president of the Geographical Section of the British Association, it will be seen that, at any rate in South America, the Dark Whites have not peopled, though they may hold the territory. He writes: "The enervating effect of the climate in the tropical portion of the continent has retarded the development of the immense resources of the land, notwithstanding the facilities presented by the navigable streams; and it is believed by some that Chinese labour alone can bring wealth and prosperity to these burning lands. In spite of the fact that the land has been so long in the hands of Europeans, it is said that there are not, in all South America, at the present day, 100 miles of what Europeans would call roads."

116. Now the area of South America is about double that of Europe, or say four times that of Australia, yet the total population is only thirty-four millions, or one-eleventh that of Europe. Of these, only about 680,000 are whites, chiefly Spanish and Portuguese.

117. As South America was colonized before North America, and has been under European control for over four hundred years, and has produced colossal wealth for the stranger, and yet has not been able to produce a white population much larger than that of Queensland, it is quite clear that in this new world even the Dark Whites have not been acclimatized. We must also remember that much of the most populous parts, along the Andes, enjoy a temperate climate, in spite of their geographical position. Further, we must bear in mind that the great wealth has been won largely by the enterprise of the Fair Whites, who are only temporary sojourners, and that most of the Dark Whites who have shown commercial energy have been direct immigrants from Spain and Portugal, not descendants of the conquerors.

118. Let us now turn to the Old World, of which I can speak from long personal experience. One of the oldest European settlements in the Far East is the holy city of Macao. Founded in 1557, it soon had a Portuguese population of over 20,000, and was dignified by the title of Cidade do Santo Nome de Deos en China, City of the Holy Name of God in China. Here their great poet, Camoens, wrote his classic epic, the Lusiad. It is now one

of the saddest places on earth, at least to those who ponder over the great things Portugal did for the Far East. The cathedral, burned in 1835, is a ruin, typical of the people. The beautiful language has degraded into a clipped patois; the Macaoese, less than 9,000 in number, are undersized, ill-nourished, and of a low intellectual grade, retaining nothing of their famous nationality but their pride and noble names. They half starve themselves to make a brave show on the side-walk: live by competing with the Chinese for poor clerkships in Hong-Kong, where they never rise, and are mistrusted; and its once famous city depends upon its gambling houses, drawing clients from outside, for the Macaoese are too poor to be of financial support, sportsmen though they be. They are stunted in growth, and often deformed, so that if you meet a well-grown man the chances are he has come direct from Portugal.

119. If you visit Timor things are worse still. The native Portuguese count for nothing, and the imported Governor and officials go in daily fear of their lives. But that I have received much courtesy from them I could draw a painfully true picture, showing that Portugal has been a dismal failure in these beautiful lands. Goa, their Indian capital, is moribund, and no one who has experience of Portuguese Africa retains much respect for the remnants, degraded in blood and physique, of the nation that did more to establish trade, to put down piracy and to infuse civilization, than all the Spanish and Dutch that ploughed these then unknown seas.

120. So, too, with the Spanish possessions. The Philippines take their name from Philip II of Spain, the author of the Spanish Armada, and his people no more conquered the Philippines than his ships conquered England. This great archipelago, stretching across fifteen degrees of latitude, and embracing 115,000 square miles, never became Spanish in the same sense that Chili and Peru have done. You can stand in Manila and see regions that the Spaniard never ventured into, whose natives never acknowledged them, never paid them voluntary tribute. On many islands —Palawan, for instance—no Spaniard dared live. I have been in Sulu when the capital, Tiangi, has been besieged by a handful of natives, and not a nose of the garrison dared show outside the city walls. And I have seen blockhouses—as in Siassi —where the guard was only permitted to re-enter the town on sufferance. To those who know not the state of matters in these rich islands it will come as a surprise to hear that Manila, with its 300,000 inhabitants, was never a Spanish city. It is a great city with a small European quarter, just as Shanghai or Tientsin are. The Spaniard ruled but did not occupy and Manila never contained 10,000 Europeans all told. The Americans made the mistake of thinking that when they beat the Spaniards they had taken the Philippines. They had learned better now, and they at least are sure that in three centuries the Spaniard had not thriven in the islands of the Orient.

121. This is sufficient evidence for our purpose. The Portuguese made a deeper impression on the Indies than the Spaniards, but neither succeeded in establishing his race. It is one thing to occupy a land by force of arms, and by wise administration, but it is quite another thing to populate it as colonists, and by natural increase. Even where Portuguese and Spanish blood has survived, as in Macao and Luzon, it has been by the infusion of native blood, and the people are half-castes, the Mestizo population of the Philippines far outnumbers the folk of true stock, even when the recent immigrants from Europe are taken into account.

The Dutch Indies.

122. The Dutch have been more successful in the East than the Spaniards or Portuguese. Java is rich and flourishing. And the Dutch belong to the Fair Whites. Moreover, they convinced Alfred Russell Wallace that the tropics could be successfully colonized. His opinion, expressed in his classic work on the Malay Archipelago—after all these years the best work on the subject—is quoted daily in support of the feasibility of the white man making for himself a new home in the gardens of the sun. I believe he has seen reason to modify his opinion, but how far I am not in a position to say.

123. Now I know the whole of the region he so splendidly describes and have spent as long in wandering over it, and have come to quite a different opinion from that usually attributed to our veteran naturalist. I fear he has been misunderstood. In conversation, it always seemed to me that Wallace never said the white man had actually succeeded in establishing himself in the tropics, but that, with proper care, he might do so. The two things are not on a par. I consider both equally erroneous. His latest pronouncement, in 1898, was that it is " because white men, as a rule, do not work enough in the open air in the tropics that they suffer in health," and he points out that the women of the ruling class suffer most, for they take least exercise.

124. M. de Quatrefages, the veteran French anthropologist, also is firmly of opinion that white men can thrive in the tropics, and while admitting (as indeed all must do) that exercise in the open air is necessary for the preservation of health (he might have included the temperate and arctic regions), yet he looks upon the high death rate as directly due to two causes, first to tropical disease, chiefly malaria, and secondly and chiefly to lack of acclimatization. Destroy malaria, he adds, and man can live in the tropics healthily, when he has become acclimatized. He proceeds to show that ten generations, say 250 years, are not more than half enough to become acclimatized, and so accounts for the death rate in French tropical colonies.

125. To this we reply that no sort of man can thrive in any kind of climate if it is unhealthy, and that if it takes five centuries to get inured to a new climate, one might as well throw up the sponge at once.

126. Dr. J. W. Gregory has an interesting chapter on the "White Australia" policy in his recent volume on "Australia" (1906), and says deliberately "there is nothing in the heat of any climate in the world which is necessarily fatal to European races." He looks to hygienic improvement in the rearing of children, as sufficient, and makes the (to me) amazing statement that "Anglo-Indian children are now sent home for education as much as for health." This begs the whole question, but let that pass. Admit that children can be successfully reared in India—and I have known many—still their physique is impaired, and they are almost invariably sterile. At any rate, no one has yet produced a single specimenn of a third generation of English-raised man or womanhood.

127. Another weighty advocate, but a fair one, in favour of a white tropical race, is the Hon. H. Demarest Lloyd, an American writer on social subjects whose work "Newest England" (New York, 1900), all Australians should read. I talked the subject over with him many times, and he has fairly stated my views. But he has no personal experience of the tropics, and only gives the views of others. As an American he is anxious as to the future of the Philippines and Sandwich Islands, to say nothing of Cuba, and perhaps his desire may have influenced his judgment. Till he can find at least one case where a white race has maintained itself in the tropics without constant recruiting from home, I must continue to affirm that opinion, unsupported by historical evidence, is of no value whatever, no matter how great may be the authority quoted. And this brings us to the critical test of the Dutch Indies.

128. The prevalent idea about a Hollander is that he is Dutch built, so to speak; bluff bowed, and slow as a galliot. This is a cruel libel. I have known him in Holland and in the tropics, and he is more like an Englishman than any European except a Dane. And in the tropics he leads a wiser style of life than most Englishmen. He dresses sensibly, takes his siesta during the noonday heat, closing his office so that none of our foolhardy countrymen may tempt him into sunstroke, and where he can, as in Java and Sumatra, sleeps in the cool air of the hills, instead of stewing on the coast. He has made a success of some of his tropical colonies, and I admire and respect him for it. But I blankly deny that he has solved the problem, and learned how to euchre the climate for his own and his children's benefit. The only test is a statistical one—has he increased in numbers without recuperation from Holland? His own population tables shall answer.

129. Java is their most flourishing possession, and it contains a total population of nearly 20,000,000, of whom only 30,000 are Dutch. In the years 1868-78 the increase of all Europeans was only 1,532, and between 1869 and 1877 there was an actual decrease in numbers. And this includes not only the Dutch who claim to be native, but those from the old country and other parts of Europe. This means that without immigration the Dutch element would die out, since it only remains stationary by the aid of the newcomers. The Chinese, who number 200,000, have increased 33,000 in the same period. That is, their increase alone is more than the whole of the Dutch population. The native population, nearly 19,000,000, has in the same period increased nearly 5,000,000, and there is no immigration to be taken into consideration in their case.

130. It is perfectly futile to say that the Dutch would have increased faster had they lived more hygienically—they are the most careful of all the white people in the East. And it is only adding proof to conviction to point out that in other parts of the Dutch Indies they have not done so well. In Sumatra they have been trying all my life to subdue the Achinese. In the Moluccas and Borneo they have never got far inland. And nowhere there, or in the Celebes, has any Hollander nursed a native-born grandchild. There is no third generation.

131. Finally, let us inquire into the opinions of Dr. A. R. Wallace and Professor de Quatrefages—that if white men took to outdoor life they would be as healthy in the tropics as at home. Here I can give personal experience, for I have done strenuous out-door work in the tropics as an explorer and pioneer. I have also been interested in the opening of many estates—tobacco, sugar, and all sorts of tropical products—and I have been intimate with many planters, Dutch and others, who have been sons of planters, and who knew every wrinkle experience could teach, and this not for a year or two but for many years. I claim to be able to speak with authority, and I affirm that it is impossible for a white man, dark or fair, to work continuously in the tropics, especially in agricultural pursuits, without becoming a physical wreck, unless he has pretty frequent change to some bracing climate. No white man could possibly work continuously as a plantation labourer. Even the Asiatic coolies cannot stand it for many years. So exhausting is the work that I have sometimes thought, as I watched the graveyards grow in extent, whether the produce was worth the sacrifice in life and disease.

The white managers and overseers suffer only in a lesser degree owing to their work not being so physically exhausting. Three years is as long as they can endure at a stretch—then a year at home braces them for another course of steady deterioration of health. Mail by mail I have met new hands from Europe full of the untasted glamour of the East, full of home-taught lessons about the necessity of avoiding the pernicious ways of life of the old hands. They came, a steady stream, and lectured us old stagers on our evil ways, and forthwith started in to set us laudable examples. We smiled the smile of callous experience; we had all been in the same boat. Every single soul of us had come out as a shining example, as a missionary of the new idea—we bided our time. Then they came back to us; not one here and there, but ninety-eight out of every hundred, with the fear of death

upon them, and we nursed them back into new life, or buried them. Those who survived were no longer griffins, and they met the next griffin with the silent grin which signifieth " you'd better bide a wee." I have stood by too many graves, have helped too many broken constitutions down to wharf, to speak lightly on this matter. Pride, and the spell of the East, which grips all us old hands, causes us not to brag of what we have gone through; familiarity of the precariousness of life has made us indifferent perhaps, but none of us is deluded for one moment by the theoretical dicta of philosophers whose language concerning things they know of is as tropic as their homes are temperate. *The white man can and will rule in the tropics, but he will never colonise it, never develop it with the work of his hands.*

132. But the great and honoured Frenchman, de Quatrefages, thinks his countrymen can people the lands of the burning sun. It is a fond desire, and methinks his wish marches ahead of his judgment, or perchance he fails to read the dry detail of his own colonial budget, otherwise he would know that in the French possessions of the Far East the officials pretty nigh equal the unofficials, so little more than a dream is their occupancy. But he would doubtless reply, they have not had time to become acclimatized. So let us take his own illustration of what a Frenchman can do where the sunshine is stronger, though not brighter, than in his own fair land of France.

133. Speaking of Bourbon, he says, " The Whites of Bourbon form, in reality, two classes, or rather two races, distinct in their manners and customs. The former includes the population of towns and large settlements, who lead the ordinary life of colonists, and especially avoid agricultural labour, considered by Creoles as degrading as well as fatal. The latter includes the " Mean Whites," descendants of the original colonists, who, too poor to buy slaves, were forced to cultivate the land with their own hands.

134. Now, of these two classes of colonists, it is the former alone which supply the mortality to which attention is so often drawn. The " Mean Whites " live as their fathers lived; they inhabit and cultivate the less fertile districts of the island. Far from having deteriorated, their race has improved, and the women, in particular, are remarkable for beauty of form and feature. The race maintains itself perfectly, and seems to be on the increase. Crossing, moreover, has no influence in the matter, for the " Mean White," proud of the purity of blood which constitutes his nobility, will not, at any price, ally himself with the negro or coolie.

135. " Thus at Bourbon, indolence, and the habits which it involves, destroy the rich and those who try to imitate them, while the poor become acclimatized through sobriety, purity of manners, and a moderate amount of work. From the latter, anthropologists and all the world may learn a lesson of grave importance, at once scientific and moral."

136. Truly, all men may learn a scientific and moral lesson from this statement of facts. Stripped of its Gallic glamour it proclaims aloud that the only Frenchmen who can live in Bourbon are the " Mean Whites," poverty-stricken and intellectually incapable of rising, so that they are exiled into the least fertile parts of the country. I will not comment upon this, save to suggest that the promise of such a fate would be but a poor allurement for an intending emigrant.

137. In my next I will come closer home and inquire whether the Fair White is holding his own in the United States; whether the Monroe doctrine is a prophetic vision or an intangible dream.

Annotations.

The Possible Incidence of River Fever (Tsutsugamushi Disease) in the Central Yangtze Valley (E. Carrol Faust, *The China Medical Journal*, December, 1923).—Two cases from the Wuhan area, with a primary diagnosis of schistosomiasis japonica, but having in blood and spleen smears micro-organisms resembling stage for stage the micro-organisms described for Japanese river fever, and exhibiting certain typical symptoms of this disease, are given that tentative diagnosis. The presence in China of many cases of splenomegaly with obscure etiology, together with the account of the presence of this infection in China in ancient times, makes it advisable to keep this point in mind in studying such cases, and to determine the distribution of trombidæ in such areas.

Mitral Stenosis without Rheumatic Fever in North China (H. E. Meleney and Irmarita Kellers, *Arch. Internal Med.*, October 15, 1924).—Mitral stenosis is the most common valvular disease of the heart in Peking, although rheumatic fever is very rarely seen. Thirty-nine cases from the medical clinic of the Peking Union Medical College Hospital are reviewed. In the histories of these patients only one case of rheumatic fever, one case of chorea and fourteen cases of " joint pains " occurred. No other infectious diseases appear to be especially involved in these cases of mitral stenosis. In sex and age incidence, in electrocardiographic phenomena and in the pathology of three cases which came to necropsy, these cases are similar to the cases of mitral stenosis of rheumatic origin seen in Europe and America.

Pseudo-Malarial Attacks in Typhoid Fever (G. Caussade and H. Le Rasle, *Presse Med.*, September 13, 1924).—Six cases are recorded of the pseudo-malarial type of fever, first described by Jaccaud, 1884, which occurs during defervescence or at the beginning of convalescence from typhoid. The attacks may be of short, moderate or long duration, and are generally daily, but, in rare instances, are bi-quotidian or tertian. The end of an attack is marked by swelling and a fall of temperature.

Polyuria often occurs at the end of an attack, and is sometimes as much as five pints in twenty-four hours for several days. The patient generally recovers. Cholecystitis, pyelonephritis and a relapse of malaria must be excluded in the diagnosis. Quinine will have a successful effect on the attack if malaria is present, this being ascertained by finding the malarial parasite in the blood.

The Treatment of Leprosy in Ceylon (R. Pestonjee and L. Nicholls and J. E. Felix, *Ceylon Journal of Science*, vol. i, part i, June 4, 1924).—From the experience of these authors at the Ceylon Asylum for Lepers, it is seen that none of the many drugs brought forward with a claim to curative value in the treament of leprosy is of any real value in this disease; some there are that cause an improvement in the patient, but even these are not sufficient. It is stated that the recovery of the majority of the patients in leper asylums cannot be expected from the use of any specific remedy because of the damage to the tissues already caused by the disease. The treatment by injections which must be continued for several years is very tedious for the patient. And even if the patient shows marked improvement no definite decision is possible as to whether or not he continues to be a source of infection to others. If the number of lepers in the British Empire diminishes considerably during the next thirty years, it will be due to general progress or to future discoveries, and not to any drugs which have been used up to the present in the treatment of the patients.

The Wadi Halfa Quarantine (Major B. H. H Spence, *Journal Royal Army Medical Corps*).—The Government of the Anglo-Egyptian Sudan, faced with the necessity of importing 15,000 labourers from Southern Egypt in the winter of 1920-1921, decided to have them all inspected, loused, vaccinated and examined and treated for parasitic worm infestation, with a view both to improving their value as labourers, and to protecting the country against the introduction of bacterial, protozoal and metazoal diseases. The existing quarantine at Wadi Halfa was adapted for the ends in view. With a staff consisting of one medical officer, one laboratory assistant, and thirty locally enlisted Berberines, the labourers were inspected, loused, vaccinated and examined and treated for parasitic worm infestation at the rate of 250 a day. 100 per cent. of 14,077 labourers from Southern Egypt were found to be lousy. All men had their heads cropped and their bodies shaved. No case of louse-borne disease occurred amongst these men throughout the season, whereas 2,000 Yemenis admitted at Port Sudan without proper precautions suffered severely from an outbreak of relapsing fever. Five per cent. of 14,077 were found to be anæmic; 0·5 per cent were so anæmic that it was considered advisable to send them back to Egypt. In the absence of parasitic worm infestation, heavy infestation with lice was the only obvious cause of anæmia in certain cases. Forty per cent. of 14,077 were found to harbour from one to four kinds of parasitic worms, 20 per cent. had ankylostomiasis. Four grammes of thymol appeared to be more efficacious than three cubic centimetres of chenopodium oil in the treatment of parasitic worm infestations amongst Egyptians. In no case were more than 200 ankylostomes recovered from a man, a result in keeping with the general appearance of the infested men. Many thousands of male and female ankylostomes were examined. All proved to be *Ankylostoma duodenale*.

8·5 per cent. of the picked labourers were found to be suffering from urinary schistosomiasis; 0·7 per cent. had to be sent back to Egypt on account of the severity of their disease. 20 per cent. of these labourers suffered from nervous retention of urine when called upon to micturate during medical inspection. These men were catheterized, and in 3,000 so dealt with only one stricture was encountered. The Government of the Anglo-Egyptian Sudan, convinced of the value of the results achieved in the first year, spent £7,000 on the erection of permanent buildings, which were completed in 1921, and have proved extremely useful ever since.

Investigations upon Flagellate Infections (R. P. Strong, *The American Journal of Tropical Medicine*, vol. iv, No. 4, July, 1924).—In studying certain infectious diseases of plants and in searching for animal parasites in the latex of various tropical plants in Central and South America, a flagellate parasite was discovered in three species of Euphorbiæ. This flagellate is of the leptomonas type and is not dissimilar in appearance to the flagellate stage of *Leishmania tropica*, giving rise to a form of tropical ulceration of the skin. In one district in Panama a very extensive phytodemic of the infection in *Euphorbiæ* was found to exist. These plants were very abundant in this region and almost every one was found infected. The infected plants showed pathological changes, and the latex of the plants was also distinctly altered, the flagellates causing disturbances in the latex of the plants, sometimes forming emboli in the lactiferous channels. The nutrition of the plant was thereby distinctly disturbed and many of the plants became atrophied.

The insect *Chariesterus cuspidatus* transmitting the infection from the plant to a species of lizard *Cnemidophorus lemniscatus* was also discovered. From extensive experiments upon animals it was demonstrated that the flagellate as it occurs in the plant, and also in the intestinal tract of the insect, is not pathogenic for vertebrates. However, after the flagellate has passed through the insect to the lizard it acquires pathogenic properties and may give rise to a form of tropical ulceration in the skin, as was demonstrated from experiments in the monkey. In this ulceration

the leishmania form of the parasite and not the flagellate stage is encountered. There is perhaps nothing very extraordinary in the idea that a flagellate found producing a disease in plants may, after passing through an invertebrate and a vertebrate host, acquire pathogenic properties for a mammal. This, apparently, is the first instance of this nature in which such a chain of infections has been demonstrated.

Myeloid Leukæmia of the Skin (J. L. Tenenbaum, *Arch. of Dermatology and Syphilology*, vol. 10, No. 5, November, 1924).—Two cases are reported of this infection. The two conditions thought of as a possible diagnosis were (*a*) malignant metastasis of the skin, and (*b*) idiopathic multiple hemorrhagic sarcoma of Kaposi. On further analysis both were discarded as lacking the essential diagnostic features. The diagnosis of myeloid leukemia of the skin was finally adopted on the following grounds. The rather sudden development of bluish tumours and nodules, scattered mostly on the trunk and extremities, which presented a globular appearance, were firm to the touch, showed no tendency to ulceration, and were practically painless, with no history of malignancy in the internal organs. The hemorrhagic diathesis of the skin including the mucous membrane, in a well nourished person who was not conscious of any grave constitutional disturbance. The glandular enlargement in the groin, which was painless, not adherent to the skin, more or less discrete with no signs of ulceration. The enlargement of the liver and spleen with symptoms of pain in the latter, which in all probability were due to perisplenitis and splenic anfarcts; and the atypical blood picture with the appearance of unripe myelogenous elements. The relatively low white blood count classifies the case as a sub-leukemic stage of myelogenous leukemia. The results of the biopsy were rather inclusive for a typical myeloid leukæmia.

Interactions of Protoplasmic Masses in Relation to the Study of Heredity and Environment in *Arcella polypora* (Bruce D. Reynolds, *Biological Bulletin*, No. 2, February, 1924).—It has been shown that, like difflugia, *Arcella polypora* will under favourable conditions, reappropriate its detached protoplasm by fusion. *A. polypora* is not attracted by a pseudopodial fragment of difflugia. If accidental contact is made the fragment is treated as a mechanical obstruction. Fusion will take place between one individual and a protoplasmic fragment of a closely related specimen. Two distantly related individuals, which have not been kept in the same receptacle, will be attracted by each other's severed pseudopods, but upon making contact the involved protoplasms will be shattered into bead-like masses. When two lines of a clone are kept under similar environments, cross-fusions between them cease after approximately twenty-two days; while if the two diverging lines are subjected to different environments, the time required for cross-fusions to cease is greatly shortened (varying from 6 to 16·5 days, depending on the factor employed). When small quantities of culture media are frequently exchanged between the concavities in which members of two diverging lines are confined, cross-fusions between them apparently continue indefinitely. After two related specimens have become negative to each other's protoplasm, cross-fusion between their progeny may be induced by (a) exchanging small quantities of culture media between the receptacles in which they are kept, or (b) by placing both of them in the same concavity. Morphological differences are not necessarily associated with different physiological states. Physiological changes do not occur among descendants of a single *A. polypora* reproducing vegetatively, but such differences are probably due to environmental influences rather than to hereditary variations.

Current Literature.

BULLETIN DE LA SOCIETE DE PATHOLOGIE EXOTIQUE. November 12, 1924.

Sleeping Sickness in Equatorial French Africa (J. Vassal).—In this paper the results of investigations in the colonies of Central Congo, Oubangui-Chari, Tchad and the Gaboon, are given. Sleeping sickness is localized along the rivers. Some places are more infested than others, such as Bouca, Marali, Crompel and Grimari, &c. Among the numerous places still free from sleeping sickness are Batangafo, Kabo, Bossangoa Katouma and others. Tchad is partially contaminated in the south. In the north it is naturally protected by the sands and a climate which excludes the tsetse, In the Gaboon districts the malady is very unequally distributed. The tsetse fly is to be found everywhere, but in diverse numbers. Mosquitoes are rare. Infantile mortality is considerable in all parts. The people are poorly nourished and their conditions of living are unhygienic.

Second Algerian Case of Mycetoma of the Foot (type Madura Foot) *due to Aleurisma apiospermum* (J. Montpellier).—The author has studied a case of mycetoma of the foot in a native of Algeria and gives the results of his mycological study. The case was one of a hyphomycete characterized by conidiaform formations, particularly adherent to the hyphæ. This is the fourth case of mycetoma due to *Aleurisma apiospermum* recorded in the literature.

On the Use of Kermes in the Treatment of Leprosy (E. Tournier).—Four cases of leprosy have been successfully treated with antimony salts—two of nervous form, one mixed, and one tuberculous. In the last two cases kermes alone was used and in the other two cases the kermes was associated with atoxyl novarsenobenzol. The amelioration of the different symptoms was very rapid, especially the nodular and mixed forms. No sign of albuminuria or gastro-intestinal intolerance was noted.

Kermes has not the strong depressive action on the nervous system and the circulation as has been observed with emetic, and can therefore be given to patients of all ages, in doses according to age of the patient.

Intermittent Inflammatory Attacks in Malaria (A. Le Dantec).—In this paper a form of malaria is described which has hitherto not been published. The patient was a Colonial of white race suffering from intermittent inflammations, affecting solely the fingers, thenar eminence, uvula, different parts of the face and the tongue. Inflammations of the tongue were particularly dreaded by the patient, which impeded respiration and the taking of food. The patient left Senegal to be treated in France. Examinations for filariæ, negative. Treated with quinine, intramuscular injections, and sulpharsenol, subcutaneous injections, the patient was completely cured. These inflammatory attacks resemble other larval manifestations of malaria, acropyrexia, urticaria, &c. The author suggests that all these syndromes should be classed under the name "sympathoses palustres."

Second Note on the Piroplasmoses of Sheep in Algeria Anaplasmosis. Anaplasma ovis, nov. sp. (F. Lestoquard).—A new piroplasma has been found in Algeria, viz.: *A. ovis*, nov. sp. *A. ovis* is transmissible to the goat. The incubation, symptomatology, the termination, the pathologic anatomy are identical in the goat and sheep. The natural disease also exists among goats, but in a lesser degree than in sheep.

Researches on Hæmaturia in Egypt (J. Khouri, of Alexandria).—During the past twenty years at Alexandria the author has examined 591 cases of hæmaturia, including 48,355 examinations of urine. The causes of hæmaturia are many and varied, but sixty per cent. of the total are cases of parasitic hæmaturia. Bilharziosis is the cause of about forty to sixty per cent. of cases at Alexandria, but further inland the percentage is higher on account of the endemic sites of infections. Fewer women are infected than men. In all cases *Schistosomum hæmatobium* has been found.

Researches on an Endemic Fever accompanied by Generalized Lymphadenitis (Toyoichi Ohtawara).—This fever was first observed in the village of Kagami (Japan) and is generally known as *Kagaminetsu*. It is a specific disease, acute, endemic, characterized by generalized lymphadenitis. After two or three weeks convalescence begins. It causes no secondary illness. The disease is more often met with in manual labourers. The pathogenic agent has not yet been discovered. Kagaminetsu is transmissible to the monkey and guinea-pig, and in the case of the monkey immunity can be acquired after complete cure of the fever. Salvarsan is efficacious in the treatment of this disease.

Note on the Mixture Emetic-Extract of Organs in the Treatment of Draconculosis (M. Peltier and H. Dominique).—Draconculosis is extremely frequent at Togo, especially where there is little rain and drinking water has not yet been provided for the natives of the country. In simple cases of guinea-worm, extraction is effected by wet dressings. In complicated cases the authors had recourse to antimony salts. Intravenous injections of emetic, however, proved more efficacious, especially in septic complications. To increase the action of emetic the process of Levaditi was tried—mixture of arsenical compositions and of antimony derivatives with fresh extract of the organs at 37°, known as trypanotoxyl, bismoxyl, &c. Stibioxyl, prepared in the same way, gave very good results in the treatment of draconculosis; the extract used was sheep's liver.

Considerations on the Connection of the Rodent Fauna with the Plague Manifestations at Dakar (M. C. Blazy).—A study has been made of the numerous species of rats found at Dakar. Examination for the plague bacillus was negative. *Xenopsylla cheopis* was found in large numbers, in one rat 124 were counted. *Sarcopsylla penetrans* was very rarely found. Inoculations of flea emulsion into mice showed the cutaneous parasites of rats to be free from plague bacilli. Reports show that murine infection coincides with human plague. Owing to disinfection of houses, and amelioration in the public service, &c., no cases have been reported since 1923.

The Sixth Case of Kala-Azar in Algeria (H Soulie).—Infantile kala-azar is very rare in Algeria hitherto five cases have been recorded; the author describes the sixth, in a boy of two and a half years. The infection was contracted at Boghni; the origin is unknown, but it is probably due to an infected dog or cat.

On the Frequence of Cutaneous Staphylococcic Infections at Tangiers (P. Remlinger).—Furunculosis, folliculitis and ecthyma in Tangiers are nearly always observed on the lower limbs, but the whole body may be affected, especially the uncovered parts, fingers, wrists, &c. The disease is nearly always multiple, appearing generally during the dry season, but can be found all the year round. Familial and house epidemics are not rare. In Tangiers, as in all other places, these diseases are seen on dirty children and adults whose profession exposes them to contact with dirt—chauffeurs, mechanics, &c. The disease is common in natives and Mussalmans; it occurs with equal frequency among the white race at Tangiers. Meteorological factors and unhygienic conditions have much to do with the frequency of staphylococcic affections in Tangiers.

Conclusive Experiments on Intradermovaccination against Bacterial Anthrax in a Severely Infected Area (H. Velu).—These experiments, carried out in Morocco when conditions were very severe, prove the efficacy of the Pasteurian vaccines; it is the same in Morocco as in France. The vaccine prepared at the Laboratory of Casablanca is as active as the Pasteurian vaccines, besides being cheaper and more practical in the colonies.

THE ÆTIOLOGY OF HÆMOGLOBINURIC FEVER.

By W. E. Deeks, M.D.

General Manager, Medical Department, United Fruit Co., New York.

THERE are few problems in tropical medicine which have caused more controversy than the ætiology of blackwater fever. Three theories have been advanced in explanation :

(1) That it is a symptom complex of a malarial infection.

(2) That it is caused by a specific organism which occurs in localities where malaria is prevalent.

(3) That the administration of quinine alone is responsible for precipitating an attack.

An enormous amount of literature and statistical data has accumulated on the subject. Most authorities now believe that blackwater fever is associated in some way with a malaria infection and that *Plasmodium falciparum* is chiefly, if not altogether, incriminated. If this hypothesis be correct the question naturally arises as to how hæmolysis occurs in a malaria infection. That it does not always follow an æstivo-autumnal infection, but only in a small percentage of these cases, is a self-evident fact to all practical workers in tropical climates where malaria is prevalent.

Certain facts in regard to its incidence appear to be fairly well established.

It is generally met with in malaria-infected individuals suffering from malnutrition, chronic organic disease, or some complicating infection which lowers resistance. It may develop in a few hours after unusual exposure to the hot sun, a severe chilling of the surface of the body, over-exertion, fatigue, mental excitement or depression—in fact, anything that tends, temporarily or permanently, to lower the resistance of the patient.

Again, it frequently develops after the administration of a dose of quinine.

Any satisfactory hypothesis as to its ætiology must, therefore, be sufficiently comprehensive to explain all these factors.

In 1898 Bordet discovered that defribrinated rabbit's blood when injected at intervals of a few days into the peritoneal sac of a guinea-pig did not materially influence its activity, but in the body fluids or blood plasma of the guinea-pig a substance developed which rendered the plasma or sera capable of dissolving rabbit red blood cells, which power it did not previously possess. In other words, a hæmolytic agent or property was developed by the guinea-pig specific for rabbit blood cells, but for no other animal. This hæmolysin when injected into the rabbit in small doses caused hæmolysis of some of its red cells and in larger doses a sufficient number of red cells were hæmolysed to prove fatal. If, however, small doses were injected at intervals of a few days the rabbit developed in its plasma an *antihæmolytic* agent which prevented further damage. It is further interesting to note that these newly-developed agents or immune bodies are specific in each instance for the cell or antigen involved. Moreover, the same phenomenon could be observed when other than cells were injected into an alien animal. In each instance cytolytic substances were formed specific for all the cells injected.

These observations form a basis for the consideration of the development of the hæmolytic agent of hæmoglobinuric fever.

The malaria parasite must be considered to be an animal organism. It is unicellular and undifferentiated, but has all the necessary functions of a parasitic animal. The protoplasmic cellular constituents associated with its vital functions are similar to those of higher animals. The organism is sensitive to temperature and other mechanical and chemical irritants; it eats, digests, grows, excretes, and reproduces itself—physiological properties possessed by all more highly specialized and organized multicellular organisms. If there be any difference in its protoplasmic activity we have no means — chemical or microscopical — of determining it. Fundamentally its structure and physiological activity is similar to that of more highly organized life. We have every reason, therefore, to believe that the hæmoglobin of the red cells, consumed by it during feeding, will develop hæmolytic agents in its body substance similar to those which are developed in the guinea-pig's blood, when the red cells of the rabbits are absorbed by it after injection. In other words, it can be logically inferred that each malaria parasite develops a hæmolytic property. In a malaria infection not only are red cells destroyed, but the colour index of the remaining individual red cells is lowered to a considerable degree. Is it not reasonable to believe that the resulting anæmia of a malaria-infected individual is due to this hæmolytic agent?

Furthermore, can we not correlate this action with that of the hookworm, which is a blood feeder, and which produces anæmia in the host? The small amount of blood which several hundred hookworms will destroy daily will not account for the severe anæmia observed in these cases — and it is now generally recognized that hookworms produce a hæmolytic agent, which is largely responsible for the resulting anæmia.

It would seem at first sight that very little hæmolysin could be produced by a malarial organism, but we know that in a severe malaria infection 20 per cent. or more of the red cells may be invaded by parasites. This is equivalent to about 1,000,000 parasites to the cubic millimetre and 1,000,000,000 to the cubic centimetre, 30,000,000,000 to the oz., 480,000,000,000 to the lb., and in a man weighing 150 lb. there are about 12½ pints of blood, so that there would be about 6,000,000,000,000 parasites present in a severe malarial infection. Each red blood cell has a cubic capacity of approximately 1/171,277,000,000 of a cubic in., and according to J. G. Thomson at schizogony the *P. falciparum* occupies two-thirds of this space; its cubic capacity therefore is two-thirds

of this, or 1/256,915,500,000 of a cubic in. This, multiplied by the number of parasites in a severe malaria infection, gives approximately 23·3 cubic in. of malarial protoplasmic material in a man weighing 150 lb. when 20 per cent. of his red blood cells are invaded.

We are all familiar with the anæmia and cachexia developed by a malignant tumour of similar cubic capacity. The malarial parasites also show a malignant action in their clinical symptomatology. The effect of 23·3 cubic in. of malarial material undoubtedly would be capable therefore of producing an enormous amount of hæmolysin in the human blood and, in response to its action, a large amount of antihæmolytic substance. As antihæmolysin undoubtedly is the result of the reaction of hæmolysin on the tissue cells, when a man is in good physical condition he is better able to develop antihæmolytic agents. Any of the depressing agencies which are considered as ætiological factors—chronic or acute—therefore, which interfere with the development of antihæmolytic bodies—a process more or less continuous in the presence of a malarial-infected individual—would permit extensive hæmolysis to ensue in such quantities that the liver and spleen would be unable to take care of the liberated hæmoglobin, and hæmoglobinæmia would result, followed by a hæmoglobinuria.

In paroxysmal hæmoglobinurias following the administration of quinine, which destroys the trophozoites in large numbers, we have a condition in which large quantities of hæmolysin are suddenly liberated which the antihæmolytic bodies are unable to neutralize as fast as it is produced, and there is a consequent hæmoglobinæmia which overflows in the kidneys, producing hæmoglobinuria.

If this hypothesis be true it gives a reasonable explanation as to why in the treatment of post-hæmoglobinuric fever small doses of quinine should be given first, so as not to destroy too many parasites at once, and thus precipitate another attack. This is very necessary, as observed by clinical experience.

The confirmation of this theory of the causation of hæmoglobinuria rests on the ability to demonstrate the presence of hæmolysis in the blood immediately before the development of an attack of hæmoglobinuria, as its presence in the blood previous to this would be largely neutralized by anti-hæmolysis.

In this connection, the following quotation from J. G. Thomson's comprehensive monograph on "Researches on Blackwater Fever in Southern Rhodesia" is suggestive :—

> "Successful cultures were obtained of the asexual cycle of eighteen cases of *P. falciparum*, and on five occasions in which no development took place I noted hæmolysis. There was no bacterial contamination, but it was observed that if the blood was drawn at a period corresponding to schizogony in the body hæmolysis invariably took place in the tubes. Simpson (1912), while working with malaria, also found evidence of hæmolysis during schizogony. Dr. Orpen tested several of the cultures by adding complement to the tubes after schizogony had taken place, and obtained some evidence that again a hæmolysin was present at this stage. This hæmolysis did not occur in controls. As, however, the numbers examined were very few, and chance results are apt to occur, we did not feel justified in being positive about these results.
>
> "We suggest, however, that by cultural methods and the use of careful technique and controls it may be possible to demonstrate hæmolysins present at certain stages of the asexual cycle, e.g., during complete schizogony. Miss Trutter kindly examined the blood groups of a number of blackwater fever cases, but here we were unable to state that the disease showed any preference for one of these. It is probable that a hæmolysin can be demonstrated only at certain periods of the asexual cycle. The chances of detecting it may rapidly vanish as the disease progresses. We were quite unable to detect any hæmolysin in the serum of blackwater fever at any period of the disease, but, as we have pointed out, this by no means proves that a serum hæmolysin is not present."

Confirmation of the observation of Dr. Thomson and others on the presence of hæmolysin at the time of schizogony would support the theory suggested on the ætiology of blackwater fever.

USE OF IODINE IN BERIBERI.

By H. W. Ridley, C.M.G., F.R.S.

During the twenty-three years that I was employed as Director of Gardens in Singapore, I had control of from 40 to 100 coolies at a time as gardeners. These were all, or nearly all, Javanese men, for whose health and sanitation I was mainly responsible, and whose minor ailments I treated myself. In serious or obscure cases I could send them to the hospital, but, as natives generally have, they had rather a fear of the hospital, and if sent off there frequently slipped off on the way, went to other native houses and took Chinese or other native medicine or treatment with often disastrous results. To avoid this I treated myself such ailments as I could manage, most of which indeed were mild cases, skin diseases, diarrhœa and debility, malaria, accident, boils or poisoned wounds, &c. But, in addition to these, we had pretty constantly with us in the coolie lines more or less beriberi, generally of a mild type, or perhaps, more accurately, incipient cases. No man was allowed sick leave unless he came to the office to report the sickness, if he was able to; if not one of the other coolies reported it to me, and I went at once to see him so that at the first onset of beriberi I was able to deal with it. It usually commenced with acute pain in the feet, and it was at this stage I usually was able to treat the patient. A great deal has been written on the disease, so that I only record here a few observations which I have not seen recorded before. But I will first premise that on one or more occasions, in order to confirm my diagnosis, I have asked one of the doctors from the hospital to examine my patients to definitely ascertain that the disease was really beriberi, which was then very prevalent in Singapore. He confirmed my diagnosis, stating that the cases were those of a mild form of the disease.

I observed that the disease was most prevalent in the coolie-lines in April and May, when I usually had from five to fifteen men attacked, and comparatively seldom did we get cases at any other time. Also that they were nearly all men who had come to the gardens in the previous year, or about three months

before the annual outbreak. Again, we never had a case among the women or children. One boy brought up in the lines was not attacked till he had attained the age of puberty. Most of those attacked were about 18 or 20 years of age. The cause of the disease is usually attributed to the patient having fed on polished rice only, so that it is interesting to note that all women and children, like the men, ate the same food, the boys feeding with their fathers after the age of about eight years, the smaller boys by themselves, and the women and girls on the same class of food prepared in the same way after the males have fed. The food consisted of boiled rice (town-bought), a small piece of dried fish and a few chillies; occasionally during the day they bought cakes, curry, or sweetmeats, and fruit, but the rice and dried fish was the chief and often only food.

At one time, as the disease was so persistent, I thought that perhaps it was established in the houses or on the soil beneath, so I destroyed all the houses where there had been cases and rebuilt them on fresh ground, forbidding the men to use any of the wood of the old houses (which to a small extent they disobeyed), but the disease broke out again. I found that they had not destroyed the box in which the rice was kept, and in this box, later, I found cockroaches, which at one time were believed to be carriers of the disease.

The Malay houses, being raised on piles above the ground, formed a suitable space beneath to keep chickens when fenced in by wire netting. These places often swarmed with cockroaches among the excreta of the fowls, and I forbade these places to be used for this purpose, especially after a case which occurred at Government House, some two miles away from the Gardens. Here the garden coolies had lines similar to ours, and no case of beriberi had been known to occur, until one year when there was an outbreak among the men. When I went to inspect the place on hearing of it, I found they had been keeping a large quantity of fowls beneath the houses, and there was a large mass of droppings, feathers, &c. I had it all cleared out and forbade any more keeping of fowls beneath the houses, and there was no more beriberi there from that time. In my stables two saises with their families used to live, and here for twenty years or more there had been no record of a case of beriberi until one year both men were attacked; on investigation I found that beneath the flooring, which was so built as to be difficult to remove, had accumulated an immense quantity of horse droppings and urine, which had drifted beneath the sleeping quarters at the back, and was swarming with cockroaches. The flooring was removed and the mass removed, the men were cured and no more beriberi appeared.

These facts made me very suspicious that the theory that cockroaches played some part in the propagation of the disease had some foundation. In any case I took care that no animals or accumulation of rubbish was permitted beneath the houses.

Now as to the treatment of the patients. I had heard some year or two after arriving at Singapore, from I think Mr. H. O. Forbes, who travelled formerly in the East Indies, that the Dutch were accustomed to administer iodine internally for beriberi, and I tried the same treatment with such success that we never used anything else. When a patient came complaining of his feet and had other marked signs of beriberi, I administered five drops of tincture of iodine in a tumbler of water, and if I had enough and the disease had risen up the legs, rubbed them also with iodine.

In ordinary incipient cases, three doses, one a day, completely cured the attack, and even when the disease had so far advanced that the breathing and heart action were interfered with, the patient was much relieved in a very short time, and if he would continue the treatment would recover.

One fine lad I had was attacked during my absence for some weeks, and the Eurasian left in charge thought he had only rheumatism. When I returned and saw him he was in a very bad state, breathing with difficulty. I gave him some iodine at once, and by the next day he was breathing regularly and comfortably, and the pain in the legs abated. Unfortunately he went off to a native house and tried some native treatment, and died in a day or two. I had, however, several others who were nearly or quite as ill as he was, who recovered very soon. Indeed, the only two beside the one I mentioned above who died from beriberi in the garden coolie lines, died during my absence on leave, when the official in temporary charge treated them for rheumatism. The favourite native treatment was to go down to the sea coast and sit with their legs in sea mud all day, and when they were nearly well, after the treatment with iodine, I used to let them go and do so. The Government dispensary medicine for beriberi was digitalis and strychnine. I do not think it was as satisfactory as the iodine treatment, as in some coolie lines near the Gardens I heard on one occasion they were losing eight out of ten patients, while I was losing none, but I imagine their patients did not come for treatment until too late, while I got hold of my men when the disease had only just begun.

I urged the use of tincture of iodine in beriberi frequently, but at first the local doctors appeared to disapprove of it, though occasionally iodide of potassium was used; eventually, in 1894, Dr. Hoad and Dr. Highet used it, and in even larger doses than I ventured on, and the latter reported it as very effective. I am not aware whether it now forms part of the treatment, but I do not think it was so when I left the East in 1911.

ON THE INFLUENCE OF HIGH TEMPERATURE ON THE PRESERVATION OF INSULIN.

By Prof. E. Trocello and Dr. A. Cruto.

WE were induced to carry out these researches by a certain paper published in the *Observer*, November 11, 1923, relating to the alterations of insulin in tropical climates. According to experiments of the "Pasteur Institute of Burma," it was proved that both English and American preparations, arrived in

India after six weeks from date of leaving the factory of production, did not retain more than one-fifth or less of their original hypoglycemic power; this of course practically rendered the drug useless. Whether the preparations used were in solid form or in solution was not mentioned, but in consideration of the date of the experiments it is to be presumed they were liquid.

Moreover, it is not specified in the communication whether the experiments which led to these conclusions were practised on animals or on man or on anything else; if on animals only, we might be led to suppose that the rabbits chosen had something to do with the results of the experiments. However, we thought it would be interesting to establish a control of the report on our usual laboratory rabbits, to be followed by experiments on wild rabbits or rabbits of different breeds.

A few experiments were carried out in Europe at 35° C. (95° F.) on insulin A.B. produced by the same firm, Allen and Hanbury, Ltd.,[1] but it was soon seen that the experiments should be carried out at a higher temperature.

It is well known that insulin with time loses its medicinal property, and after a few months the deterioration is already noticeable. The opinion of many experimenters on this point is unanimous. And we may also add that more than one manufacturer inherent to the preparation and preservation of the drug will agree to this. Not the last point to be considered is the state of watery solution in which the almost entire total of the preparations of different origins (English, American, French, German, &c.) is preserved.

Our comparative experiments clearly show that solid insulin shows a far greater resistance to deterioration than liquid insulin.

EXPERIMENT No. 1.

With insulin kept in an incubator at 60° for 10 hours.

Solid Insulin.

Rabbit ♂ weight 1,560 grm.
Time 9.20, injection of 2 mg. of insulin.
,, 11.30, glycemia = 0·48 per thousand.
,, 11.35, typical convulsions.

Insulin in Solution.

Rabbit ♂ weight 1,430 grm.
Time 9.15, injection of 0·3 c.c. = 2 mg. (10 units per c.c.).
,, 11.20, glycemia = 0·54 per thousand.
No convulsions.

EXPERIMENT No. 2.

With insulin kept in incubator at 85° for 10 hours.

Solid Insulin.

Rabbit ♂ weight 1,900 grm.
Time 8.55, injection of 2 mg. of insulin.
,, 10.45, glycemia = 0·50 per thousand.
,, 10·55, typical convulsions.

Insulin in Solution.

Rabbit ♂ weight 1,600 grm.
Time 8.50, injection of 0·3 c.c. (10 units per c.c.).
,, 10.50, glycemia = 0·6½ per thousand.
,, 12.10, typical convulsions.

[1] *The British Medical Journal*, January 12, 1924.

EXPERIMENT No. 3.

With insulin kept in incubator at 100° for 10 hours.

Solid Insulin.

Rabbit ♀ weight 1,530 grm.
Time 8.50, injection of 2 mg. of insulin.
,, 10.20, typical convulsions.
,, 10.35, glycemia = 0·39 per thousand.

Insulin in Solution.

Rabbit ♀ weight 1,370 grm.
Time 8.50, injection of 0·3 c.c. (10 units per c.c.).
,, 11, glycemia = 0·40 per thousand.
,, 11.10, typical convulsions.

EXPERIMENT No. 4.

With insulin kept in incubator at 100° for 24 hours.

Solid Insulin.

Rabbit ♂ weight 1,210 grm.
Time 8.50, injection of 2 mg. of insulin.
,, 10.50, glycemia = 0·52 per thousand.
,, 11.15, typical convulsions.

Insulin in Solution.

Rabbit ♂ weight 1,230 grm.
Time 8.50, injection of 0·3 c.c. (10 per c.c.).
,, 10.55, glycemia = 0·75 per thousand.
No convulsions.

EXPERIMENT No. 5.

With insulin kept in incubator at 42° for 15 days.

Solid Insulin.

Rabbit ♂ weight 1,650 grm.
Time 9, injection of 2 mg. of insulin.
,, 11, glycemia = 0·51 per thousand.
,, 11.10, typical convulsions.

Insulin in Solution.

Rabbit ♂ weight 1,760 grm.
Time 9, injection of 0·3 c.c. (10 units per c.c.).
,, 11.05, glycemia = 0 62 per thousand.
No convulsions.

EXPERIMENT No. 6.

With insulin kept in incubator at 36° for 16 days.

Solid Insulin.

Rabbit ♂ weight 1,570 grm.
Time 9.15, injection of 2 mg. of insulin.
,, 10.35, typical convulsions.
,, 10.40, glycemia = 0·48 per thousand.
,, 10.45, subcutaneous injection of 0·4 grm. of glucose.
,, 11.20, typical convulsions.
,, 11.20, subcutaneous injection of 0·4 grm. of glucose.
,, 13·00 typical convulsions; injection of glucose and food.

Insulin in Solution.

Rabbit ♂ weight 1,670 grm.
Time 9.15, injection of 0·3 c.c. (10 units per c.c.).
,, 11.10, glycemia = 0·75 per thousand.
No convulsions.

EXPERIMENT No. 7.

With insulin kept in incubator at 37° for 34 days.

Solid Insulin.

Rabbit ♀ weight 1,320 grm.
Time 9.15, injection of 2 mg. of insulin.
,, 11, typical convulsions.
,, 11.10, glycemia = 0·46 per thousand.

Insulin in Solution.

Rabbit ♀ weight 1,230 grm.
Time 9.05, injection of 0·3 c.c. (10 units per c.c.).
,, 11.05, glycemia = 0·69 per thousand.
,, 11.45, convulsions.

EXPERIMENT No. 8.

With insulin kept in incubator at 42° to 45° for 33 days.

Solid Insulin.

Rabbit ♀ weight 1,300 grm.
Time 9.30, injection of 2 mg. of insulin.
,, 10.45, typical convulsions.
,, 10.55, glycemia = 0·48 per thousaud.
,, 11, subcutaneous injection of 0·4 grm. glucose; rapid cessation of the convulsions; administration of food.
,, 14.40, convulsions.

Insulin in Solution.

Rabbit ♀ weight 1,900 grm.
Time 8.30, injection of 0·3 c.c. (10 units per c.c.).
,, 10·40, glycemia = 0·61 per thousand.
No convulsions.

N.B.—In these experiments the same preparation of insulin was used, of recent date (September, 1924). Its hypoglycemic property was previously ascertained by repeated controls as follows: two milligrams of insulin, after two hours' reduction of the glycemic compound about 0·45 per cent.; successive beginning of typical convulsions. The glycemia was, as seen in the above results, constantly determined two hours after the injection of the insulin. The animals were kept fasting before the experiment for twenty hours.

From the above experiment we may infer that the insulin used by us, kept constantly at high temperature even for a long time, maintains its hypoglycemic property integrally, or remarkably well.

The preparation kept in solid form shows itself incontestibly more resistant than insulin in liguia solution. In fact, in the experiments at 100° for twenty-four hours, and in the experiments at 42° for thirty-five days, the property of the former was in no way modified, while the latter lost about one-half of its hypoglycemic property and did not cause convulsions.

Another consideration on the resistance of the experimented insulin is the length of its duration at a high temperature. The solid preparation in this respect, in the limited time of the experiments (twenty-four hours at 100° and fifteen and thirty days at 42°), did not undergo any alterations at all. Insulin in solution form appeared to be peculiarly influenced by the time of exposure; in fact, while it resisted integrally the temperature of 100° for ten hours, it lost about one half of its hypoglycemic power, both at the temperature of 100° in twenty-four hours and at a temperature of 36° in sixteen and thirty-four days. In consequence we get the following practical corollary in relation to the preservation in tropical climates of insulin experimented with by us: *the possibility of preserving the original hypoglycemic properties even at very high temperature and for a considerable length of time.*

These experiments were carried out with "Insulin Ergon" prepared in the Instituto Nazionale Medico Farmacologico of Rome.

THE ÆTIOLOGY OF BLACKWATER FEVER.

(*Concluded from page* 92.)

By W. M. HEWETSON, M.B., D.P.H.
Government Medical Officer, Sinoia, S. Rhodesia.

HÆMATOPORPHYRINURIA.

ROOF states definitely that "hæmatoporphyrin, the iron free derivative of hæmoglobin, is the precursor of bile pigments, which become reduced in the intestine to stercobilin, and stercobilin is identical with urobilin" [23]. Garrod's collection of the available information on hæmatoporphyrinuria in his "Inborn Errors of Metabolism" [24] is extremely important. And though the original should be read in full, I must here take leave to quote it very freely. Obviously work of the highest order pertaining more to pure than applied science, questions of general metabolism are raised by the subject, questions which cannot be ignored. They cannot be ignored because "pigments of this class are present in traces normally and in larger amounts, but still traces in sufferers from many maladies and in still larger quantities cause pathologic sensitization to light." Chlorophyll and hæmoglobin absorb light readily, but this intermediate product in anything beyond the normal traces sensitizes *other* tissues to light, causing it to have a *destructive* action. Yet so little of this substance is present that in Gunther's patient it was estimated at one-thousandth of a gramme in 100 c.c. of blood serum.

Gunther's case suffered from hydroa vacciniforme, and owing to the scarring, stiffness of the joints, and atrophy of the terminal phalanges, his index fingers were eventually amputated (Garrod).

The case of Meyer-Betz is now classic. He injected three grains of hæmatoporphyrin into a vein and rendered himself hypersensitive to light. Sunlight caused giant œdema, &c., and he had to live in a cellar for months, though hæmatoporphyrin *could only be detected in his urine for the first few days.* (*Ibid.*)

It may be of advantage to first make a short *précis* of the main facts given by Garrod, as follows: The porphyrins are not one, but a group. All have the four-pyrrol ring constitution. Their spectra are very complex and characteristic. They are present in traces in normal urine fæces, bile and meconium. They are present in larger quantities, but still minute, in many maladies.

"Upon a wholly different plane are cases in which the urine has a deep red colour, like that of port wine, rich in porphyrin, *and other abnormal pigments of which as yet we know little*" (italics mine).

Gunther's classification of this latter class:

(1) Cases of acute onset associated with severe toxic symptoms, abdominal pain most common and ascending paralysis most grave.

(2) Cases due to sulphonal and trional taken over

months or years, with similar associated grave symptoms—fatal ending the rule.

(3) Congenital hæmatoporphyrinuria—acute toxic symptoms wanting but greatly exalted sensitivity of tissues to light.

(4) (?) Chronic hæmatoporphyrinuria—probable that some of these congenital.

Total number of cases of congenital to date, about twenty.

It occurs in other mammals, e.g., bovines and pigs.

Nothing characteristic in the blood picture—in some cases. Enlargement of the spleen conspicuous, in some cases anæmia.

Hæmatoporphyrin in vitro sensitizes Red Blood Corpuscles to Light of 500 Microns, causing Lysis, and *in vivo Causes Death of White Mice.*

The paragraph following is taken as printed from Garrod, p. 157, but the first italics are mine. "Some twenty years ago Tappeiner and Raab discovered that certain fluorescent pigments, of which eosin is one, induce hypersensitiveness to light in lowly organisms such as paramecium. When a solution of such a pigment is added to a culture of the organisms they are killed by exposure to sunlight, but remain unharmed in a shaded portion of the same vessel. Hausmann showed that hæmatoporphyrin, which has likewise the property of fluorescence, exercises this photo-sensitizing power, not only with paramecium and red blood corpuscles, but also when injected into higher animals such as white mice. With infusoria and red corpuscles the effect is only obtained when the pigment is exposed in contact with the organisms. Hausmann showed that when $\frac{1}{100}$ gramme (= $\frac{1}{6}$ grain) of hæmatoporphyrin was injected into a white mouse subcutaneously the animal showed no ill effect so long as it was kept in the dark, but when exposed to bright light it died within a few hours."

"Hausmann (p. 161) showed by convincing experiments that the effects observed in the injected mice are mainly due to the *invisible* [italics in original] rays in the region of 500 microns, which is the region of maximum absorption in the porphyrin spectra."

Of course *in vitro* and *in vivo* are totally different, especially for red blood corpuscles. But at any rate we know that there is this specific sensitization by hæmatoporphyrin. *In vivo* any given corpuscle can only be exposed to light for a very brief period, possibly a second or so.

Relation of Hæmatoporphyrin to the Liver.

"We have still much to learn as to the source and origin of the metabolic porphyrin," says Garrod (p. 157), "but such knowledge as we possess is consistent with the view that hæmoglobin is its parent substance and the liver the seat of its formation, and with the hypothesis that what is lacking is an enzyme which is responsible for one of the stages in the conversion of blood pigment into bile pigment." . . . "Nor do we know whether excessive hæmolysis causes increased excretion of porphyrin by a porphyrinuric, as it should do if this hypothesis be correct" (Garrod).

"Guner (p. 155) found that hæmatoporphyrin (prepared in the laboratory), when injected into a dog, did not appear in the urine, but when the animal's liver was damaged by the administration of small doses of phosphorus for a fortnight injected hæmatoporphyrin did so appear" (Garrod). Details of other experiments follow, showing that the liver is the seat of the defect.

A Prima Facie Case.

Seeing that the hæmolysis of blackwater is so great and that in any given attack there is a strongly marked tendency for relapses to occur, the non-discovery of hæmolysins in the blood is remarkable and throws weight on the suggestion of the possibility of some such sensitizing product as hæmatoporphyrin being present and the cause of the hæmolysis.

The first objection, of course, to accepting this is that no excess hæmatoporphyrin has ever been noted. I can find no record of it ever having been sought for, and as the far greater quantity of hæmoglobin gives the usual bands in the spectrum, minute quantities might be overlooked.

"Some urines (of congenital hæmatoporphyrinurics) show only two bands very like those of oxyhæmoglobin, but if albumin be absent the presence of that pigment may be excluded" (Garrod). In blackwater fever albumin is always present, hence detection of porphyrins of such a class would be extremely difficult and call for high technical ability.

"In the cases (two brothers) described by Arzt and Hausmann the amount of porphyrin in the urine was far less than in other recorded cases, so much less that it is with some hesitation that the diagnosis is accepted. Nevertheless these cases cannot be excluded" (Garrod).

Besides the variety of porphyrins and the variation in amount we must not forget the "other abnormal pigments of which as yet we know little." Hammarsten, quoted by Dixon Mann, says that the colour of the urine in sulphonal hæmatoporphyrinuria remains the same after the porphyrins have been extracted.

At present, therefore, we can only study the peculiarities of blackwater and hæmatoporphyrinuria to see if these support a *prima facie* case.

To what are "Relapses" of Hæmoglobinuria due?

"Who has had blackwater once is prone to have recurrences," says Deaderick, opening his paragraph on "Previous attacks." Every practitioner who deals with the disease is aware of this. The tendency to relapses of hæmolysis is acutest during the period of illness due to any given attack. After recovery the tendency is still present, as Deaderick says, but in the course of a few years wears away (if the patient survives). Deaderick,

instancing the number of attacks of several individuals, some running into the teens, closes: "The only immunity except natural being conferred by prolonged residence in an endemic focus."

There is therefore in blackwater an acute sensitization during the attack of a less acute and semi-permanent one afterwards.

Some years ago I had brought to hospital for treatment an extremely fair-haired lemon-tinted child of 2½ years with a very enlarged spleen. The relative implored me not to give quinine as "she could not take it." She was treated with great care for several days, and no quinine, in order to "get her into a better condition in which she could be started on quinine." This was years before I had any idea of a sensitizer, but it shows the attitude of mind of a practitioner. I started her on a small dose—I think half a grain—and she promptly had hæmoglobinuria, which lasted some twelve hours. After a few more days' rest I gave an intramuscular injection of about three grains. This also, to my surprise, produced the same effects. Then I remembered a case of urticaria in which quinine could not be taken without it developing, but the patient could take it in combination (tabloid form) containing one grain per dose with iron and arsenic. This plan succeeded in this case also, and the patient, though she has had some attacks since in which I have not seen her, is now a fine schoolgirl of twelve, has at last lost her enlarged spleen entirely, and can take her quinine with impunity. Such cases are not at all uncommon. Children do not have nearly such grave symptoms as adults with blackwater.

In the white mice experiments of Hausmann, if smaller (non-lethal, i.e., less than ⅛ grain), doses of hæmatoporphyrin are given or "the animals are kept in a feeble light, a definite syndrome or true light disease, is presented." . . . "*The effect of the infection wears off in time.*" In the clear-cut personal experiment of Meyer Betz he was rendered "hypersensitive to light for two or three months," yet "hæmatoporphyrin could only be detected in his urine during the first few days." In these cases there was no recurring, liver-disturbing infection, as in malaria.

A second difficulty arises in Garrod's statement that "sufferers from hæmolytic diseases and paroxysmal hæmoglobinuria do not excrete porphyrin in excess." In the preceding sentence he says: "All the available evidence tends to show that an excessive excretion of porphyrin does not imply excessive hæmolysis." Well, in one class of case Prof. Dixon (*vide post*) stated that "the patient may bleed half the blood in his body in a few hours," that is, the distinct class of hæmatoporphyrinuria due to sulphonal. It is perhaps not a hæmolytic disease, but it is a hæmolysis of a severe type.

Let us examine these statements, however. With regard to hæmolytic disease, no information is available whether any congenital hæmoporphyrinurics have died in early infancy as a result of hæmolysis. In the first few days of life there occurs normally a considerable reduction in the number of corpuscles per c.mm. Icterus neonatorum, implying hæmolysis, is very common, in this country at any rate. Hæmatoporphyrin is present in the meconium. Why should sepsis of the umbilical cord in particular cause hæmolysis?

Of the hæmolytic diseases paroxysmal hæmoglobinuria most closely resembles blackwater, and the very close similarity is freely admitted. Blackwater, however, is vastly more common than this rare condition, and though no hæmatoporphyrin has hitherto been found, I submit that, in spite of this, it is worth careful investigation in blackwater.

Hæmolytic diseases, so far as their ætiology is known, appear to be widely different in manner of causation to blackwater fever, with the exception of paroxysmal hæmoglobinuria.

But I must take cover in Garrod's very guarded closing words: "So the matter stands at the present time (1923), and it is obvious that much remains to be done. Only by the investigation of fresh cases in the light of the knowledge which is now at our disposal can we hope to solve the problems still outstanding."

Diversity of Degree and Manifestations in Hæmatoporphyrinuria.

Preceding this (remembering also the main classification of Gunther, with their wide diversity of symptoms), he quotes some of the remarkable variations in the manifestations. "Hydroa is not an inseparable accompaniment of congenital hæmatoporphyrinuria," as is shown by the case of the bearded woman.

"Yet although the natural cutaneous eruption and the symptoms induced experimentally are not comparable phenomena, we cannot doubt that the sensitiveness to light which results from the presence of porphyrins in the tissues is the cause of the hydroa and the failure to reproduce the natural syndrome is presumably due to faulty technique."

"It is more difficult to explain the apparent discrepancies between the degree of porphyrinuria and the severity of the hydroa": Arzt and Hausmann's cases already quoted are instanced.

"In some cases, notably in one of McCall Anderson's, the urine is said to have been of normal colour between the attacks, and in others also it would seem that exposure to bright light causes both the porphyrinuria and the hydroa."

"Fischer suggested that the explanation of such observations may lie in the presence in the tissues of a chromogen of the porphyrin, a colourless reduction product which does not sensitize them to light. Saillet demonstrated the presence of such a porphyrinogen in the urine. Schumm has shown that it is promptly converted into the pigment by potassium permanganate and slowly by the action of light." This, if correct, is very significant, suggesting the possibility of oxidation in the blood by luminous rays which penetrate the skin on exposure to fierce light. Colourless porphyrinogens in the urine would escape detection by spectroscopy.

It is difficult to summarize the situation emer-

ging from this evidence, however. Experimentally hæmatoporphyrin and light cause lysis in red blood corpuscles.

Hæmatoporphyrinuria is due to a lacking liver enzyme.

Extensive acute hæmolysis with hæmatoporphyrinuria occurs with prolonged sulphonal taking; indicating from foregoing damage to the liver.

Chronic hæmatoporphyrinuria results in sensitization and destruction of tissues exposed to light.

That while the congenital liver defect, with excess of hæmatoporphyrin in urine, is extremely rare, the presence normally of traces of such an active substance in the urine, fæces, bile and meconium indicates that the substance plays a by no means insignificant part in metabolism.

That along with this theorem must be granted the enormous importance of the correlative factor —" reacting substance "—which can oxidize the colourless porphyrinogen to that of the pigment—namely, light.

The part played by these factors in ordinary metabolism awaits investigation.

There is only one known manner—sulphonal taking—in which urine rich in porphyrin is producable, and it is not known precisely what the relation between the hæmolysis and the hæmatoporphyrin is.

The Action of Quinine on Protoplasm and on Ferments.

An extremely valuable discussion on " Quinine and its Related Alkaloids in Pharmacology and Therapeutics," which took place at the annual meeting of 1920 and covers the exceptional experiences and lessons of the war, must be referred to at length. We shall take first the pharmacological action of quinine, by Prof. Dixon, who opened the discussion, and then in connection with it the question of blackwater and the sulphonal-caused hæmolysis with its peculiar feature of hæmatoporphyrinuria.

" Quinine is peculiar among alkaloids in that it has no very definite specific action on any particular tissue in the body. Since quinine depresses all living tissues in much the same way, its effect should be clearly discernible in metabolism. Our facts in this respect are not uncertain, though it is not simple to understand their interpretation. Under the influence of quinine and its derivatives general metabolism is lowered, as shown by the diminution in the excretion of urea, sulphates, phosphates and chlorides in the urine. The diminution of urinary metabolites is of such a nature as to leave us no option in concluding that there is a diminished protein breakdown, and we might from this with some confidence prophesy that there would be a simultaneous diminution in the absorption of oxygen and carbon dioxide output. Such however is not the case; the gaseous metabolism is hardly influenced. Furthermore, in febrile conditions the temperature is brought down, though the heat loss is not increased; that is to say, there may be other important sources of heat in the body besides the oxidation of carbon compounds. These facts are true in health and fever. Quinine therefore prevents excessive protein breakdown. It is unlike arsenic and many other drugs in that it does not diminish oxidation, so that no danger arises from increased production of acid, lactic, butyric, &c., from the incomplete oxidation of carbon compounds " (*Brit. Med. Journ.*, July 24, 1920, p. 115).

Absorption and Excretion. (*Ibid.*)

" It has long been known that the liver destroys morphine, nicotine and other alkaloids, and we have reasons for believing that this action is due to a ferment. . . . Ramsden has performed a similar experiment with quinine, and finds that the liver, kidney and intestinal wall have considerable power to destroy quinine post-mortem, but that the suprarenal bodies, spleen, bone marrow, &c., have not this property. It will be noticed here that the quinine tends to collect in high concentration in the spleen and suprarenal organs, and that it is just these organs which are unable to destroy it."

Prof. Ramsden, who followed, said: " Quinine is very rapidly destroyed by liver pulp. One of the products is quitenine."

It used to be taught that " Quinine is therefore very constant and very powerful in interfering with oxidation," but now we know, whatever the explanation may be of the temperature reduction, that this is not the method.

Prof. Dixon discusses quinine and blackwater with diffidence. " The story of the attack is clear in its suddenness, and points to a sudden liberation into the blood of poison which destroys the corpuscles. Many such poisons are known, but quinine is not one of them. Sulphonal given daily in large doses accumulates in the tissues, and the patient may be free from its ill effects for weeks, but on the sulphonal attaining a certain concentration it suddenly acts, and the patient may bleed half the blood in his body into the urine in the course of a few hours."

Sulphonal Hæmolysis and Hæmatoporphyrinuria.

He did not refer to the question of the hæmatoporphyrinuria associated with this delayed sulphonal poisoning, which one wishes he had done, nor did any of the others. Why should this feature be present with this particular cause of hæmolysis? Is the porphyrin merely *post hoc?* The experimental evidence submitted by Garrod that hæmatoporphyrinuria is due to some liver defect, probably an enzyme lacking, is fairly conclusive. In sulphonal hæmolysis, therefore, does this defect only appear after, and as a result of, the hæmolysis? If so, porphyrinuria should be constant with such hæmolyses. But if, on the other hand, sulphonal produced a special degenerative change in the liver cells, involving the production of a morbid quantity of porphyrin, not noticeable till the crisis occurred, but sufficient to cause sensitization to light, naturally we would, after the hæmolysis, get a urine very rich in porphyrin and attracting attention. And it would

then be assumed because *post* to be *propter hoc* also.

This hypothesis may be rather jumping to conclusions, but the grounds seem reasonable. At any rate it may be useful to assume it for the sake of conclusive investigation of the point. Should it be proven to be so, we would have a case of hæmolysis due to sensitization instead of hydroa and other syndromes.

It is further suggested that with recurring attacks of blood destruction, as by malaria, *vice* sulphonal, in which the liver undertakes the chemical clearing-up of the pigment debris—there is histological evidence of cell degeneration—that a sudden lowering of its already embarrassed activity by such means as quinine may interrupt the chemical changes of hæmoglobin into bilirubin and allow the production of this intermediate substance.

" Quinine retards all vital processes."

" The synthesis of hippuric and salicyluric acids by the surviving kidney is stopped by minute amounts of quinine. The action of quinine is therefore not confined to intact protoplasm, but extends to the ferments." (Dixon: *ibid.*)

" Washed tetanus spores given hypodermically to guinea-pigs or monkeys do not produce tetanus; if quinine is injected into the animals the day before or the day after the spores are injected, then tetanus is contracted (sample). Other alkaloids like morphine have not this action." (Dixon: *ibid.*)

Thus we have ample and definite evidence of the depressant type of action of quinine.

In the same category of lowered hepatic activity may be placed the other specially noticed immediate antecedents of the onset of blackwater, such as chill from a sudden wetting and exhaustion due to unusual exertion. And we have also by the same token an explanation of the fact that in non-malarial conditions and in malaria, when blood destruction is not actually in progress, no hæmolysis follows the use of quinine.

Statement of Theory.

My paper is already too lengthy. For some years it has been borne in upon me, from many observations which cannot all be detailed here, that there was some relation between light and the development of blackwater. Such connection could not, of course, be of a simple nature; it could only be associated with the occurrence of a morbid condition. Obviously that morbid condition must be malaria, by its peculiarities of association.

With due diffidence I suggest that the hæmolysis which constitutes blackwater fever is due to the presence of an optical sensitizer, probably one of the porphyrins, which is developed under certain conditions, causing lowered hepatic activity in the course of the active stages of malarial blood-destruction. The relations between the substance postulated, light and the red blood corpuscles are of a nature, according to the following summary of such processes, as laid down by Sir Wm. Bayliss:—

" Optical sensitizers belong to the class of catalytic light reactions. A system, insensitive to light of a particular wave length, can be made sensitive to it if a dye be present which absorbs this wave length. Since the light is absorbed by the sensitizer, it must act by means of the changes produced in this, resulting in the formation of some substance, frequently active oxygen or some catalyst, which acts on the system, which is by itself insensitive to the particular light in question " (p. 577) (26).

While not excluding simple photo-chemical action on hæmoglobin from a possible, predisposing share in the process of this hæmolysis, it is to the different, " trigger-like " action of a photo-dynamic sensitizer I attribute its occurrence. The investigation of the conditions which render such action possible are not less important than the discovery of the actual trigger.

Without going into any further analysis beyond that contained in the descriptions already mentioned of the circumstances in which blackwater occurs, I submit that we have here an hypothesis which fits like a glove to the facts of what Sir David Bruce calls " the conundrum of blackwater." How else can the co-relationship of the curves of malaria and blackwater shown by Thomson to exist be explained, and at the same time the disparity between the number of infected corpuscles and the extent of the hæmolysis, along with its inconstancy of development in malaria—its association with mild malaria and exceptional exposure to light and such circumstances as the use of a drug which depresses the vital activity of protoplasm and ferments, and finally with the sensitization which follows a first attack?

We come back to that most valuable simile of Manson, expressed in this country actually, of the oak and mistletoe, the former representing malaria and the latter the blackwater. Malaria is the primary condition, but again I refer to the fundamental significance of light action—just beginning to be understood and correctly appraised. My endeavour, though I confess to a sense of its inadequacy, has been to present the *a priori* evidence for the hypothesis stated and to indicate the satisfactory manner in which it explains the observed circumstances of the occurrence of blackwater. Proof of its correctness my limitations do not enable me to submit, but I feel confident that it will appeal strongly to those in practical touch with the disease. I trust that it will be fully investigated and hope that it may lead to the removal of the principal incubus to rural settlement of one of the otherwise most exhilarating climates in the world.

The question of the dynamic effects of light energy on the animal half of creation opens up a vast and, be it admitted, difficult field for research in physiology and pathology, one which may prove specially valuable in the problems which chemotherapy, as recently expounded by Dale, has to solve, while should it be proven in the future that catalytic light reactions occur it must have a bearing on the problem of the mechanism of evolution.

I am indebted especially to the great work of Sir Wm. Bayliss, " General Physiology," to Garrod's important work, standing like a finger-post on the road, and to the stimulating monograph by J. R.

Fulton, for many data which give a solid basis for the views expressed here, and to the last-named and Sir Arthur Shipley for kind encouragement in this study.

Some Observations on Blackwater Fever (E. P. Carmody, *Brit. Med. Jour.*, January 17, 1925).—Observations on thirty-six consecutive cases of blackwater fever in Southern Rhodesia are given, also an account of the method of treatment used. The conclusions of these observations are that a case of blackwater fever should never be moved if it can be avoided, and then only with the greatest care and for the shortest possible distance. No case should be moved for at least fourteen days after the onset, however slight the case may be. If possible a trained nurse should be obtained to see that the treatment is properly carried out. If subcutaneous saline injections are given at once the urine will clear up more quickly. The author feels confident that quinine does not cause this disease, or even act as the fulminant, and thinks the reason this idea has been entertained is that, the premonitory symptoms being indistinguishable from malaria, quinine is taken, and the onset of blackwater is credited to it. That blackwater fever is undoubtedly due to malignant tertian malaria has been conclusively proved by Professor J. G. Thomson, of the London School of Tropical Medicine, during his recent researches in Rhodesia. The prevention of malaria, and therefore of blackwater, lies in the hands of the colonists, if they will only take the extremely valuable advice published for their benefit by Dr. A. M. Fleming, the medical director for Southern Rhodesia.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All literary communications should be addressed to the Editors.

4.—All business communications and payments, either of subscriptions or advertisements, should be sent to the Publishers of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank Ltd.

5.—The Subscription, which is Thirty Shillings per annum, may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—Special Notice.—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to 25 reprints, free of charge.

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints if the order for these, with remittance, is given when MS. is sent in. The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 " "	1	3	3
200 " "	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 " " "	2	6	0
200 " " "	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

A WHITE AUSTRALIA: IS IT A POSSIBILITY?

By SYDNEY J. SKERTCHLEY, J.P.

(*Continued from page* 97.)

CHAPTER VIII.

The United States and Canada.

138. The unparalleled success of the United States seems, at first sight, to settle in the affirmative the question we are trying to solve.

The growth of the United States has been phenomenal, and to none does it appeal so powerfully as to those who, like myself, have seen the expansion of that great land and of Canada, and have watched the wilderness give place to township, to city, to thriving agriculture and the teeming population of mining centres. But yesterday, it seems to me, and Chicago was still spoken of as the Far West. To-day the Far West is almost a memory of the past. There are millions of good Americans who never set eyes upon a cowboy, save in the Wild West show, and there are more millions who have never seen a Redskin at all. "The Britishers licked the world, and we licked the Britishers," is no empty vaunt; and we Australians are still enthusing over the visit of the American fleet, a body that had practically no existence twenty years ago. I remember when the American flagship in Chinese waters was the old "Monocacy," a wooden paddle steamer, that dare not put her nose outside a harbour if it blew a capful, and whose top speed was about five knots. I saw the first American ironclad come into Hong-Kong, and her engines had well-nigh torn her plate rivets out. I, at any rate, can appreciate the wonderful advance of the United States. Is it permanent?

139. President Roosevelt put the case in a nutshell: *America cannot fill her own cradles.* She has depended on immigration, and this artificial increase cannot be maintained. Europe cannot stand the drain, and the rate of immigration has steadily declined. In 1893 the returns showed a decline of forty-two per cent., and last year so great was the deficiency that the huge German steamship companies for the first time failed to pay a dividend, and expended all their reserve capital. The North German Lloyd Company alone lost £892,000 in the year 1908. Their total earnings were but £460,900, as against £1,634,850 the previous year. Their steerage passengers were 185,000 less than in 1907. In 1907 the two chief German and two chief English steamship lines carried as many as 605,535 passengers, in 1908 the number had fallen to 175,518, a decline of no less than 430,017. The Cunard line did not actually make a loss, but, owing to heavy decreases, failed to pay a dividend. The directors say that "the total number of passengers landed at New York and Boston fell from 1,116,000 in 1907 to 335,000 in 1908," a decline of 781,000.

140. Of course, there were exceptional conditions prevailing, and all the passengers are not immigrants. But, allowing for this, the decline in the number of immigrants is part of a steady decrease that has been going on for years. Between 1893 and 1902 the immigration returns show a decline of forty-two per cent., and the decrease continues, though nothing like the late sudden drop in numbers has occurred before nor is likely to be repeated. Still, it shows how artificially bolstered up is the present system of immigration, it is no longer spontaneous.

141. Even to keep up the numbers of this declining migration great and artificial efforts had to be made. The exodus from Europe was ceasing to be spontaneous, and the great German shipping firms have flooded Europe with agents who, as recruiting sergeants, will lay the most tempting, and not always strictly veracious accounts of the wealth, or at least the comfortable existence that was the lot of all in those far fields that are always fairest. During a recent visit to Holland, Germany and Austria, this fact was driven home to me. It is hardly overstating the case to say that, for instance, in every little town in Bohemia these shipping firms were better advertised than in Brisbane, and the allurements were set forth in artistic posters, in attractively written pamphlets, and agents and railways vied with one another to make the would-be wanderer's ways paths of pleasantness. There was a Moses in every hamlet ready to conduct the children to the promised land —for a fee. And this is how the United States have for some years been stocked; these are the recruiting wiles that have filled the ranks of an army that was always being decimated at the front.

142. From 1654 to 1800 the immigration amounted to some 600,000, or say, 4,000 per year. By that time the natural increase of the English population of the States had become almost phenomenal, and justified Jefferson in prophesying that by 1875 his country would contain eighty million inhabitants. Franklin called the world's attention to the wonderful fecundity of the colonists; in some parts the population had doubled in twenty-five years, and at the beginning of the last century the States held some five and a half million of people. But this state of things was only temporary. In 1860 a most exhausting search was made of town records in the New England States, "when it was discovered that the first generation of Americans had families of ten and twelve; the second, third and fourth, families of seven and eight; the fifth, families of four and five; the sixth, families of three and less." Indeed a report by Dr. Jesse Pickering to the city government of Boston, in 1851, had already shown that there was no natural increase in the strictly American population. I am chiefly indebted for these and other statistics to a remarkably able paper by Mr. J. Waston, in the *Nineteenth Century* review of December, 1902.

(143) The fact is that the White Race, like many introduced plants and animals, tends to run riot in fertility when transplanted into new soil, but by the very effort they expend their vital energy and a deadly reaction ensues. If the American soil is so fitted for us Fair Whites we ought to prove it in the case of Massachusetts. Yet its life-blood has been foreign these fifty years. In 1900 the population was 2,805,346 of which 1,743,710 were foreign born or of foreign parentage; that is out of every ten six were foreigners. As Mr. Waston says, "To put it shortly, two hundred and seventy-five years after the landing of the Pilgrim Fathers the stronghold of Puritanism is held, not by the ever-declining American, but by the Irish, the German, and the French Canadian."

(144) Nor is this decrease due to the opening up of the West by the eastern Americans. These lands have been peopled rather by Old England than by New England. The population of Illinois, which includes the great city of Chicago, was in 1902, 4,821,550, of whom less than half are of native American stock.

(145) The decline in the native birth-rate began in the second decade of the last century. "As late as 1840 the increase in the population by reproduction was 28·01 per cent., by immigration 4·66. By 1890 the first had dwindled to 14·40 and the second had increased to 10·4." In New York in 1890 the registered births of Americans was 27 per cent. and of foreigners 73 per cent. of the whole. So one might go on, taking city after city, State after State, always with the same result, that there is no natural increase of the native American, and that the population is only kept up by immigration. This is not due to any diminution of the virility of the Fair Whites as a whole: on their own soil they are steadily increasing as the English statistics show. Old England has not only filled her own shires, but has sent her surplus abroad over the world in greater numbers even than to the United States.

(146) But even with the enormous influx of foreign blood the States have not maintained their anticipated increase. It was faith in this steady increase of the Fair Whites that alone permitted the formulation of the Monroe doctrine of "America for the Americans." Unless the Americans could more than hold their own the cry was absurd. President Roosevelt said "I believe in the Monroe doctrine with all my heart." Yet soon after, and many times, he has had to insist that, "A man to be a good citizen must first . . . be a good father; I hope the father of many children." Why this appeal, this half despairing cry, if he did not realize that it was in the cradle and not in the immigration bureau that the future greatness of his country lay?

(147) According to actuarial statistics the population of the United States in 1893 should have been 100,000,000: it was only 63,000,000: a shortage of 37,000,000. And of this population nearly 9,500,000 are coloured people, negroes or Asiatics. In 1900 the population was 76,000,000, but as Mr. Waston shows "it can readily be seen that only half the population of the United States is American in the true sense of the term." From 1850 the foreign birth-rate has gained on the American until now it is four times as rapid. This does not mean that the foreigners are naturally more prolific but merely that on the new soil the stimulus is being felt, as it was by the English of the earlier date: the foreigner himself will slow down in his rate of natural increase. A writer in the *Popular Science Monthly* goes so far as to aver that "we have not so many people as we should have had if immigration had never come to us, and the native stock had continued their old rate of increase." This is undoubtedly true. No nation can possibly maintain itself by immigrant accessions: the native stock first dies, the newer stock succumbs in like manner after awhile; and the issuing countries become exhausted. The armies of immigrants lose nearly every battle, and the mother countries cannot stand the strain and drain of incessant recruiting. The solid glacier ice, impelled by gravity, supplied by annual snows, can protrude its foot into the midst of the vineyard, but an unseen foe inexorably slays the advance guards: and in the human glacier the recuperating snows are not inexhaustible and the ice-foot melts as before.

(148) We have already (pars. 139—142) demonstrated this last fact: we have now to illustrate an alarming danger in the character of the immigrants themselves. The real stamina of the Americans is derived from their Fair White blood; they are heritors with ourselves of all our glorious traditions; their law is our law; their polity our polity. Nothing, under present conditions, can bring us into armed conflict again. Only this week the English Premier called attention to the significant fact that the increase of the American navy was not a menace but a strength to England, and that the number of her warships would not, need not, could not, be taken into consideration when keeping our fleet up to two-standard power. "Blood is thicker than water" was proven in Manila Bay as clearly as at the Taku Forts. But be it remembered it *is* blood that binds; if that blood be altered the whole condition is changed. Let us see if it is changing, and again I take my figures (which are official) from Mr. Waston.

(149) Here is a table showing the numbers and nationalities of the immigrants from Europe to the Republic during the last two decades:—

Year	British Isles	Germany	Scandinavia	Russia	Italy	Austria-Hungary	Roumania
1881	153,718	210,485	73,597	10,655	15,401	27,735	—
1886	112,584	84,403	48,005	21,739	21,315	28,680	—
1891	122,085	92,247	41,002	43,880	51,799	56,199	517
1896	64,827	31,185	30,062	45,828	68,060	65,103	785
1901	48,237	18,507	28,225	90,789	100,135	114,847	6,459
1902	45,273	28,304	48,378	107,347	178,372	171,989	7,196

(150) This is an appallingly significant table. The first three columns may be taken as representing the Fair Whites, exclusive of the Slavs, and the last three the Dark Whites. For our purpose we must take the first three in contrast with the last four, for the Slavs have no connection with the Anglo-Saxon (Teutonic) stock. That is to say, that whereas in 1881 the emigration from south-eastern Europe was only 12 per cent. of that from Britain, Germany and Scandinavia, by 1902 it was double that of the Fair Whites.

(151) Mr. Waston puts the case thus: "The stream of British emigration to the United States has thus declined to less than one-third of what it was in

1881, Scandinavian to about two-thirds, and German to less than one-seventh. On the other hand, the stream of Italian immigration is more than eleven times greater than it was twenty years ago, Russian ten times, and Austro-Hungarian six times. Roumanian immigration, which in 1881 was so small as to be included in official returns under the heading various nationalities, increased nearly fourteen times. The number of Scots who settled in the United States in 1882 was 16,441. It is now 2,560, and last year (1901) was 1,000 less. The number of English immigrants has declined from 77,570 to 13,575. It is therefore evident that the only people of Teutonic origin which goes to the United States in anything like its former strength is the people of the Scandinavian peninsula."

(152) Between 1820 and 1899 no fewer than 19,050,328 persons settled in the United States, of whom over 6,250,000 were Germans and Scandinavians. The bulk of the immigrants came from western Europe: since 1893 the tide has changed. "As long," says our much-quoted author, "as the new blood poured into the United States was largely of Teutonic origin, she could look into the future without misgiving, but now that it is a mixture from Southern and Eastern Europe, it is another matter. Rightly enough the Republic prides herself on her Anglo-Saxon spirit, and creative force, and admits that it is essential to her wellbeing to preserve her racial affinity with the mother country. . . . It is these who made the United States what it is, not the people of South-Eastern Europe, and by them it will be [rather, can be] alone maintained. Hence the anxiety of thoughtful Americans as they perceive more and more clearly that the Old World no longer sends to them of her best." I would that Mr. Waston's thoughtful paper were studied by every Australian. I had arrived at my conclusions before discovering it, and am pleased to let so calm and able an expositor take this action practically out of my hands.

(153) The United States are getting further alarmed at the vast influx of Americans into Canada: a few years ago the tide was all the other way; but upon this we must not enlarge. Still the question will be asked, have we been more successful in Canada?

(154) Canada has an area of close on 3,500,000 square miles, about one and a quarter the size of Australia. Her population in Jubilee year was about 4,400,000, or say twice that of Australia at that date. Yet her first permanent settlement was almost exactly 300 years ago (1608). Surely this is not any very striking proof of natural increase; and Canada has received her full and continuous gift of immigrants. But this refers to the Dominion of Canada, which only came into being in 1867, prior to which Canada was only about 1,000 miles long by from 200 to 400 miles broad, and was divided into Upper and Lower Canada.

(155) M. de Quatrefages cites the French Canadians and Acadians (Newfoundlanders) in proof of French blood being able to sustain itself on American soil, and as practically there is no French migration whatever to Canada or Newfoundland, the case is a good one.[1] Let the learned French savant be heard first.

(156) Criticizing Dr. Knox and those who see things as I have been compelled to see them, he proceeds: "If the human current, which sets from Europe towards the colonies, were to be stopped, they maintain that the population would rapidly diminish, and the local races would regain the ascendancy, that the United States would return to the Redskins, and Mexico to the descendants of Montezuma." I break the quotation here to remark (1) that as the Paleface has destroyed the Redskins' food—buffalo, deer, bear, &c., this is not a fair statement, and (2) what he thought impossible of Mexico when he wrote in 1886 has come to pass before 1908. But to continue.

(157) "This assertion will be easily answered by a few statistics. They are taken from the history of the French races, which, since the Treaty of Paris in 1763, have, although in a slight degree, directly contributed to the peopling of Canada. There were in this country:—

In 1814	...	275,000 inhabitants of French Origin	
,, 1851	...	695,945 ,, ,,	,,
,, 1861	...	1,037,770 ,, ,,	,,
In Ottawa State there were:			
In 1851—Total population	...	... ...	15,000

"The history of the Acadians furnishes statistics which are quite as convincing. From the information obtained by M. Rameau, it appears that the entire population was descended from forty-seven families, numbering 400 souls in 1671. In 1755 there were 18,000. Dispersed and driven out by the English they were reduced to only 8,000. In 1861 the number rose to 95,000 persons" ("Human Species," p. 215).

(158) We will take the case of Canada first, and admit the correctness of M. de Quatrefage's figures; and also that since the land became British France has not materially contributed to its population. He shows that in forty-three years the French have increased by 762,770, an average of 17,739 per annum. Now the census of 1876, the latest available to me giving details, returns the French population as 1,082,940, or an increase of only 3,011 per annum. If M. de Quatrefage's figures are right here is a terrible falling off: if they are wrong they cannot be used in argument. But let that pass. Surely the fact that in 300 years the French population has only grown to little over a million is significant.

(159) With respect to Newfoundland, the French author's figures are clearly incorrect, of course quite innocently. So far from there having been only forty-seven families and 400 souls in 1671, we have an official record that in 1654, or sixteen years earlier, there were 350 families, numbering 1,750 souls, settled in fifteen settlements on the east coast. By 1680

[1] In 1901 there were only 7,944 of French origin, as against 27,300 Germans and 31,231 Russians in Canada, and no less than 386,545 from the United Kingdom.

the number of persons had risen to 2,280, by 1763 to 7,000, and the numbers rose steadily till in 1883 the total (not merely French) population was about 185,000. Taking this entire French and British population we find the rate of increase was :—

Between 1845 and 1857	25 per cent.
,, 1857 and 1869	18½ ,,
,, 1869 and 1874	10 ,,

These official figures most certainly do not confirm the French writer's statement.

(160) I gladly, even proudly, admit that the native-born Canadian, British and French, have not deteriorated in intellectual powers. I think they have proved themselves the wisest and most far-seeing colonists the world ever saw, and that splendid French-Canadian-Britisher, Sir W. Laurier, is assuredly a world-compeller of the first rank. I am not so certain about the physique; it is hard to judge in such a mixed community, but I incline to think it too has maintained its vigour in the land of the maple-leaf. But a man to possess a fine physique and a strong intellect must get himself born to start with, and statistics do not show the Kanuck to be a better cradle-filler than his American cousin the other side of the forty-ninth parallel. If my supposition be true then Canada is the happy hunting-ground of the would-be pioneer.

(161) The typical Yankee, as he depicts himself, the Uncle Sam of his own cartoons, shows that he has spindled out in the air of the States. He is lank, shambly, and goat-bearded; he even depicts himself as becoming hawk-beaked like the Redskin he exterminated. Nations do not willingly libel themselves, especially people as sensitive as the Americans, and yet their ancestors were the sturdy, farmer-like John Bulls delineated as the English type alike in London's *Punch* and New York's *Puck*.

(162) Canada's population is now considerably over 4,000,000, exclusive of some 85,000 Indians. But she has not peopled it with her own blood. An analysis of the 1876 census makes this startlingly clear, and this is before the recent great influx from the United States, which now amounts to several hundred thousand. Here are the figures :

French population	1,082,940
United States immigrants	64,447
Irish	850,000
English	700,000
Scotch	550,000
German and Dutch...	230,000
African (negro)	22,000
Welsh	7,800
Scandinavian	7,000
Italian	1,000
Spanish	900
Total ...	3,516,087

If we deduct the French, who are natives, and the United States whites and negroes, who are American born, we have a non-American addition of 2,346,700; that is to say every other person in the Dominion was born in Europe.

(163) But this is hardly fair to Canada. It supposes that she kept all her children at home, like the United States, and did not supply immigrants to other countries. Such is far from being the case. Canada was rather sore when the neighbouring Republic in 1882 said that over 70,000 Canadians had settled in the States; but facts cannot be denied, and the 1890 census showed how great the exodus had become. It recorded 980,938 American citizens of British North American birth, and estimated there were nearly as many of Canadian extraction. Hence one must add nearly 2,000,000 to the figures above given. Canada had copied the Mother Country in sending forth her young sons, but she felt the strain, and made a mighty and successful effort to keep the young folk at home. Since 1890, she has reaped the benefit of her statesmanlike, far-seeing policy, and the tide of immigration has set the other way, till now it is the States that are apprehensive.

(164) Still this was only an ebb and flow across an arbitrary border; it was a tide on American soil; and does not affect our argument. The glaring fact remains that both the Dominion and the Republic viewed with alarm the crossing of their own peoples over the frontier. They knew they could not afford it, and this is the most significant fact of all. The old country was so fertile that though she sent out but 100,000 in the years 1815-48, in 1847 alone 258,270 persons left her shores, and between 1860-73 the annual average was no less than 274,645. Between 1820 and 1869 Great Britain sent 1,303,959 colonists to British North America, and 971,285 to Australasia, and benefited instead of being crippled by the effort.

(165) Now observe what this means. It shows that neither the United States nor Canada, collectively or individually, is in the condition to take up the rôle of England as mother of nations. They have received much and have given nothing in exchange, for they had nought to give. Cut off the supply of immigrants and North America would be paralysed. I do not think the United States would survive; I am not so sure about Canada, and for the following reasons :—

(166) If the United States and Canada had a physiographic instead of a political frontier, it would not be drawn along the 49th parallel, but along the waterparting of the rivers draining into the Arctic seas. This is, broadly speaking, a northward sloping plain that is swept by the cold north winds; and it is the wheat land, as distinguished from the maize land to the south. In other words, it is the exact counterpart of the native home of the Fair Whites, and here, if anywhere on earth, he has a fair chance to establish his race. I fancy he will and can; I am afraid he will not and cannot, in the less rigorous United States proper. And if these cease to be Fair White, then good-bye to the Monroe doctrine, good-bye to the blood-thicker-than-water federation, good-bye to all that has made the American, as he proudly calls himself, the amazing giant that he is.

Annotations.

Nervous and Mental Complications of Antityphoid Vaccination (G. Rousselet, *Thèse de Paris*, No. 129, 1924).—Nervous and mental complications in typhoid fever are rare. Among more than 3,000 patients admitted to the Nantes Psychiatric centre from 1914 to 1919, Benon found only four or five cases in which the origin of the affection could be attributed to this cause. Only five cases, in which neuropsychic symptoms developed after antityphoid inoculation, occurred at the centre for psychoneurosis of the military Government of Paris in 1916. Eleven cases have been observed by Mairet and Pierou.

Ectopic Gestation in Chinese Women (Arthur W. Woo, M.R.C.S., *The Journal of Obstetrics and Gynæcology of the British Empire*, No. 3, vol. xi, November, 1924).—Ectopic gestation occurs frequently in China. Probably its incidence there is about the same as in the countries of Europe. It is found in all the provinces of the Republic. Its features are the same as in the West, but owing to the reluctance of many patients to come to hospital or submit to operative procedures, a large number of cases never come to light and some are admitted to hospital only after the trouble has been allowed to drag on for some time. When the cases are submitted to immediate treatment the results are as good as those obtained in the West.

Korsakoff's Psychosis and Typhoid Fever (P. Gerbeau, *Thèse de Paris*, No. 203, 1924).—The author records an illustrative case, and states that typhoid fever may be complicated during the acute stage by a number of mental disturbances, the commonest of which being mental confusion, ill-systematized hallucinatory delirium, and Korsakoff's psychosis. The essential features of the latter in typhoid fever, as in other infections and intoxications, are amnesia of fixation, fabulation, false recognition, and euphoria. As a general rule Korsakoff's psychosis in typhoid fever is not accompanied by polyneuritis, which is not an essential feature of the syndrome and may be absent in other infections and intoxications. The prognosis is usually grave. The treatment should be carried out in a psychiatric clinic and not in an asylum.

Some Etiological Factors of Tuberculosis in India in General and in Bengal in Particular (Ashutosh Roy, *The Indian Medical Journal*, No. 11, vol. xliv, November, 1924).—Tuberculosis is on the increase in India especially in Bengal and Calcutta. The author states that it is wrong to ascribe it to one etiological factor. The immediate cause is the entry and lodgment of the bacilli in the organism, rendered suitable for reception of the germ by a multiplicity of causes, which he enumerates; among them, change of country life for the city the debilitating effects of malaria, the miserable economic conditions of the middle and poorer classes, insanitary public restaurants, &c. In Bengal the chief cause of the disease is protein insufficiency. Tuberculosis should be studied from social, economic, racial-atmospheric and climatic points of view, besides the bacteriological, to prevent further spread of infection.

Pulmonary Infection with the Spirochætæ and Fusiform Bacilli (Clyde McNeill, *Johns Hopkins Hospital Bulletin*, November, 1924).—The spirochætæ and fusiform bacilli are widely distributed throughout the world, and have been known to cause a great variety of lesions in the human body, including infections of the skin, external ear, middle ear, gums, mouth, throat, gastro-intestinal tract and bronchi. To this list is added an infection of the parenchyma of the lung—a disease that may be clinically and roentgenologically indistinguishable from pulmonary tuberculosis, but which is easily diagnosed from a stained smear of the sputum, and heals like magic under intravenous salvarsan therapy. A case is reported in detail with full clinical, laboratory and X-rays studies.

Oleum Morrhuæ in Typhoid Fever (Kartic Chunder Dutt, *Indian Medical Record*, No. 11, vol. xliv, November, 1924).—The author has used cod-liver oil in numerous cases of typhoid and paratyphoid fever during the last twenty years, and has found this method of treatment appreciably diminishes the mortality in these maladies. It supplies the fat and vitamin necessary to make up for the tissue waste which inevitably occurs in all cases of fever.

Correspondence.

DISEASES OF CENTRAL AMERICA.

To the Editor of the JOURNAL OF TROPICAL MEDICINE AND HYGIENE.

SIR,—I was much interested in reading in the issue of the JOURNAL OF TROPICAL MEDICINE AND HYGIENE for January 1, 1925, the paper by Dr. Castellani relating his observations on some of the diseases of Central America. As I had the pleasure of visiting and working for some time in British Honduras in 1923, perhaps I may be permitted to detail a few observations I was able to make on certain of the disease conditions mentioned by Dr. Castellani.

Filariæ.—I was not fortunate enough to meet with the interesting condition described by Dr. Castellani as Guatemala onchocerciasis, but apparently its geographical distribution, as far as it is at present known, is a very limited one. Moreover, it is to be noticed that all reports on its occurrence appear to show that it occurs in individuals living at a considerable altitude. In British Honduras the vast bulk of the population

live on the low-lying lands, and in the interior where higher land is met with the population is extremely scanty; no case of nodules on the scalp was ever seen by me, and even if such a condition exists in British Honduras it must be extremely rare.

I quite expected, however, to find cases of infection with other filariæ, especially *Filaria bancrofti* and possibly *F. perstans* (*Acanthocheilonema perstans*) seeing that these organisms are met with in many of the southern of the West Indian islands, and especially in British Guiana. Although I examined over 200 individuals, including patients in hospital, and inmates of poor houses and the lunatic asylum, I was not able to find a single case of infection with any filariæ.

No condition suggestive of filariasis was met with, and the annual medical reports of the colony over several years, which I was able to study, make no mention of the condition.

Medical men in practice for a number of years in the colony assured me they had never seen any indigenous cases.

In British Guiana many of the wild birds harbour filariæ of various species, which appear to be peculiar to birds and not capable of infecting man. In order to ascertain whether the birds of British Honduras were likewise affected, I shot a large number of different species of birds and submitted them to examination. In only one instance was I able to find microfilariæ in the blood. These occurred in a species of water-hen, known locally as the "Two-penny Chick." In passing, it may also be noted that it was quite common, in the blood of birds in British Guiana, to find some species of *Plasmodium*, but none were ever seen in the blood of any birds I examined in British Honduras.

Myiasis.—I was fortunate in coming across several cases of this condition, all of which presented the "boil-like" type described by Dr. Castellani. In one case I was able to hatch out the fly from extracted larvæ. Having obtained some mature larvæ from a case, I induced them to pupate in a dry bottle with some cotton wool. Having within two days passed into the pupal stage, they remained in this stage for almost exactly a month, when the adults hatched out, presenting the characters of *Dermatobia* (? sp).

The maggot is known locally as the "beef-worm." I was much interested in the possible way by which man became infected, and had the opportunity of discussing the matter with an extremely observant Government officer. His duties necessitated frequent journeys into the unfrequented hinterlands where he often had to literally hack his way through dense bush. His clothing consisted of a bush shirt, widely open at the neck, and riding breeches, with the usual covering of the legs and feet. He was in the habit of wearing a belt around the top of his breeches.

Each time he came back from his expeditions he was the unhappy host of some ten or a dozen or more of these "beef-worms," which almost invariably were embedded in his body just above the line of his belt. He stated it was his belief that the eggs of the fly were deposited on foliage, and that in cutting his way through the bush the eggs fell off on to him. Some of these would fall on his neck and upper part of his back, and would get inside his shirt and come to rest just above the constriction of his belt. The heat of his body would hatch the eggs, and the larvæ would proceed to bore into his flesh. He had also noticed that if he went without his belt, it would appear that the eggs were able to make their way down his legs, until obstructed at the knee by the tight-fitting breeches. It such cases the maggots were found embedded in the flesh at that position. He did not consider that the infection was obtained through the intermediary of any biting insect, e.g., *Janthinosoma*.

Leishmaniasis.—No instance of the Brazilian type of leishmaniasis known as espundia was met with, but a form of ulceration almost certainly leishmanial in nature, and known locally as "bay sore," was met with on several occasions. This form of ulceration, which clinically is indistinguishable from leishmanial lesions, commonly attacks the ear and more especially the lobe, from which it slowly invades the surrounding part. The condition is a very chronic one, but will eventually heal with the loss of a considerable part of the external ear.

It appears to chiefly attack people engaged in mahogany cutting, or in the collection of chicle (gum used in the manufacture of chewing gum), and whose work is carried on in the bush. Although I am convinced that the condition is a manifestation of leishmanial infection, I was unable to demonstrate the causative organism in scrapings of the sores, but this failure was in all probability due to the fact that all the cases I saw had existed for many months, and, as is well known, there is often a great difficulty, or even impossibility, to detect the organisms in such cases.

Unfortunately I had not the means at hand to undertake cultural experiments. Two cases of what Dr. Castellani described as the oriental sore type, were seen, the lesions in each case being on the back of the hand.

The treatment most favoured for these cases consisted of the injection into the periphery of the sores of a solution of emetine, and certainly, in my experience, it worked very well.

Pinta.—Several cases of this interesting condition, attacking the forearms and backs of the hands and also the lower part of the leg and dorsum of the foot, were seen. The manifestations were all of the black and white patchy variety. Opportunities for cultural work were not available.

It is interesting to note the native's idea as to the cause of this condition. One and all firmly believe that it is caused by the consumption of the flesh of the "mountain cow." What this particular animal is, I am not quite sure, but as far as I could ascertain it seemed to be the tapir. Be that as it may, it is firmly believed that the eating of the flesh of this animal is invariably followed by the appearance of pinta.

I am, Sir,
Yours truly,
H. B. NEWHAM, M.D.

A CLINICAL STUDY ON MALARIA IN THE NEAR-EAST AND IN EUROPE.

BY

A. PAGNIER, M.D.,
Paris.

P. SCHRUMPF-PIERRON, M.D.,
Professor of Internal Medicine, Cairo.

INTRODUCTION.

THE Investigations of which we publish the results lasted upwards of ten years. Some of them were made in the Malarious Centre (Orient Army) of Gradobor, a village fifteen kilometres from Salonica, in the marshy valley of Galliko, which centre was under the direction of one of us from July 1, 1916, until September 1, 1918.[1]

To the observations made at Gradobor are added those touching the numerous malarial patients treated by us before, during and after the war in Europe and who contracted the disease in the Near-East, Southern Russia, Poland, Roumania, Holland or along the Rhine.

It amounts, therefore, to a study of the types of malaria met with, especially in the Near-East and around the Mediterranean Basin generally, to the exclusion of tropical malaria.

In these parts, as also in those European countries where malarious centres still exist, two main forms of this malady are found: the form due to *Plasmodium vivax* and the one due to *P. falciparum*, whereas infections caused by the third variety, *P. malariæ*, are exceedingly rare.

Malaria, so far as it is a parasitic disease, comes under the general laws of all such maladies. It presents:

(1) Variations corresponding to the infecting agents predominating in given areas and at given times.

(2) Variations in the gravity of the infections.

(3) Variations as to the organ selected for attack: spleen, liver, bone-marrow, &c.

It ensues that:

(1) *Malaria cannot be studied and classified at a distance from its seat of evolution and predilection. This can be done with advantage only by long observation on the spot from the beginning, i.e., the infection period, until its time of full development and chronicity in one and the same individual.*

(2) *No exact knowledge can be had concerning the fate of malarial patients after their departure from the country where they became infected, except by keeping them under close observation for several years.*

If, as will be seen to be the case, the conclusions drawn by us from our observations do not always tally with generally accepted opinions, and even differ considerably therefrom in many respects, it is because the majority of writers who have studied malaria have ignored the above principles.

INFLUENCE OF ATMOSPHERIC TEMPERATURE ON THE EVOLUTION OF MALARIA.

Chart I, which is a document unique of its kind, was made in the hospital at Gradobor, and extends from July 1, 1916, to September 1, 1918; that is to say, twenty-six months.

It shows in the clearest way the influence of the several atmospheric factors upon the development of malaria.

This drawing has the following curves:

(1) *Upper Curves.*— These relate to malaria sufferers in whose blood parasites were found. The full curve indicates the *P. falciparum* cases; the dotted one those due to *P. vivax*. The indications are summarized by decades.

(2) *Middle Curves.*—By these are shown the maximum (dotted curve) and minimum (full curve) temperatures in the shade.[1]

(3) *Lower Curves.*—These indicate the rainfall, measured with the pluviometer.

(4) At the bottom of the drawing there are some general meteorological details as to wind, storms, snow and so forth.

The conclusions to be deduced from this drawing are the following:

There are two outbreaks of malaria per annum; a mild one in winter (February and March in 1916 *and* 1917, *April in* 1918), *and a severe one which attains its culmination from September to November. These two outbreaks have characteristics differing widely, as follows:*

(a) During the active period, lasting from February to April, the circulating blood is always found to contain *P. vivax to a predominating extent.*

(*b*) *During the severe increase in September-November the circulation contains a markedly predominating quantity of P. falciparum.*

Furthermore, P. vivax, which always appears first, begins to decrease when P. falciparum makes its appearance in the circulation:

Is this because:

(1) One form disturbs the other? or

(2) Does quinine destroy *P. vivax* quicker than it disposes of *P. falciparum*?

We think not, for its administration preventively, effectively, and its administration curatively, in large doses, neither of which was done in 1916, would, in 1917 and 1918, have modified the proportions. Now this has not been the case. Moreover, there are mixed forms, where we find simultaneously *P. vivax* and *P. falciparum*.

We lay stress on the fact that these curves are true; they do not merely represent percentages more or less factitious.

[1] In these investigations as a whole we were aided by the work of Dr. Casenave (Algeria), Dr. Carabinas (Greece), Dr. Dziffras (Greece), Dr. Magallon (Martinique), Dr. Guérard (Colonial Army), Dr. Scheniot (Russia), Dr. Karlinsky (Russia), Dr. Nattanson (Poland) and Mr. Noel Nougat, hospital attendant.

[1] The original Gradobor curve gives them, of course, day by day, but, for typographical reasons, that original could not be reproduced here in its entirety.

If the 1917 and 1918 curves are higher, it is perhaps because the paludism was more severe (yet all the cases examined were treated therapeutically with heavy doses according to official prescriptions); but especially is it because there were then many more soldiers in Macedonia than during the first-named year.

Therefore, some general cause, other than individual resistance, other than the treatment, and other than the mutual antagonism of the forms of parasite, must be held to govern this alternation of species.

This cause is the medium, the external temperature. This is the vital factor.

In analysing Chart I we find that:

(1) *P. vivax always appears when the temperature is near zero (Centigrade) with considerable variations during the day (1917 and 1918 February-March) in relation to the rainfall. It is most prevalent when the lowest temperatures of the day are about 5° C., from which time it diminishes progressively.*

(2) *P. falciparum always appears when the minimum temperature reaches from 25° C. to 30° C., after which time its frequency increases in spite of the progressive fall in the temperature towards zero. Between 5° C. and 0° C. it begins to decrease and P. vivax reappears.*

(3) *During the period of rising temperature, between 5° C. and 25° C., eastern paludism, whether in vivax or falciparum form, is in the latent stage.*

(4) *Assuredly there are mixed forms. These have the drawback of displaying the symptoms in winter and in summer and autumn.*

Two other features are brought out by the examination of these curves.

(1) *P. vivax makes its appearance in the wet season.*

(2) *P. falciparum turns up in the dry season,* so long as the minimum temperature has not gone beyond from five to ten degrees.

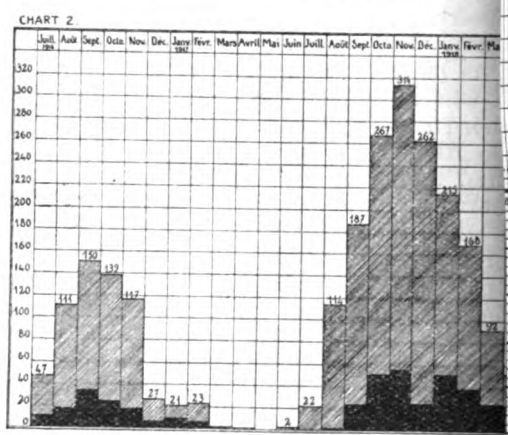
Why does *P. falciparum* continue coming forth during the period of falling temperature (we are dealing all the time with "quinined" cases) when it does not do so during the corresponding upward trend of the thermometer?

This phenomenon is due to the fact that a high temperature is necessary for the appearance of gametocytes in the blood, i.e., to start the reproductive stage, which lasts until the external temperature has again reached 5° C. At this point a reproduction seems no longer possible.

Now since the war, we have, in all the malaria patients observed by us, verified this fundamental law: that the onset of both vivax and falciparum attacks depends chiefly on the temperature of the air.

Recapitulation.

(1) *All the patients to whom this curve relates were treated in hospitals in the officially prescribed manner, with as much as three grammes of quinine daily. The absorption of the drug was closely watched, and most of the cases were treated by injections.*



(2) *The advent of real attacks is periodic and dependent upon the outsid ture and meteorological conditions in ge*

(3) *The onset of P. vivax is determine peratures reaching about zero, and conti the thermometer rises, so long as it d beyond from 5° C. to 10° C.*

(4) *The falciparum outbreak only begin minimum temperature reaches between 2 30°C., and it lasts, in spite of the ther progressive fall, until a temperature of a is again reached.*

PROPORTION OF GAMETES AND SCHIZ THE BLOOD.

Chart II relates exclusively to the pr numbers of gametes (full-grown forms) an

(young forms) of *P. falciparum* found in th ing blood of patients under treatment. O that:

(1) *The gametes appear when the outside ture is about 25° C. (see July, 1916, 1917 a*

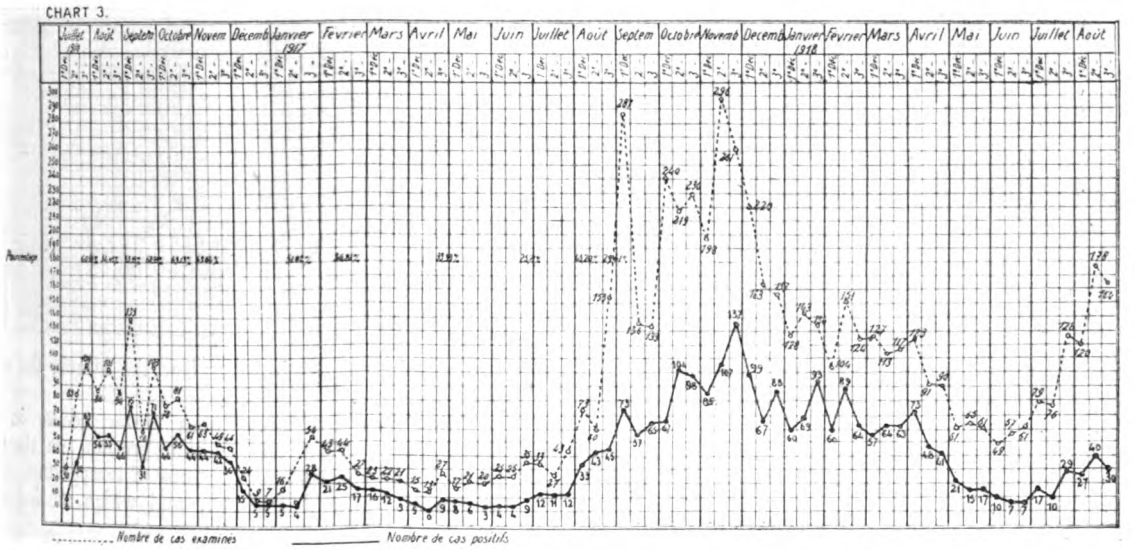
(2) *The schizonts (sexual reproduction appear before the gametes and during the preceding the arrival of minimum temper 25° C.*

Only these latter are found in the ci blood during attacks; *therefore it is certa coming of the gametes which governs t swarming of falciparum, which lasts into N and December.*

The schizonts appearing before the ga the circulating blood, and surviving them, proof that production *begins in the tissu* temperature below 25° C., and that afterw gametes leave there and continue reproducin circulating blood, only disappearing at the the period of attacks.

Further on we shall return to the the importance of this phenomenon. For the we confine ourselves to pointing out that i case where many gametes are found in th the curative effect of quinine is practica *Thus the drug would appear to act upon th ductive capacities of the gametes only whe are still in the tissues.*

vier 1918 Février



Recapitulation.

The schizonts appear in the blood before the gametes. (This was so in every case treated.) The latter never attain, in the circulating blood, a higher portion to the schizonts than one to six.

Lastly, the maximum of gametes corresponds to the maximum of schizonts.

Cases of Clinical Paludism in which the Blood Examination was Negative.

Chart III shows how very often, in cases treated with quinine and suffering from attacks, the examination of the blood gave a negative result.

On the other hand, there are many patients who, clinically, appear to have malaria, but who are not parasite carriers in their peripheral circulation.

The dotted curve indicates the total number of sufferers from clinical paludism.

The full curve shows the patients the examination of whose blood gave a positive result.

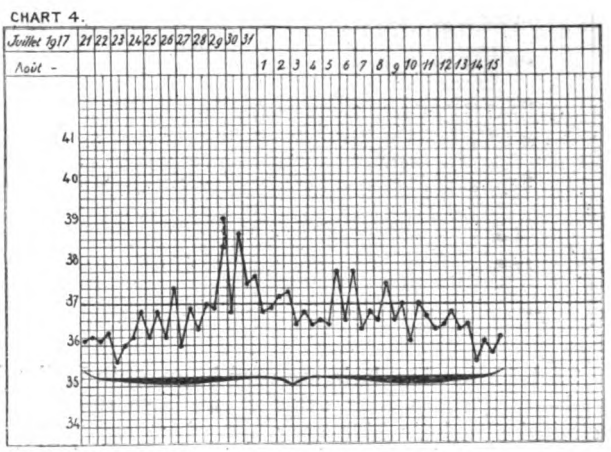
We find:

(1) *A similarity between the two curves, marking the close clinical connection between the cases with positive blood and those with negative blood.*

(2) *The percentage of cases with negative blood is especially high in the periods of severe febrile attacks.*

(3) *These periods are necessarily the ones during which the patients are given quinine in the strongest doses.*

We can, therefore, conclude that quinine, while not warding off attacks of fever, does lessen the chances of carrying the parasites by mosquitoes.

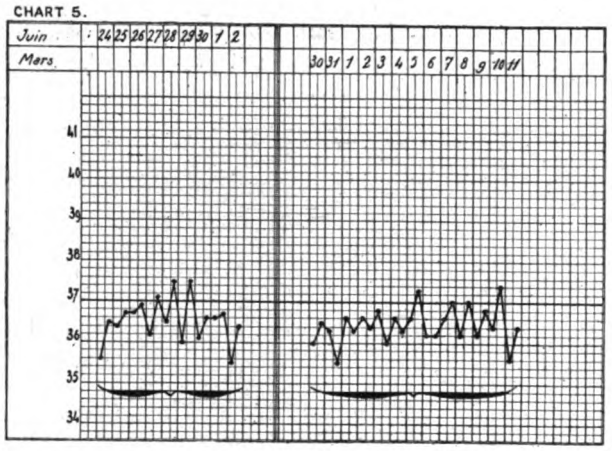


Special Study of the Thermal Curve in Malaria Cases.

The purpose of the following analysis is to show that a paludal attack does not consist of a rise of temperature by one or more steeples over 37° C., but, *in every instance*, of a number of oscillations (which often begin at 35·5° C.) extending over fifteen or twenty days, the return to normal only taking place after this length of time.

Let us take Chart IV (*falciparum*) as an example. The patient showed uneasiness on July 21, and had a rectal temperature of 36° C., but the real attack was not actually observed until the 29th.

Now in ordinary language one may say that the attack ended August 1, whereas, on the contrary, in spite of the quinine taken, two steeple jumps occurred, on September 5 and 6, and final stability of temperature only came on September 14 and 15, viz.: at about thirty-six degrees. (Rectal temperatures are not to be always understood.)

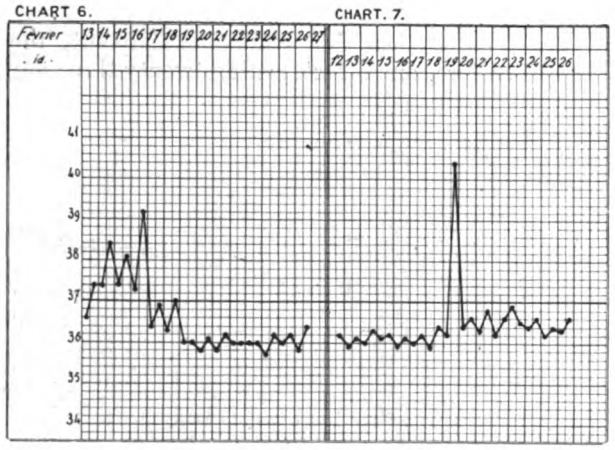


From a practical and clinical standpoint, there was, therefore, one attack lasting twenty-three days,

and not two separate attacks, on the 29th and 30th and on the 5th and 6th, as is the general assumption.

Chart V gives two examples tending to prove the above phenomenon. Both patients are *falciparum* carriers, and in both cases the rectal temperature has never exceeded 37·5° C. It is to be noted that we are not here in the *falciparum* multiplying period, that the patients show a clinical state of fever, and that their temperature oscillates to the extent of 1·5° C. above 36° C. for nine days in one case, and thirteen in the other, which, in spite of

CHART 5.



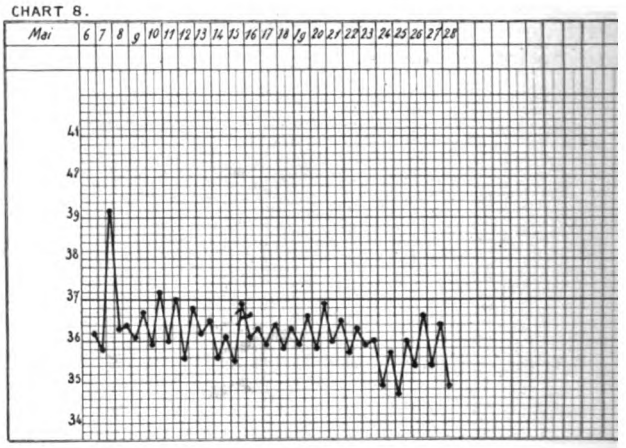
the absence of jumps, amounts to actual attacks of long duration, to be considered and treated as such.

Attacks of this kind are nearly always unrecognized clinically, as they take place in cases considered cured.

Yet these cases, having parasites in their blood, are naturally contagious.

CHART 6. CHART. 7.

Such forms of malaria are very frequent in Holland.



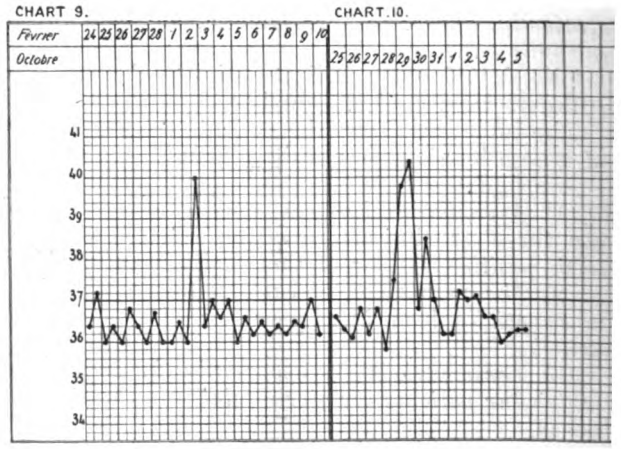
Besides these long attacks, we also meet with clinical attacks, which are much shorter.

However, they are characteristic of *P. vivax* infection. This infection, moreover, presents the features shown in Chart VII. *The vivax attack is strong and sudden*, the temperature rising above 40° C. in a few hours, and falling again to normal in the next few hours; but what denotes the presence of pure *vivax* is the steadiness of th thermal curve before and after the attack, whic period of stationary temperature, prior to an following the febrile crisis, we will call the "*calm vivacien.*"

Vivacian Steadiness.

Chart VI, which is much more fluctuating because it is a matter of double infection (*viva*

CHART 8.



and *falciparum*) shows, after the attack, the same phenomenon.

This thermal steadiness never occurs in the *falciparum* infections, which present, on the contrary, characteristic variations of temperature, going at times beyond 1·5° C., and which are indicated in Chart VIII.

This we will term "*l'inquiétude falciparique,*"

CHART 9. CHART. 10.

Falciparical Unrest.

The diagnosis to distinguish between falciparum infection and that due to vivax can, consequently, be made clinically by means of the thermal curve, even in those periods when the blood examination is negative.

In double infections, where we find *falciparum* and *vivax* schizonts together, the curve has shapes which we will call "cathedral shapes," in which we

clearly decipher the sudden vivacian attack overriding the falciparical uneasiness which both precedes and follows it. (Charts IX and X.)

These details are still better understood if the patient's temperature is taken hourly, day and night, and the blood examined every two hours.

Chart XI reproduces the hourly progress of a *P. vivax* attack. It will be noticed how rapid is its advance from 11 a.m. to 8 p.m., succeeded by the "calme vivacien" during the next twenty-four hours, and that, despite the constant presence of schizonts in the blood.

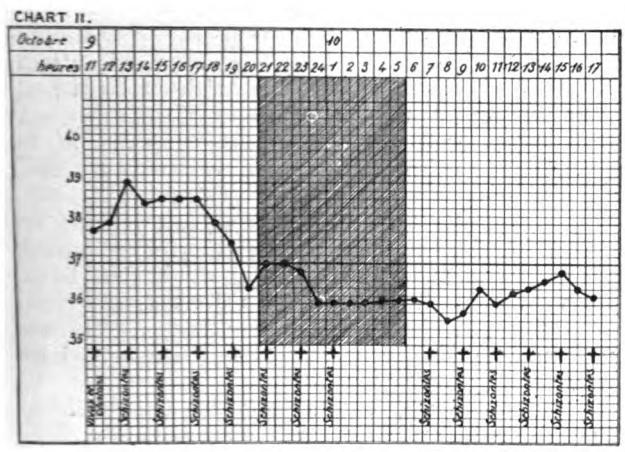


Chart XII shows, on the other hand, the hourly progress of a *P. falciparum* attack.

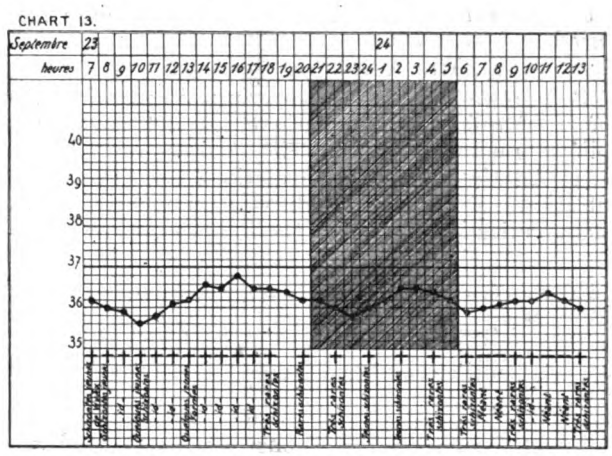
The blood was examined hour by hour. It will be noticed that the attack lasted two days and two nights, that the temperature rose by irregular oscillations (falciparical uneasiness), and that in the next twenty-six hours—between 4 p.m. on September 10 and 6 p.m. on the 11th—there was a difference of 1 to ½ degrees. It should be noted that the blood examination throughout this attack was now positive, now negative, notwithstanding the severity of the treatment.

To elucidate the reasons for the "*calme vivacien*" "*l'inquiétude falciparique*," hourly examinations of the blood were made during the forty-eight hours following an attack.

Chart XIII covers the period succeeding a pure *vivax* attack. One sees that the temperature has kept below 37° C., with slight and regular oscillations, despite the constant presence of young *vivax* forms in the blood. Near the end of the curve it is seen that the number of negative examinations increases.

Therefore, the manifestation of the schizonts lasts longer than the attack, and is not the sole factor determining the same, as is generally believed.



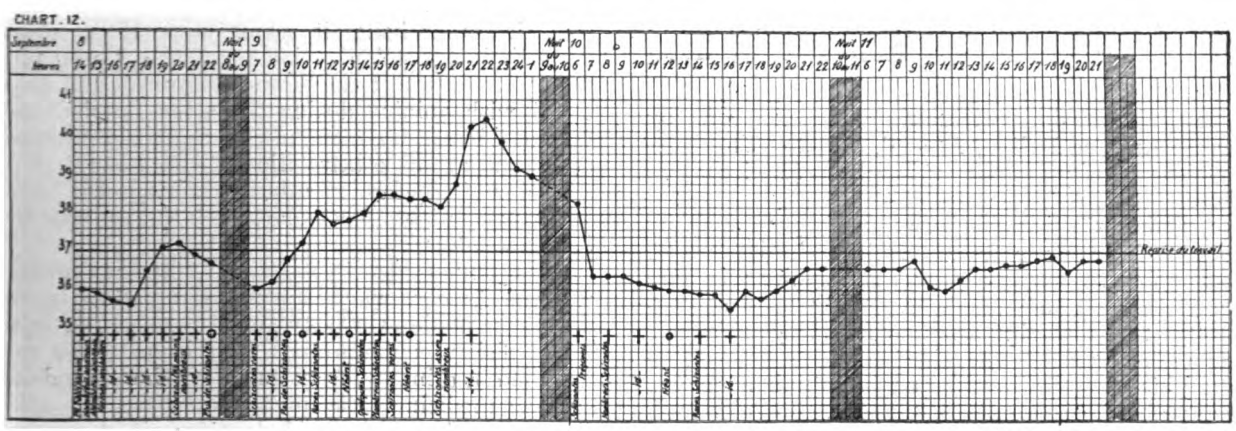


Chart XIV is a sign of the disturbance following a *falciparum* attack. Up to and over 37° C., the temperature oscillates through a range of 2° C. This patient is cured, "clinically" speaking, and yet he has gametes and schizonts in his blood.

Recapitulation.

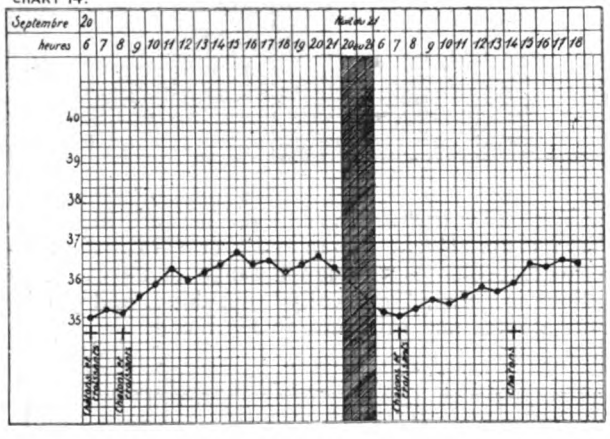
(1) *The vivax attack is sharp and short; it is preceded and followed by a pause, the "vivacian steadiness" ("calme vivacien").*

(2) *The falciparum attack, on the contrary, approaches gradually, and its acme is lower than that of the vivax attack It is preceded and followed by a series of thermal oscillations of as much as*

2° *C., which constitutes the "falciparical unrest"* (*"l'inquiétude falciparique"*).

This acme may fall short of temperatures regarded as febrile, and the entire attack, which may last as long as thirty days, begins and ceases with the "falciparical unrest." It may be marked down entirely between 35 *C. and* 37·5 *C.*

(3) *The presence of schizonts in the circulating blood is not in direct relation to the patient's temperature. They are also met with in attacks accompanied by a sub-normal temperature.*



(4) *It is wrong to conclude that a sufferer whose temperature does not exceed* 37·5 *C. has not or no more, an attack, and it is unwise to consider him cured.*

THE ACTION OF QUININE.

Before we discuss the drawings illustrating the effect of quinine on malaria cases, let us fix the following points:

(1) All the rules and regulations for the administration of quinine, whether preventively or therapeutically, were strictly followed, as was repeatedly verified, particularly at Gradobor, by Messrs. Armand Delille, Abrami, Wisbek (Physician in Chief and Head of the anti-Malaria Mission), and others.

CHART 14.

(*a*) Quinine in solution was given preventively by the mouth in daily doses of fifty centigrammes. Every morning for two years A. Pagnier was present at the call and witnessed the thorough absorption of the medicine in the following manner: each man advanced when his name was called, received his spoonful, swallowed it and then opened his mouth. No man was exempted. Pagnier himself took the same dose of quinine. *Result: all the men, without exception, as well as the head physician, contracted malaria.*

(*b*) The sufferers from paludism either swallowed their quinine as above or had intramuscular injections.

The following curves give, therefore, an exact idea of the real effect of quinine upon malaria development in patients who remained in the district where they caught the disease.

In this connection, two points must be emphasized, viz.:

(1) *It is impossible usefully to study the effect of quinine upon patients who have gone from the place of infection to their own country, because the factors of temperature and climate come in and there is risk of crediting the quinine with recoveries due to atmospheric temperature.*

On this account, conclusions such as Ravaut's must be accepted with caution, seeing that such and such a patient who, in the East, notwithstanding the treatment, had subintrant attacks because, according to the form of infection, it was either winter or the æstivo-autumnal period, might, on his return to France, seem to react admirably to the quinine given "*lege artis*," whereas his attacks would probably have disappeared without treatment.

(2) We repeat that in spite of normal or subnormal temperatures the patient may be in the attack stage, and that, therefore, *temperature alone is no criterion of the efficiency of quinine.*

(3) Moreover, quinine is itself an antipyretic, and so may mask, and not suppress, a febrile attack.

Having laid down these points, we hasten to say that we are far from wishing to deny that quinine has any effect. We only believe that, as the tracings indicate, its action has been wrongly interpreted and exaggerated.

In the first place, it is indisputable that although they all, without exception, contracted malaria, those of our patients who took quinine preventively had the disease in a comparatively mild form, whether the agent was *vivax* or whether it was *falciparum.*

Therefore, if, according to our experience, quinine does not prevent infection, it nevertheless does render the same less severe. Further on, we will try to explain this phenomenon.

On the other hand, it seems clear that quinine has a distinct specific action upon the young plasmodiæ, for, as Chart III shows, the number of cases treated with quinine during the attack periods and in whose blood no schizonts were found is much larger than at any other period of the year.

We now proceed to examine certain typical curves concerning patients who underwent the quinine test *therapeutically.*

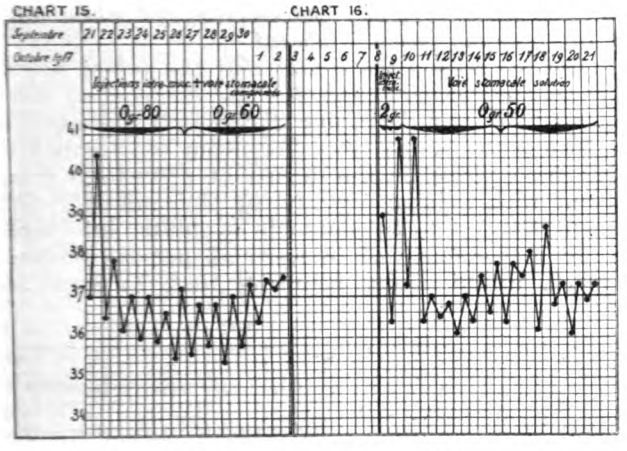
Let us take Charts XV and XVI as an example.

In the former, where a double infection is concerned, we made every day an intra-muscular injection of eighty centigrammes of quinine. We were warranted in thinking, from and after the second day, that the medicine had cut the attack. Nevertheless, we continued the said dose for six days, and, though the temperature had dropped from 35·5° C., we added sixty centigrammes of quinine in tablet form. In spite of this extra dose, the temperature had risen again to 37·5° C. by the twelfth day, and in the interval the curve showed falciparial uneasiness.

In Chart XVI (*P. falciparum*) we administered the first day, on an attack at 39° C., two grammes by intra-muscular injection. Next day, when the

temperature was 40° C., we again injected two grammes. The third day the temperature was 41° C. and we gave only fifty centigrammes *per os*, and on the fourth day the temperature dropped abruptly to 36·5° C. We continued the fifty centigrammes for eleven days, and saw the temperature rise again about the eighth day as high as 38·5 C. by wide falciparical oscillations, falling back afterwards to normal.

CHART 15. CHART 16.



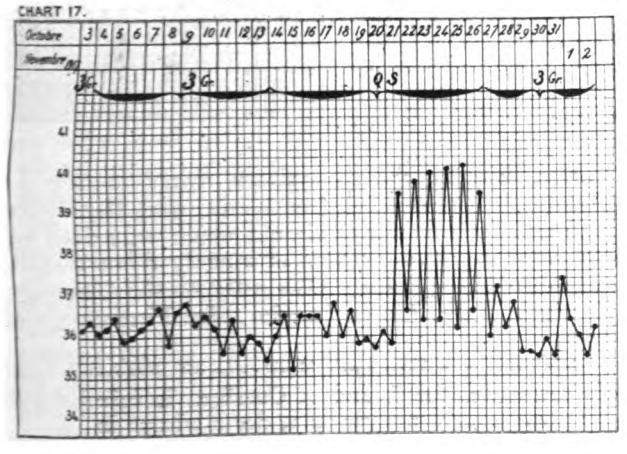


Chart XVII has to do with a patient who, from the 3rd to the 20th October, presented the oscillations characteristic of falciparical unrest. From the 3rd to the 13th, although there was clinically no attack, he received three grammes of quinine daily *per os* without there being any effect on the thermal curve. From the 14th to the 26th the quinine was

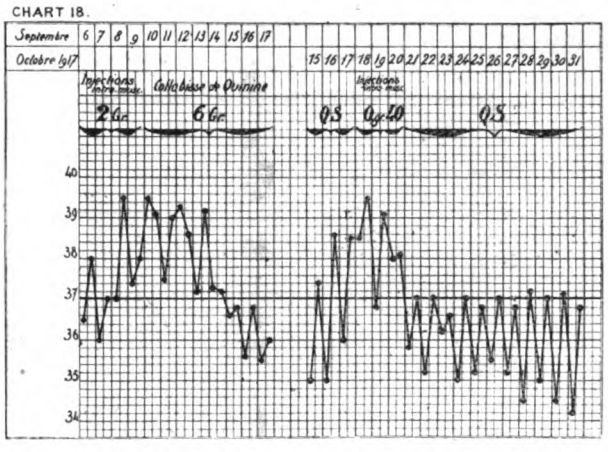
CHART 17.



stopped. From the 21st to the 25th there was an attack every day at 40° C. The temperature fell of itself on the 27th without quinine. From that day the dose of three grammes was again given, and the curve returned to its previous shape.

Chart XVIII applies to two patients (*falciparum*). In the first case the patient received from the start of the attack three grammes of quinine per day by intra-muscular injections. On the fourth day of this treatment the temperature was still at 39·5° C. Then six grammes of "collobiase" of quinine were injected, and it was only on the fourth day that the temperature fell back below 37° C.

The second *falciparum* patient, notwithstanding his rising temperature, had no quinine for three days; then for three days he was given forty centigrammes by intra-muscular injections. The temperature remained between 38° C and 39·C. On the seventh day it had dropped to 35·8° C. The quinine was stopped entirely, and there were oscillations of 2·5° C., without 37° C. however ever being exceeded. (All the temperatures of our drawings were rectal, and they were checked.)

Chart XIX extends over a space of two months, during which quinine was administered in variable doses. For the first ten days and the last fifteen the patient had no quinine. In this time the curve moves about a good deal, much more than during the middle period, when he had doses (capsules or injections) varying from 1·20 gr. to two grammes, regardless of the thermal curve. Yet it is while

CHART 18.

two grammes of quinine was being taken that we see the strong attacks on September 20, 22 and 24 and October 13.

We remark that those attacks extended through the period which, in the matter of climate, was the worst of the year.

Recapitulation.

(1) *Preventive treatment with quinine does not ward off infection, but it does render it less severe.*

(2) *In a vivax and falciparum infection curative treatment with quinine does not seem to stop an attack from following its course.*

(3) *The chief curative effect of quinine is to destroy more or less completely the schizonts circulating in the blood, and thus make the attacks less dangerous in their clinical manifestations and the patients themselves less contagious.*

CONCLUSIONS.

We deem ourselves justified in drawing from our investigations the following practical inferences:—

(1) *Prophylaxis of Malaria.*

The common idea that malarial infection can be avoided by taking forty or fifty centigrammes regularly every day is certainly erroneous. *The constant absorption of quinine does not prevent infection.*

On the other hand, it seems certain that the forms of paludism met with in persons who have taken quinine as a caution are generally milder than in those subjects who, before becoming infected, did not take quinine.

Preventive treatment seems, therefore, to have an inhibitory influence over the virulence of the plasmodiæ, as well as on their vitality in general.

But it is quite unlikely that quinine in preventive doses can, as some authors have stated, fortify the body's natural resistance to paludal infection. Quinine, being theoretically poisonous to protoplasm, we might take the opposite to be the case.

Hence, it is idle to surmise whether heavier doses of quinine would bar infection, because they would not be tolerated for long, any more than would adequate doses of arseno-benzol, if given to prevent a syphilitic infection; and there would be the risk of lowering the natural resistance of the organism.

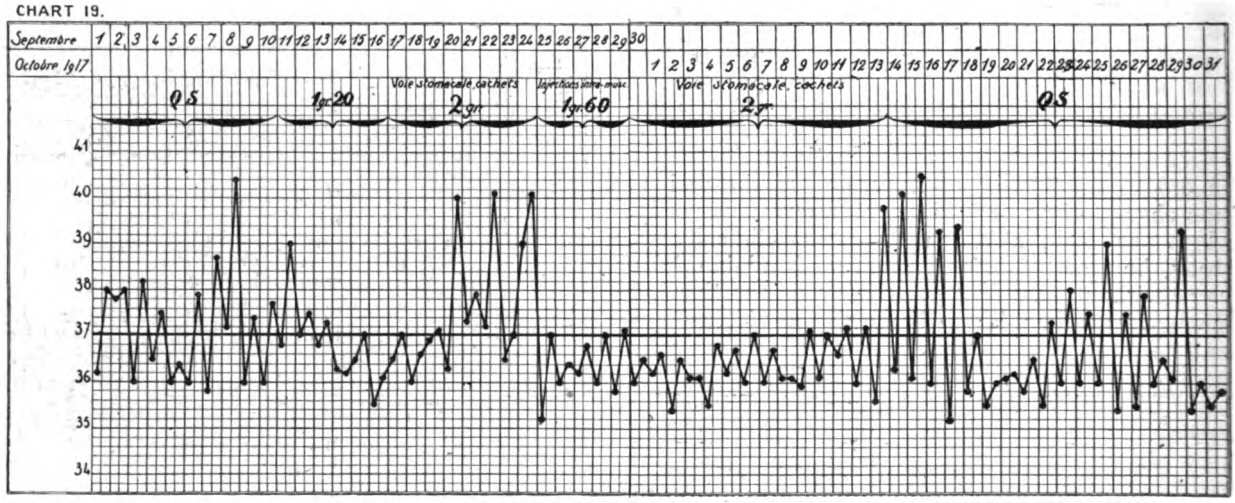
Resistance to malaria seems to be considerable in certain persons, just as it is to other infections. We know of many individuals who have lived in malaria-stricken countries without taking quinine as a preventive and yet have not been infected. *So the fact of having escaped malaria after such preventive action is no proof of the latter's efficacy.*

We cannot conclude in such a case that, without quinine, infection would not have been avoided just the same.

We will further say that most of the writers who believe in quinine and in preventive treatment ignore the importance of the algid, sub-normal or afebrile forms of paludism described above.

The absence of fever in the usual clinical meaning of the term does not prove that the subject is not suffering from malaria, and it is often these apparently afebrile forms, the nature of which is moreover masked by the quinine's purely anti-pyretic effect, that produce those severe cases of anæmia and cachexia of obscure origin which are only alleviated by a change of climate.

To sum up, we consider it logical to continue advocating preventive treatment with quinine; not, however, in the hope of warding off infection (which only inherent immunity can do), but to lessen the gravity of the type of paludism acquired when sufficient resisting power is absent.



But we remind the reader that the surest means of escaping malarial infection lie in avoiding mosquito bites and destroying the insects themselves.

The truth is too often forgotten on account of the trust placed in the dogma of preventive treatment with quinine, exactly as Metchnikoff's ointment has led to innumerable syphilitic infections.

It is therefore well to warn all persons proceeding to malaria-ridden countries that, to avoid infection, keeping the mosquitoes away is more important than preventive treatment; and the Governments of such countries should wage organized warfare on mosquitoes, instead of merely recommending people to take quinine. (We refer to the Campagna, Southern Italy, Rio de Janeiro, the Panama Canal, &c.)

We may mention here that one of France's finest departments, the Island of Corsica, is infected with paludism and yet nothing is done about it.

CHART 19.

(2) *Therapeutics of Malaria.*

(*a*) *Abortive Treatment.*— Some authors, like Ravaut, admit that it is possible, by strong treatment with quinine, to arrest a malaria infection just as one can stop an attack of syphilis.

We find it difficult to understand on what this idea is based. We know neither the premonitory symptoms nor the length of the incubation in paludism, and we have no means of getting to know them.

The disease starts with a first attack, and although this attack is foreshadowed by certain prodromata, these only appear when the plasmodiæ have already penetrated deeply into the tissues, especially the spleen.

Thus it is impossible to compare the course of malarial infection with that of syphilis.

We can stop an attack of syphilis because, in the beginning, the infection is strictly local.

In malaria the infection is general at the first onset, and once the parasites circulate in the system and plant themselves in the tissues we can as little hope to exterminate them as we can so do with syphilis which has passed the primary stage. The abortive treatment of paludism is impossible theoretically, and in practice we find this confirmed.

The opinion of those authors who believe in abortive treatment must be founded on errors of interpretation. There may be two causes for these.

Firstly, one often sees very mild cases of paludism, especially in *vivax* infections; these are limited, even in untreated cases, to a few attacks, after which there appears to be a recovery. This may be really so sometimes, but in most instances a fresh attack comes sooner or later, proving the contrary.

Those slight sufferers had strong powers of resistance or were not infected with very virulent parasites.

We have met with the same features in many syphilitics.

Then, in other cases—and they are apparently the most numerous—one can admit the value of abortive treatment, because the patient has no fever and his malaria shows at once an aglid aspect. Such cases are nearly always due to *P. falciparum*, and occur not only in the Mediterranean Basin, but elsewhere as well, viz.: along the Rhine, Holland, Poland, Galicia, on the banks of the Volga and in certain provinces of Roumania, where one of us has specially studied them. These are subjects who have never had a temperature above 37·5° C., and yet have always—particularly in summer—had their malarial attacks, with plasmodiæ in their blood.

The conclusion is that abortive treatment of the disease is impracticable.

(*b*) *Treatment of declared Paludism.*—Basing our opinion on the observation of more than 6,000 malarial cases, both on the scene of the disease's development and after the patients' return to their own country, which observation has extended over upwards of ten years, we believe ourselves justified in affirming that a sufferer from paludism very rarely recovers, strictly speaking, and that while he may have no more attacks, he continues almost invariably, just as the syphilitic seems to do, to be a "germ carrier"; his gametes may remain dormant for longer or shorter periods, but under certain conditions they are capable of arousing swarms of schizonts and inducing new attacks.

Now our investigations show the main cause for the reproduction of plasmodiæ to be the variations of temperature of the air, and its degree of humidity.

The influence of these variations differs according to the species of plasmodiæ.

The P. vivax victim cannot stand cold weather, especially if it be wet at the same time.

The P. falciparum sufferer cannot bear hot weather.

A glance at Chart I, which, so far, is a document unique in the literature of the subject, suffices to bring conviction of the truth of this statement.

It follows that the vivax carrier must avoid temperatures lower than 5° C., and the falciparum carrier heat above 25° C. (Minimum temperatures in both cases.)

This, to our minds, is the chief thing in the therapeutics of clinical paludism. Lucky are those who can afford to act upon it!

The most unfortunate are those persons who are *doubly infected*, it being more difficult for them to find a suitable climate. They should select the mildest climates possible, or change their residence periodically, according to the time of year and their types of parasite.

Besides climatic influences, the other causes helping to induce an attack are of minor importance. They are, in general, those tending to reduce the body's resistance to any infection; bad hygienic conditions, intercurrent maladies, traumatic disorders, and so on. Their effect upon chronic malaria sufferers has long been known.

(3) *What is the part played by Quinine in the Treatment of Paludism?*

Quinine cannot cure: it merely mitigates, more or less, the clinical manifestations of the disease.

The drug seems to act most strongly upon the young plasmodium elements; that is to say, the schizonts. Apparently, it destroys many of these before they have been able to enter the red globules of the blood. Therefore, we can, thanks to quinine, restrict the number of cases of severe anæmia of pernicious types, and such dangerous manifestations as, for example, those due to miliary embolism of the brain.

But quinine seems to have no effect upon the full-grown forms, the gametes, especially when they are in the tissues and have not yet entered the circulating blood.

In attacks not treated with quinine we almost invariably find schizonts in the blood. On the other hand, in patients who take adequate doses of quinine we frequently note the absence of schizonts from the blood. This is the effect of the quinine. (*See* Chart No. 3.)

We may further deduce that the patient dosed with quinine during his attacks is less infectious than he who does not take the medicine. We are, therefore, obliged, in acute paludal cases, to administer quinine in sufficient quantity (two grammes *per os*, 0·6 to 0·8 gramme, by intra-muscular injections); but as soon as the patient's state admits we must endeavour to send him to a climate suited to his kind of infection, i.e.:

The vivax patient to a hot country,

The falciparum patient to a cold country.

Even in the worst cases of hæmoglobinuric paludism, it does not seem to us that there can be any contra-indication to the administration of quinine. Koch's opinion that hæmoglobinuria is caused by the quinine strikes us as unfounded, but, in this case, above all, the patient's prompt transfer to an appropriate climate is called for.

As to the use of quinine in chronic cases where the attacks are rare, we think there is little utility in it. It will suffice to administer the drug at the time of an attack, in order to kill the excess of schizonts. Taking quinine during the intervals between attacks has no effect upon the gametes in the tissues, and will not bar the new attack, which, *if the patient's natural resistance is insufficient*, the atmospheric temperature will bring on by arousing the dormant germs.

Definitely, the fate of the malarious person will hinge upon three factors:

(1) *His degree of relative immunity, which will vary according to his general state of health.*

(2) *The virulence of the "germ family" by which he was infected, which virulence will certainly weaken more or less in time, through advancing age and the natural defensive powers of the organism.*

(3) *Atmospheric conditions and climate, with reference to the species of infecting parasite.*

Our investigations have especially borne upon the *P. vivax* and *P. falciparum* types of malaria. We have had but little experience of the *P. malariæ* forms, and hence we abstain from formulating any conclusion thereupon. The small number of cases observed by us showed distinctly periodical onsets, at least in the beginning, so that one could often predict the day and hour of the next attack.

In these cases it seems possible to moderate to some extent the clinical gravity of the attacks by administering a proper dose of quinine a few hours before.

This possibility does not exist, however, when it is a *vivax* or a *falciparum* case, in which the attacks, even from the start, are nearly always extremely irregular.

DENGUE *v.* MALARIA.

By R. E. Ingram-Johnson, L.R.C.P.Ed., &c.
Labu, Negri Sembilan, F.M.S.

Regarding malaria as almost, if not quite, the disease of most importance to humanity, both owing to its effects on those suffering from it, and its world-wide incidence, the question arises as to what is the best way to deal with it. Since the discovery that it is mosquito-borne, wonderful work has been done in the fight against its carrier, with the effect of clearing vast areas and rendering them habitable, but it is absolutely impossible to eliminate entirely the Anophelene mosquito from areas just outside those under anti-malarial treatment. So long as these conditions obtain, and so long as there are any human beings with parasites in their blood within reach of the mosquito, malaria will exist, and, until the whole inhabited world is cleared, in tropical and temperate climates, these measures are only palliative.

Again, quinine, though it puts a stop to an actual attack of malaria, and when taken continuously may act as a prophylactic against infection, does not prevent a second infection soon after its administration is stopped.

The objective that, to my mind, is the one which one should try to attain, is the discovery of some agent which will not only destroy the malaria parasite actually present in the circulation, but will also produce a condition in the blood of persons employing it, which prevents the proliferation of the parasite when introduced into the circulation by infected anophelenes. The attainment of this objective means that the human body eventually ceases to act as a host of the parasite, and hence infected anopheles die out, leaving the remainder as irritating but not poisonous-carrying insects. It is with this idea that I bring forward my theory of "dengué *versus* malaria."

In my two previous papers on this subject, published in the Journal of May 1, 1922, and January 15, 1923, I endeavoured to show that an attack of dengué fever has the peculiar property of causing immunity from infection by the malaria parasite, and also of preventing a recurrence of malaria in persons previously affected. I also propounded the theory that dengué is a modification of malaria brought about by a degeneration of the malaria parasite after its ingestion by the dengué-carrying mosquitoes, *Culex fatigans* and *Stegomyia fasciata*, or *calopus*.

It is objected that dengué is caused by a blood spirochæte, as spirochætes have been found in the blood of dengué patients. Against that idea is the fact that serum obtained from the blood of a dengué patient, filtered through the finest possible filter and examined microscopically without any organisms being visible, has caused dengué after injection into the bodies of healthy persons, thus showing that the spirochæte is not necessary to produce dengué. That being the case, is it not more than possible that the spirochæte form is an intermediate stage in the degeneration of the protozoan malaria parasite, which ultimately results in the formation of the ultra-microscopic dengué germ? This dengué germ produces fever of a somewhat similar type to that of malaria, to saddle-back temperature, but instead of going on proliferating and causing high temperatures every forty-eight or seventy-two hours, its first struggle towards reproduction, shown by the second rise of temperature, ends in its death, and the probable formation of an anti-toxin, which does not protect against dengué itself, as a second attack may speedily follow the first, but, as I hope to be able to show, acts against the malaria parasite, the *fons et origo mali*.

In my former papers I produced evidence of persons who, having themselves suffered from malaria, contracted dengué and thereafter, though living

under the same conditions, had no more attacks of malaria, and other persons who, having had an attack of dengué, were later exposed to infection in malarious districts and remained immune. These cases were too numerous to be classed as coincidences, so I suggested that a " serum " could be made from the blood of persons recovering from dengué which should have a prophylactic and a curative effect against malaria.

Acting on this idea, I tried, whilst in Colombo, to find a case of true dengué from whom to obtain some blood for experiment. By *true* dengué I mean a case conforming to the following course of events: (*i*) saddle-back temperature; (*ii*) initial roseolar; (*iii*) secondary rubeolar eruption on hands and forearms, coinciding with the terminal pyrexia; (*iv*) severe pains in fingers, hands and wrists. I was unsuccessful there, so migrated to Rangoon, with no better result. Believing that there would be better opportunities of studying both diseases in Malaya if I could secure some estate work, where there are numerous hospitals for coolies, I came here in February, 1924. I found many cases of so-called dengué, but at last succeeded in getting hold of three cases such as I wanted, and obtained some blood from them. This I took to the Institute of Medical Research, Kuala Lumpur, where I was very kindly received by the staff, who collected the serum, examined and prepared it, and certified it sterile. Having obtained the serum, I proceeded to try its effect on four persons suffering from acute attacks of malaria, and also on two other cases on the same estate who were in hospital suffering from injuries, both as controls and also with the idea that the serum (or vaccine) would act as a prophylactic. At this time there was a virulent outbreak of malaria on the estate, the subsoil drainage system having broken down and adult *Anopheles maculatus* being commonly found in the hospital itself. Firstly I ascertained that the six cases had had no treatment for malaria and then gave instructions that no other treatment than the vaccine should be given, and gave 1 c.c. intramuscularly to each person. All but one case had a second dose of 1 c.c. after seven days. In this one case after the first dose the temperature went down rapidly and stayed down for eight days, so that I believed that one dose was sufficient, as all parasites had disappeared. However, on the night of the eighth day the temperature rose to 102° F., so the following morning I gave a second injection, as a few parasites had reappeared. The temperature in this case rose nightly and was down in the mornings, so as the vaccine was only in the experimental stage, I thought it better to give a dose of quinine, so I gave one single dose of ten grains on the fifteenth night, after which every sign and symptom of malaria disappeared. As the temperature had been hectic in its character for seven days, it seemed to me remarkable that one small dose of quinine should have such a striking effect, so I felt justified in concluding that the amount of vaccine administered had not been sufficient to destroy the numerous parasites present in the circulation, and that probably one more dose of the vaccine would have had the same effect. In two other cases, after an initial fall of temperature for a day or two, there was a nightly rise of temperature and a morning fall, gradually dying away to normal without any other treatment.

In the fourth case there was a gradual defervescence of temperature and disappearance of parasites.

The two cases of injury who were treated with injections, though sleeping in hospital without mosquito nets for three weeks, and then going back to the lines have remained free from infection, and are among the very few coolies who escaped out of between 200 and 300 coolies on the estate.

I also experimented on two persons who, for seven or eight months, had had attacks of malaria (with parasites visible) at regular intervals of four weeks.

One of these was the European manager of an estate, who offered himself for experiment, the other being a coolie. After their last attack of malaria, five months ago, it was arranged that neither of them should take any quinine or medicine of any kind, and that they should have an injection a few days before the date on which the next attack was expected. I prepared blood films from both cases just before the injection and found parasites present in both cases. Three or four days after the injection, both were perfectly well and blood films were free from parasites. Seven days after the first injection blood films showed a few scattered chromatin dots only and a second injection was given. Since that time up to date neither of them has had any fever, and blood films taken at intervals of a few days prove absolutely negative, all the red cells being perfectly normal.

The above cases, I am well aware, are not sufficient in number to be accepted as positive proof of either the cure of malaria or its prevention, but the next series of experiments I made, I have confidence in stating, do actually prove that the blood serum I obtained is truly a vaccine, which differs from the vaccine against typhoid inasmuch as it is formed by the natural death of the dengué germs in the human body, whereas the latter is prepared from cultivated *B. typhosus* artificially killed. Secondly, that this vaccine has a destructive action upon the the malaria parasite.

These later experiments are some that I have made on children with greatly enlarged spleens. As splenomegaly in these cases is caused by the presence of multitudes of living parasites in the spleen, and as the enlargement remains so long as they *are* present, it is not begging the question to argue that if they are destroyed and absorbed, the spleen itself, if it has not already become fibrous, should diminish in size, and conversely if the spleen *does* become smaller, it is practically a proof that the parasite has been destroyed and absorbed. I am aware that people have left the tropics with enlarged spleens which have undergone considerable shrinkage after a residence in temperate climates. I also know that even in tropical climates enlargement of the spleen has been considerably reduced by appropriate treat-

ment after many months, but the majority of cases remaining in the same place show practically no diminution, even under regular and continuous treatment. All cases in which the enlargement has disappeared are cases in which the disease causing the splenomegaly has disappeared also.

It struck me, therefore, that if this vaccine has the power of destroying the malaria parasite, or at any rate of preventing its proliferation, the surest proof, and one practically incontrovertible, would be to try its effect on these chronically enlarged spleens in children, in the hope that, if fibrosis had not already set in, and that the vaccine had the effect I expected, these spleens would begin to diminish in size just as soon as the irritation of the presence of living parasites was removed. I therefore selected three boys, aged respectively five, eight and thirteen years, with enormously enlarged spleens. I first stopped all treatment and then gave each of them 1 c.c. of the vaccine intramuscularly, having marked out the area of enlargement with silver nitrate, so as to have a fairly permanent outline. There was no febrile or other apparent reaction after the injection. On examination a week later, I found a distinct shrinkage, both vertically and laterally, and I gave them each a second dose. At the end of the second week I found a still further shrinkage and I left them for another seven days before giving a third dose, when I found a still further diminution in size.

I think I am safe in saying that no such rapid shrinking has taken place previously, under any form of treatment in cases of chronic splenomegaly though in acute splenitis, which these cases certainly are not, enlarged spleens have rapidly diminished in size as the inflammatory conditions have subsided.

As controls, I have watched other similar cases, living under exactly the same conditions and having the usual treatment with quinine, iron and arsenic, without the slightest change having taken place. I feel justified in claiming that these results are due to the destruction of the malaria parasites in the spleens of these children. That being so, the vaccine being obtained from the blood-serum of patients known to have suffered from dengué, and being certified free from all visible organisms, and having an effect on the malaria parasite such as no other known form of treatment can produce, surely proves that there is a distinct connection between the infections of malaria and dengué, as certainly as there is a connection between the infections of varicella and variola.

Again, as the vaccine has such an effect on living parasites already in the blood cells, one may reasonably conclude that its introduction into the circulation, before a chance of infection has arisen, will prevent the maturation of sporozoites introduced by infected anophelines, and hence it is a true prophylactic against malaria.

As regards its curative power against acute attacks of malaria, I have not yet been able to secure a sufficient quantity of the vaccine to make a lengthy series of experiments, but I am convinced that it has the power of destroying the parasite in its quiescent state, and of preventing its proliferation, therefore, I see no reason why it should not destroy the parasite speedily when in an active state, if it be administered in larger and more frequent doses.

CONDITIONS OF MEDICAL WORK IN A WEST AFRICAN BUSH STATION.

By M. C. E. Easmon, M.B.B.S.Lond., M.R.C.S., L.R.C.P. Cert. of London School of Tropical Medicine.
African Medical Officer Sierra Leone.

Very little, I think, is known to others than the men actually there of the nature and duties of a medical man in the average bush or out-station in British West Africa; away from the modern adjuncts and conveniences of our profession, where frequently bricks have to be made without straw. This was brought home to me by the questions of my old hospital colleagues whom I met when I was last on leave in England, in 1922, after nine years' consecutive work in West Africa. A little more is known about work in the large coast towns, with their well-equipped hospitals, sanitary departments and research laboratories, from the occasional papers that emanate from them.

My excuse for this article on Bo, a bush station in the Protectorate of Sierra Leone, is the hope that it will be of interest to medical men practising in England, to those considering working in the tropics, and to those who, working in another part of the tropics, would like to know conditions in regions they are unfamiliar with. After eleven years' work out here, mostly in bush stations, I can write from personal experience.

W. A. Young, in 1919, published an article in the Journal of Tropical Medicine and Hygiene (vol. xxii, p. 9), in which he showed the extent to which diseases ordinarily met in any out-patient department in England were found here in Sierra Leone. He based his article on the statistics of the Colonial Hospital, Freetown, the capital. I am going to show briefly all the types of diseases, both those peculiar to the tropics and those also occurring in temperate zones, and all the other duties of a medical man.

For the purpose of this paper I am taking the cases that I have seen during the last seven months—September, 1923 to March, 1924—as typical of any similar period. Seven months ago I was transferred to this district and began to keep a record for this purpose.

But before getting on to the diseases I must give a short account of the country and the people.

Bo Medical Station is situated at the western end of the Kennema District of the Central Province of the Sierra Leone Protectorate. The Kennema District lies between long. 10° W. and long. 11° 55" W., and lat. 70° 36" W. and lat. 8° 34" W., approximately. According to the last census—1921—the area is 2,100 square miles with a population of 168,526. The country consists of rolling downs with ranges of hills in the northern parts. It is like all the Protectorate, very well watered, and is covered with the usual thick tropical bush. It is traversed from west to east by

the railway dividing it into two unequal parts, of which the northern is the larger. All the large communities and important towns are on the railway line, such as Bo, Gerihun, Blama, Kennema and Hangha. Kennema is the Administrative Headquarters and has a branch dispensary. Most of the medical officer's work is on the railway line, it is very rare for him to have to go off it.

The People.

The indigenous people are the Mendis, a typical negro race, short, sturdy and cheerful people, very virile, as shown by the fact that the use of the Mendi language is fast spreading among the adjacent tribes. Along with the Mendis you find:—

(*a*) I.—Members of the adjacent tribes, pagan, Konnoh, Timnee, Kissi, Lokkoh, Sherbro.

II.—Members of the Mohammedan tribes from the north, Susu, Fulah, Korankoh, Mandingo.

(*b*) Inhabitants of the Colony proper, or Creoles. These Creoles are a race in the process of fusion and consist of the descendants of slaves from the whole of the West Coast of Africa who were taken to America and the West Indies in the days of the slave trade. The immediate ancestors of the present Creoles came from Nova Scotia, England, the West Indies, and all the coast of West Africa. They were placed on the peninsula of Sierra Leone and provided for by the generosity of Granville Sharpe, Wilberforce, Macaulay, and the other abolitionists of the eighteenth century. Missionaries soon came among them and they have been a civilized and literate and educated people for two or three generations. They understand and appreciate the benefits of modern medicine and are on a higher developmental plane than the Mendis and other tribes.

(*c*) *Asiatics.*—Syrians from Beyrout, and Indians.

(*d*) *Europeans.*—From the British Isles, France and Switzerland.—In other districts many American missionaries are found.

According to the Census of 1921, out of 168,526 inhabitants, 995 are foreigners to the Protectorate. Of these:—

Creoles are	828
Syrians ,, ...	113
Indians ,, ...	7
Europeans ,, ...	38
Miscellaneous	8

The indigenous tribes are mainly engaged in agriculture and preparing produce—palm oil and kernels, &c., for sale, and supply the unskilled labour. The Creoles supply the mechanics and artisans, and smaller traders and Government clerks. The Europeans conduct the large business firms and the senior official posts, and a few are missionaries. There were five European ladies in the district during this period.

Climate.

There are two seasons; dry from October to April, wet from May to September. From December to February, at the time of the N.E. trades, a persistent dry wind called the Harmattan blows. Owing to the great evaporation that accompanies it there is a marked lowering of the temperature at this time. The following metereological particulars from the observation taken at Bo for 1923 will be of interest:—

Maximum shade temperature ..	98° F.
Minimum ,, ,, ..	60° F.
Greatest daily range of temperature	34°
Smallest ,, ,, ,,	9°
Total rainfall for the year	106·41 in.
Greatest amount on one day	3·96 ,,
Wettest month—July with	19·59 ,,

Communications.

Most of the important towns are on the railway. There are motorable roads for cars and lorries or motor cycles in the following places:—

Bo.—Twenty-five miles to south and twenty-eight miles to north.

Blama.—Twenty-four to north. Twenty-one miles along the line through Kennema to Hangha.

Hangha.—Twenty miles to Panguma, away from the line. Away from these roads and the railway the usual means of transport is by hammocks supported on the heads of four men. Horses do not thrive and are rarely seen here. The energetic can go on most bush roads and native roads on a bicycle, with frequent stoppings to get over small irregular rough stick bridges. The large rivers in this district are not navigable and so there is no river transport. The greater part of the travelling to be done is done by the railway.

Medical Personnel—Staff and Buildings.

At the present time in this and other Protectorate Districts where there is a Government Medical Officer there is no scope for a private practitioner, as the mass of the people do not yet sufficiently appreciate modern medical methods and the foreign element is not large enough to support a doctor adequately. All Government Medical Officers, however, except the Heads of the West African Medical Staff and the Sanitary Service, are allowed private practice.

There are two classes of medical officers employed under the Government: members of the West African Medical Staff (of pure European descent) and African Medical Officers (of West African or mixed West African and European descent). These two classes have received the same training and hold the same qualifications and degrees obtained and registered in the United Kingdom, and individual members relieve each other at out-stations as occasion arises. The main difference is that the West African Medical Staff receive better conditions of service and hold all the higher posts.

Staff.—In addition to the Government Medical Officer—who is without rival in his district and the last word on any medical or sanitary point, and who is looked up to by the populace as the only person who can order about the great District Commissioner, under certain conditions—there is a dispenser who is also a trained nurse. The dispensers are trained at the Colonial Hospital, Freetown, for five to six years before being sent out. Then there is a sanitary inspector who is also the vaccinator. The dispenser is assisted by one hospital labourer, and the sanitary inspector has two sanitary gangs. At Kennema there is a branch dispensary with one dispenser and one hospital labourer. No nursing staff is provided for

the hospitals, all serious cases being sent down by train to the Colonial Hospital, Freetown.

Quarters, &c.—In bush or out-stations the quarters provided for medical officers vary from a mud-walled thatched native house to the latest in concrete block bungalows. Similarly with the dispensers' quarters, on a less pretentious scale, of course. In this station the medical officer has a rather dilapidated wooden bungalow, which was formerly a temporary railway construction bungalow. Next door to the medical officer's bungalow is the dispensary, another wooden bungalow, the former railway construction club house; it consists of two rooms, a dispensary, an office and consulting room in one. A little way off is the dispenser's house, a native house, and near by is the hospital building—a single-roomed native house with no beds or any suitable furniture. Near the dispensary is a small mortuary, a hut with palm leaf walls and roof. There is also stationed here a railway ambulance coach—a converted covered goods wagon.

At the branch dispensary at Kennema there is the usual dispenser's house and a single-room dispensary. The medical officer occupies the Rest House on his visits. My predecessor acquired an old disused stone building, a former office, and had it adapted to a small hospital with one ward of four beds and a small office. This has been equipped with iron beds and bedding and a sink with a tap has just been installed. Only those who have had to work for years without it can appreciate the luxury of a pipe-borne water supply inside the premises.

The dispensaries are equipped with the usual stock of drugs and dispensary adjuncts. There is a portable metal operating table and the usual minor surgery instruments with chloroform mark and drop-bottle. Chloroform is the only general anæsthetic used here. There is a good Zeiss microscope with $\frac{1}{12}$, $\frac{1}{6}$, $\frac{2}{3}$ objectives, mechanical stage and condenser, &c., also slides, cover-slips and the commoner stains.

Duties of the Medical Officer.

The first charge, I take it, of the medical officer is the care of the Government officials, then the general populace who attend the dispensary, and lastly, his private patients. He has to deal with any of the usual or unusual cases that may occur—medical, surgical, gynæcological, obstetric, as well as ear, nose, throat and eye cases. In addition to his purely medical work he is medical officer of health for the district, and here he has three sanitary districts at Bo, Blama, and Kennema. At Bo he has two sanitary gangs, one for the town and one for the European reservation. He has to deal with all sanitary affairs, and be ready to tackle any outbreak of infectious disease. Meteorological observations are taken at Bo daily by the dispenser, but the medical officer is responsible for their correctness.

The medical officer is the medico-legal expert of the district, and is called upon to make post-mortem examinations or superintend exhumations, as well as to give evidence in the District Commissioner's Court and Circuit Court.

Scientific.—The average medical officer is not a trained laboratory worker, but there are opportunities of doing minor research works such as collecting the different mosquitoes and biting flies in the district, examining children for the local splenic index, examining children for ankylostome and other helminth ova. During this time (in my spare time) I have been doing helminthic investigations, and also collecting figures for a paper on fertility and infantile mortality rates.

Lastly, he has a good deal of clerical work to do, official correspondence, monthly, quarterly, and yearly returns. At present at Bo there are fourteen monthly returns to be made. I am told that in the army there is an excessive amount of office work. I do not know, but I think the medical department out here is a good second.

The day's work begins in the dispensary at 8.30 or 9 a.m. The old ulcer cases come earlier and are all dressed by now. One sees first of all the Government officials from the various departments; at this station there are the railway, public works, roads department, and Bo school (a Government School for the sons and nominees of chiefs). At Kennema there are also prisoners, court messengers, and headquarters administrative staff. After this one deals with the general populace—the proportion of Creoles attending is very high. The rest of the morning is taken up with clerical work and sanitary inspection with the inspector. In the afternoons operations can be done, if any, or microscopical work and any urgent case that may be brought in. Also the claims of private patients can be considered.

Recreation.

Recreation.—"All work and no play makes Jack a dull boy." Tennis—there are two courts at Bo and one at Blama and Kennema. There is a golf course at Bo, and at Bo school occasional games of cricket and football with the schoolboys are to be had. There is little shooting—bush-fowl, guinea-fowl, and pigeons round about Bo. The bush is too thick for other shooting. There are good roads, as already mentioned, for walking and cycling.

Types of Cases Treated.

During the period under review 2,067 new cases attended at the dispensary and I had 200 private patients. Though this is the most populous district there are only eighty to the square mile, the average for the whole Colony and Protectorate being about sixty to the square mile; not by any means a dense population.

The commonest are ulcers, constipation, dyspepsia, minor injuries and coughs and bronchitis, and rheumatic affections.

Ulcers of all kinds are met, and, in children, the tropical ulcer with its rapid extension and sloughing is very common. Any little cut or abrasion if neglected soon becomes one of these foul ulcers. Even at the Bo school, where the boys have daily access to the medical officer and dispensary and live under much better hygienic conditions, these ulcers occur.

Venereal diseases—primary syphilis and recent gonorrhœa cases do not present themselves in large numbers. One sees relatively much more of advanced tertiary syphilis and stricture cases with perineal

abscesses and fistula of old-standing gonorrhœa. The gonorrhœal stricture cases are seen very late and often have several strictures. The tertiary syphilitics respond very well to novarsenobillon, stabilarsan, bismuth salts sufarsenol, all of which I have tried here by intramuscular or intravenous routes.

Phthisis is not common, but only a virulent type is met with and a fatal result soon follows. No typhoid cases occurred.

The idea that primitive races have perfect teeth and have no need for dentists, in this part of the world at any rate, is quite erroneous. Dental caries, especially of the molars—the sixth year molar being the first to go—and pyorrhœa is frequent among both the Mendis and Creoles. The commonest minor operation done is the extraction of teeth.

Only a few of the diseases described in standard works on tropical diseases are fortunately met with here. As far as I know plague, cholera, kala-azar, pellagra, sprue, guinea worm, trypanosomiasis, relapsing fever, dengue have not been described. Bilharzia and ankylostome infections (*Necator americanus*, 98 per cent.) are present, but do not seem to cause symptoms as in other parts of the tropics. Yellow fever has occurred but is rare. Leprosy, too, is not common and the people do not seem to have any particular dread of it and allow lepers to move about freely. Amboeic dysentery occurs, but not to a large extent, considering that the land near or on the banks of the streams is the common latrine ground of the Mendis. The commonest tropical diseases, next to the tropical ulcers mentioned above, are malarial (subtertian or æstive-autumnal) with its sequelæ. Benign tertian and quartan malarias are rare. A large part of the infantile mortality may be due to cerebral malaria. Blackwater fever has occurred at Bo but not during this period. Trachoma is rare.

Of the infectious diseases most commonly met with out here, small-pox and chicken-pox, there have been no cases. Two mumps and one case of measles were seen.

Yaws is rare in the primary stage, and the secondary manifestations are so like those of syphilis that in the absence of the Wassermann test it is hard to differentiate them, especially as both are cured by the 606 group.

Filarial embryos are common in the blood, but the clinical manifestations are proportionately few. Elephantiasis scroti is the commonest, with one or two cases of elephantiasis of the legs.

To show what class of surgical work one has to deal with out here, the following operations, except those for cataract, were done under chloroform:—

For Elephantiasis scroti	1
Radical cure of hydrocele	2
Senile cataract	3
Aspirating liver abscess	3
Incision of large mammary abscesses, buboes, &c.	6
Removal of keloids	3
Incision of eyeball	1
Circumcision	4
Suturing large wounds	2
Obstetric complication for incomplete abortion	1
Emptying uterus sapræmia	1
Internal version for transverse presentation	1

Eye cases are not as common out here as in India, the ones that come up for treatment are mostly cases of simple conjunctivitis, and cases of old extensive scarring of the cornea for which nothing can be done. Trachoma is very rare, none seen here in this period and only a few cases of senile cataract.

The European population is small and can therefore be considered in detail. The average is 38, distributed as follows: Bo 15, Gerihun 1, Blama 11, Baoma 1, Kennema 1, Hangha 1, and Boajibu 5. European ladies resided at: Bo 1, Kennema 1, Blama 2, and Boajibu 1.

No European died but 4 were invalided: 1 for phthisis, 1 for wound on the leg, 1 for liver abscess and 1 for toxæmia of unknown origin. Europeans treated: women 1 (malaria), men 9, in addition to those invalided, bronchitis 1, malaria 3, sprained ankle 1, local boils 1, bronchitis 1, nasal catarrh 1, dyspepsia 1.

Private Practice.

The amount of private practice depends more than anything on the medical officer's attitude towards the Natives and Creoles. The sympathetic medical officer gets all that is going, and the man whose general attitude the people do not like gets little or none. Two hundred cases may be taken as on the large side for eight months. The relative proportions of the different elements of the population met with in private are quite different to those met in the dispensary. In private the bulk of patients are better-class Creoles and Syrians. The following is an analysis of the different nationalities:—

Creoles	93
Syrians	57
Natives, including chiefs	42
Europeans	8

Two-thirds of the Creole cases are females, and the great bulk of the private work is of gynæcological and obstetric nature. Nearly every type of disease of women is met with: dysmenorrhœa, amenorrhœa, menorrhagia, pseudocyesis, normal and abnormal delivery, eclampsia fever abortion, prolapse and retroversion filbroids, ovaritis and ovarian tumours, chronic erosion of the cervix. Among the aboriginal tribes very few of these cases are seen as the women will not tell a man about such symptoms, or allow a man to make the necessary pelvic examinations.

Of the general cases treated in private, malarial type of fevers are commonest, next comes tertiary syphilis, than cases of dyspepsia. Gonorrhœa, a few cases. The proportion of eye cases is greater than at the dispensary, and includes the cataract cases mentioned in the operation list. Rarer cases are heart cases, amœbic dysentery, liver abscess, hemiplegia, hydrocele and elephantiasis scroti, and bronchial affections.

In the above account I have not been able to give any thrilling accounts of exceptional cases to be treated, but as the benefits of medical science become more and more widely known and more equipment is obtained, more and better work will be done. The foregoing particular account of eight months' work at Bo is typical of any similar period at any other district in this Colony and Protectorate, and, with the changing of a few names and figures, is a fair index of work in the other West African Colonies.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed to the **Editors.**

4.—All **business communications and payments,** either of subscriptions or advertisements, should be sent to the **Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank Ltd.

5.—The Subscription, which is **Thirty Shillings** per annum, may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—**Authors of original communications are entitled to 25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints if the order for these, with remittance, is given when MS. is sent in. The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 " "	1	3	3
200 " "	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 " " "	2	6	0
200 " " "	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

THE JOURNAL OF

Tropical Medicine and Hygiene

MARCH 16, 1925.

NOMENCLATURE IN MEDICAL ZOOLOGY.

THE present state of confusion that exists in the nomenclature of the animal parasites of man is most distressing to the medical man, and any steps which will result in a greater uniformity are highly to be commended. In consulting a series of text-books it is quite frequent to find oneself at sea, owing to the diversity of names to be applied to any one organism, and it is next to impossible to expect the busy practitioner to carry in his mind a long list of synonyms. Possibly the greatest trouble in this respect is found in the names of the pathogenic and non-pathogenic human protozoa, and, as an example of the extreme confusion which exists, the pathogenic amœba of the human intestine and the commensal, which so closely resembles it, may be cited. To the systematist it is no doubt a matter of some importance to decide whether these amœbæ should be given the generic name *Entamœba*, *Endamœba* or *Poneramœba*, and whether it is correct to apply the specific name *coli* to the commensal or to the tissue parasite. But to the medical man, on the other hand, who has his interest centred on diagnosing the presence of the pathogenic form in the fæces of his patients, it is confusion worse confounded to find in his works of reference different names for the same organism.

It is not for a moment suggested that there should be any gross departure from the established rules of zoological nomenclature; the point at issue is that in the past there has been disagreement under these rules even among those who make a study of the systematic position of the various organisms, and there does not seem to be any prospect of this diversity of opinion being settled in the near future. Now, since these controversies chiefly rage round questions of historical import rather than on matters of present-day research, and since the utmost the authorities can do is to produce a series of "opinions," which as often as not clash one with the other, some other means, either of a temporary or permanent nature, will have to be adopted to straighten out the mazes of the literature and so lighten the already all too heavy burden of the student of medicine.

The same muddle exists in practically every branch of medicine which deals with parasitic organisms of man, be they animal or vegetable. A good example of this is the spirochætes. What does it matter whether the spirochæte of syphilis be called a *Spironema*, a *Treponema* or a *Spirochæta* so long as the patient has adequate treatment?

The human whip worm is variously referred to as *Trichuris trichiura* and *Trichocephalus dispar*.

To suggest any means of rendering order out of the present chaotic condition of affairs is extremely difficult, and a matter to be approached with the greatest delicacy. It seems feasible, however, that the Zoological Congress might arrive at some solution of the problem by agreeing on the names to be applied to organisms whose morphological characters and life cycle are now more or less established, but about whose names, owing to diversity of opinion in the past, there is now some doubt. Next it might be suggested that, so far as the medical side is concerned, one name might be adopted for any given organism for a stated period, and if further research—by which is meant true investigation into the character of the parasites and not merely an expression of opinion on the findings of some worker, say of the last century—should show that any alteration in the adopted name was necessary or advisable, such alteration would only take place after due con-

sideration and at the expiration of the stated period.

While there is no doubt that the systematists are the worst offenders in this changing about of names, vacillating from one to another without practical reason, attention must be drawn to the frequent "rediscovery" of organisms already known and described as a fertile means of increasing the crop of synonyms. Such rediscoveries are certainly from the present viewpoint of less importance than the *obiter dicta* of the systematists, since the bulk of opinion usually causes their stultification in a comparatively short time; but, nevertheless, as no textbook would be complete without their mention, they do add to the continually growing synonymic list.

On this matter of nomenclature there seems to be no question of what the opinion of the medical profession really is; unfortunately, it is notoriously difficult to raise enthusiasm to a pitch sufficient to ensure the necessary change.

J. G. T. and A. R.

Annotations.

Injuries and Diseases in Australia attributable to Animals (except Insects) (J. Burton Cleland, *Medical Journal of Australia*, October 4, 1924).—The first injuries mentioned in this paper are those from aboriginals, which are often very serious and end fatally. Camels have been known to inflict fatal injuries, also the flying fox. Rats, of course, are numerous and are well known as the reservoir of the plague bacillus and the transmitter of the organism of rat-bite fever. Injuries are also recorded of wombats, crow-shrikes, butcher birds and cassowaries, and a case is described of a "severe lacerated wound of the leg, caused by the bite of a shark." The numb-fish is known for the electric shocks it conveys to man, and there are several fish known to convey injuries by their spines. The consumption of the toad-fish has caused death in many instances. Among other injuries described are those from scorpions, ticks and spiders.

Tetanus Cured by Large Doses of Serum (Trabaud and Baur, *Bull. Soc. Med. des Hop. de Paris*, October 16, 1924).—Two cases are reported. The first, a girl, 6½ years, admitted into hospital complaining of stiffness of the jaw of five days' duration. There was nothing in the mouth to account for the trismus, but for the last three days there had been general tetanus. The pulse varied from 120 to 130 and the temperature was 100° F. The cause of the tetanus was a small wound in the sole of the foot, due to treading on a nail about ten days previously. In the first three days 430 c.c. of antitetanic serum were given; some chloral was also given at night. The patient quickly recovered, suffering no inconvenience from the serotherapy beyond slight erythema and enlargement of the glands. The second case was a woman who had fractured her astragalus; a fragment projected through the skin. The fragment was removed, and 10 c.c. of antitetanic serum given, the wound dressed and put in plaster, 30 c.c. of antigangrene serum was then given. Temperature 105° F. Pulse 98 to 110. Sloughing of the skin occurred six days later, and 50 c.c. of antigangrene serum was administered. After a few days a localized tetanus set in and doses of 100 c.c. of antitetanic serum were given daily, which was later followed by doses of 50 to 20 c.c., 740 c.c. being given in all the course of the disease. The patient eventually recovered.

The Effect of Alcohol and Nicotine on Salvarsan Treatment (Hubner, *Dermat. Woch.*, October 22, 1924).—The number of cases within recent years which have been refractory to salvarsan are not few. Silberstein's experience at the Konigsberg University Skin Clinic is particularly interesting. During 1911 to 1916, the Wassermann reaction became negative in 100 per cent. of the cases treated, and remained positive in 23 per cent. during the years 1921 and 1922. At Elberfeld the author has had similar experience, 1919 to the middle of 1922, but since that date the results have been decidedly better. The improvement may have been due to the use of silver-salvarsan, but is chiefly attributed to a restricted consumption of alcohol and nicotine. The author maintains that alcohol and nicotine paralyse the natural defence of the body, without which salvarsan cannot produce its effects. His conviction is based on the much better results obtained in patients in the prison at Elberfeld, among whom the action of alcohol and nicotine could be eliminated both before and during treatment. At the end of the course of treatment only nine out of 100 patients still gave a positive Wassermann reaction.

On the Dissolution of the Precipitates produced in the Leutic Precipitation Test by the Fresh Serum (Kiyowo Taoka, *Kitasato Arch. Experimental Medicine*, vol. vi, No. 1, August, 1923).—By allowing carbonic acid gas to pass through the fresh serum or by adding some N/400 acid into the serum, the capacity of the fresh serum to dissolve the leutic flakes disappears although no changes are met with in the complimental activity. Both the leutic flakes treated with acid and the flakes not complement-fixed are dissolved by the fresh serum. By heating the serum the pH is lowered to 7·0, when the capacity of the serum to dissolve the leutic flakes is lost. The dissolution of the leutic flakes by the fresh serum is due to the alkalinity and is quite independent of its complemental activity.

The Role of Monilia Psilosis (Ashfordi) in Experimental Sprue (L. Weld Smith, *Journal of the American Medical Association*, November 15, 1924).—Experiments support Ashford's theory of the specific etiology of sprue as due to *Monilia psilosis* by the production in guinea-pigs of a chronic moniliasis with gastro-intestinal lesions roughly comparable to those found in man. The development of the lesions, however,

was rarely noted except in animals fed on a diet partially deficient in vitamins, especially the anti-scorbitic vitamins. This favours the view that a deficient diet, or diminished resistance such as is common following long residence in the tropics associated frequently with gastro-intestinal infections such as amœbic dysentery, are contributory factors in its production. Mycologic studies on twenty-one strains of monilia obtained from Manila and from cases in Boston invalided home are in accord with the tentative classification into three subtypes—A, B and C—as suggested by Boyd and Hannibal.

The Production of Immunity Against Plague by Vaccine. III. Immunization by Oral Administration of Plague Vaccine With and Without Bile (J. Morrison, B. P. B. Naidu and C. R. Avari, *Indian Journal of Medical Research*, October, 1924).—Rats which are very satisfactory for estimating the prophylactic value of plague vaccines, when administered by the subcutaneous route, are not suitable animals for the oral administration of bile and vaccine. They have not been induced to eat baits prepared with bile and when bile is administered by a catheter they appearently die readily of œdema of the glottis. Guinea-pigs can be fed with bile by a catheter. The treated guinea-pigs receiving doses similar to those given by M. Leger and A. Baury afford no evidence that any immunity is conferred by the oral administration of bile and the plague prophylactic or by the oral administration of the plague prophylactic alone.

The Production of Immunity Against Plague by Vaccine. I. Haffkine's Plague Prophylactic. (J. Morrison, B. P. B. Naidu and C. R. Avari, *Indian Journal of Medical Research*, October, 1924).—Rats imported from Madras for these experiments showed mortality of 9·2 per cent. within six days of their arrival. When infected with 0·003 mgm. of spleen of a plague infected rat, these rats showed a mortality of 95·3 per cent. within ten days of infection. Nutrient broth from which Haffkine's prophylactic is made is not toxic to rats and it has no immunizing value. The whole prophylactic given in a dose of 0·5 c.c., killed 35 per cent. of rats from toxæmia and produced an immunity which reduced the mortality among infected rats from 95·3 per cent. to 55·6 per cent. The sediment in the dose employed showed neither toxic nor immunizing properties. The supernatant fluid caused a mortality of 19·8 per cent. from toxæmia and produced an immunity which reduced the mortality to 53·11 per cent.

The Production of Immunity Against Plague by Vaccine. II. Agar Cultures (J. Morison, B. P. B. Naidu and C. R. Avari, *Indian Journal of Medical Research*, Oct., 1924).—When compared with 0·5 c.c. of Haffkine's prophylactic, agar cultures treated with formalin and acetone are not toxic and show no evidence of immunizing power, even in doses of 12·5 mgm. Agar cultures treated with chloroform vapour and 1 per cent. carbolic acid show no immunizing power until the weight of the dried vaccine exceeds 13·6 mgm. Agar cultures treated with 1 per cent. carbolic acid possess immunizing properties when used in a dose of 8 mgm. When heated at 60° C. for fifteen minutes and then carbolized to contain 0·5 per cent. carbolic acid possess immunizing value with doses of 4 mgm. and upwards. Only with heated vaccine does the toxicity regularly increase with the dose.

The Nature and Pharmacological Action of Cholera Toxin (H. W. Acton and R. N. Chopra, *Indian Journal of Medical Research*, October, 1924).—The cholera vibrio, as is well known, can liquefy gelatine, and reduce the amino-acid tryptophane to indol: the authors show that it can also decarboxylate amino-acids into poisonous bases. The protein bases found in a ten days' cholera broth culture consist of two main fractions, volatile and non-volatile bases. The volatile bases are almost devoid of pharmacological activity on the tissues tested, but they cause a tonic contraction of the rabbit's intestine. The non-volatile bases contain the poisonous toxins, which depress blood-pressure, &c. These poisonous bodies are found in the arginine fraction of the non-volatile amino-acids so that they only form a small proportion of the non-volatile bases. The main action of these toxic bases are: (1) A fall of blood-pressure due to vasodilation of the vessels supplying the small intestines, combined with an increased permeability of the vessel endothelium; (2) direct action on the secreting tubules of the kidney which are further hampered with the occurrence of an intertubular œdema as soon as the blood-pressure rises to normal. (3) An oxytocic action on the pregnant uterus, causing miscarriages. The optimum conditions for the production of these bases are the necessary amino-acids, pH on the alkaline side, and a liberal supply of oxygen.

Contribution to the Biological Study on the Hæmolytic Streptococci (Koji Ando, *Kitasato Arch. Experimental Medicine*, vol. vi, No. 1, August, 1923).—Hæmolytic streptococci isolated from diseased sites, as a rule, have a certain hæmolytic zone. Among the hæmolytic streptococci isolated from normal mucous membrane there are some which show the same hæmolytic zones as those isolated from diseased sites, while others have different zones. Therefore, those hæmolytic streptococci which show a certain definite hæmolytic zone without regard to the sources, isolated from either normal mucous membrane or diseased sites, are classified as typical β type, and all others which are not included in the typical β type are classified as atypical β type. About half of hæmolytic streptococci found normally on healthy mucous membrane is atypical β type. The atypical β type may be divided into five types by the characteristics on blood agar plates. While the typical β type has marked pathogenicity, the atypical β type has very little. This was proved by the virulency and hæmolysin producing function in bouillon not containing serum.

The Relation of Silver Arsphenamin to the Involuntary Nervous System and to the So-called Nitritoid Crisis (I. Rosen, E. Friedrich Müller and C. N. Myers, *Archives of Dermatology and Syphilology*, vol. x, No. 5, November, 1924).—In these observations it is shown that every intravenous injection of arsphenamin is followed by a slight decrease of leukocytes in the peripheric vessels of the entire body, indicating a reaction of the involuntary nervous system. This decrease is marked in patients who develop manifestations of the so-called nitritoid crisis. Intravenous injections of silver arsphenamin are generally unaccompanied by any change in the leukocytes, thus indicating that there is no reaction or disturbance of the involuntary nervous system and the vascular system of the body. The only exceptions to this rule are found in a few persons, namely, the same who develop symptoms of the so-called nitritoid crisis after injections of arsphenamin. This is further proof that the rare reaction after silver arsphenamin is caused by a previous disturbance of the involuntary nervous system and is not occasioned by the drug itself.

Hepatosis (or Tropical Abscess of Liver) : An Examination into the Diagnosis and Treatment of this Disease in India, with Special Reference to the Use of Emetine (R. S. Townsend, *Journal of Royal Army Medical Corps*, December, 1924).—During the past fifteen years the author has carried out many investigations on this subject and has seen numerous patients suffering from the disease. The summary of his paper may be given: "I know that it may be said that there are few new statements and facts in this thesis. I may, however, claim that a review of the literature, before and after the introduction of emetine, and one's own experience show that liver abscess must now be looked at from a new perspective. The diagnosis has become even more difficult, and the typical cases are not so common. I will sum up my findings as follows:—

The disease is irregularly distributed in the Tropics. It has definite relation to amœbic dysentery, and is definitely caused by *Entamœba histolytica* in the liver substance. Whilst the treatment by emetine has reduced the incidence and mortality tenfold, it has still a high mortality rate. In India it is much more common in men than in women. Whilst alcohol is a most important factor, debility and congestion of the liver are also predisposing causes. Distribution is most irregular in India, and it may occur at any season. That, as a result, the chances of missing cases are very greatly increased. Unlike before the days of emetine, it is now rare to find abscesses and acute dysentery at the same time. They are generally sequelæ of dysentery. There is no royal road to diagnosis. The train of symptoms is various, and little aid is obtained from X-rays and chemical tests. A history of dysentery, a muddy complexion, a remittent septic temperature, a tender liver, drenching perspiration, a relative anæmia and leucocytosis are sure signs of liver abscess. Shoulder pain is not so sure a sign as text-books suggest. When a liver abscess is diagnosed, operative procedure must be continued until it has been evacuated. If emetine does not clear up the hepatitis, it should be treated by surgical means at a very early date. The causes of failure in order of rarity are: (1) Non-diagnosis, especially of abscess of left lobe. (2) Incomplete evacuation. (3) Secondary infection, by evacuation into the chest or abdominal cavity.

Final Report on the Use of Urea Stibamine in Kala-azar (H. E. Shortt and Ram Taran Sen, *Indian Journal of Medical Research*, October, 1924).—A series of cases of kala-azar have been treated, further to those reported in 1923, which show that the value of urea stibamine has been established as the most efficient drug at present in use for the treatment of Indian kala-azar. This conclusion is based not only on the cases published, but in addition on experience gained in many other cases, both Indian and European, which have passed through the hands of the authors, or which have been treated with urea stibamine under their direction, a number totalling nearly 100 cases.

Attempts to transmit Rheumatic Fever to Rabbits and Guinea Pigs (C. P. Miller, *Journal of Experimental Medicine*, October 1, 1924).—In a series of attempts to transmit a virus from patients in the acute stages of rheumatic fever, twenty-seven rabbits and fourteen guinea-pigs were inoculated with one of the following materials: whole blood, serum, joint fluid, pleural fluid, throat washings, suspensions of tonsil tissue. Subsequent transfer inoculations from animal to animal brought the total number of animals employed in the experiments to sixty-seven rabbits and forty guinea-pigs. Only two animals developed an acute non-bacterial arthritis. No other evidence of successful transmission of the disease was obtained. In about one-half of the rabbits and two-thirds of the guinea-pigs myocardial lesions were encountered which consisted of interstital accumulations of lymphocytes and endothelial cells. Similar lesions were found in control animals.

Amœbic Liver Abscess with a Report of Two Cases occurring in Connecticut (M. Lear and E. S. Merrill, *Ann. Surgery*, May, 1924).—Two cases of amœbic abscess of the liver are described, and an account of a small local outbreak of amœbic dysentery in Connecticut is given. The first case occurred in a male and the second in a female. X-ray examination showed elevation and fixation of the right dome of the diaphragm and enlargement of the liver. In both cases a definite solitary abscess was found; open operation by the subcostal route was performed. In the authors' opinion treatment by aspiration and systematic emetine medication gives better results than open incision and drainage, in which failure may result from secondary pyogenic infection. There was no evidence of recurrence in either case.

Current Literature.

BULLETIN DE LA SOCIETE DE PATHOLOGIE EXOTIQUE. December 10, 1924.

On Human Intestinal Spirochætes in Portuguese India (F. de Mello and B. P. Mesquita).—Examination of a number of individuals, without the least sign of intestinal trouble, either at the time of examination or during the previous six months, showed the presence of *Spirochæta eurygyrata*, often in abundance, so that it is difficult to attribute any pathogenic rôle to this parasite. The presence of this spirochæte in patients suffering from intestinal trouble varied from 0 to 50. The spirochætes of the alveolar arch *S. buccalis* are found in the human intestine, where they retain the same characters as in their usual site.

Experiments on the Treatment of Human Spirochætosis due to S. eurygyrata, by Modern Spirillicides (F. de Mello and B. P. Mesquita).—Neosalvarsan in intravenous injections of 0·3 to 1·7 grm. has no action on *S. eurygyrata*. Results were also negative with the use of the bismuths, Muthanol, Neotrepol and Trepol, the first in doses of 10 c.c., the other two of 6 c.c., given in intramuscular injections of 2 c.c. every other day. Dermatol, given *per os*, 1·5 grm. per day for six days, had no effect on *S. eurygyrata*. Stovarsol tablets administered *per os*, three tablets per day for six consecutive days, has a remarkable action on *S. eurygyrata* and is considered the best medicament for spirochætosis.

Anatomic Considerations on the Structure of the Paranasal Tumours of Goundou (Botreau-Roussel and L. Cornil).—Contrary to the affirmation of a certain number of authors, paranasal formations of goundou are not tumours in the anatomopathological sense of the word, but are osteogenic inflammatory hyperplasias, as previously shown by Durante. These hyperostoses present general characters, trabecular and medullary modifications, comparable to those of syphilitic osteitis. The histological characters of the lesions prove goundou to be of frambœsial origin.

Trachoma at Tangiers (P. Remlinger and L. Bernard).—Trachoma does not exist at Tangiers, either in endemic or epidemic form. The cases found are imported. The disease is rarer at Tangiers than in equally important towns of Algeria and Tunis, and other ports of the Mediterranean. It is more commonly seen in adults than in children. It is only slightly contagious, and does not constitute a danger for the town itself or for the countries with which it trades. Under present conditions, simple measures of surveillance are necessary rather than an aggressive prophylaxis.

On the Parasitology of Arequipa (Peru) and the Neighbouring Places (E. Escomel). This paper gives the results of the author's fifteen years' investigation. Arequipa is one of the healthiest towns of South America, and the least rich in parasites pathogenic for man and animals. The maladies met with are generally of foreign origin.

On the Abusive Use of Quinine in the Treatment of Pyrexia (H. Lhuerre).—The author points out the too common mistake of giving large doses of quinine in cases of pyrexia and malaria, which often cause serious trouble. The condition of the patient should first be taken into consideration, also the pathological differences of each patient; and the words of Pasteur on his death-bed, relating to this subject, should be borne in mind, " Ce n'est pas le microbe, c'est le malade qui fait la maladie." Three instances are given where the prolonged illness of the patient was due to too large doses of quinine.

Note in the Intestinal Affections in the French Sudan (Cercle de Mopti) (R. Lefevre).—Intestinal diseases, contrary to general belief, are very widely spread in the Sudan; dysentery, especially is frequently found in the Valley of the Nile and the region of Mopti. In the white race fifteen cases have been observed in one year; all of amœbic type. This is accounted for by the consumption of raw vegetables and polluted water from the Nile. In the examination of 127 stools, *Entamœba dysenteriæ* was found sixty-nine times, *Lamblia intestinalis* once, *Schistosoma hæmatobium* once, *Ankylostoma duodenalis* once and *Balantidium coli* once. The sixty-nine cases of amæbiasis do not signify the number affected, as the natives only come for consultation when in the acute stage of the disease.

Characters of Spirochæta bronchialis Castellani (Froilano de Mello).—This paper is based on a study of the spirochætes of six cases of broncho-spirochætosis observed in Nova Goa. Broncho-spirochætosis is generally discovered by chance in the laboratory, sputums being nearly always sent for the discovery of the Koch bacillus or other agents. The spirochætes have been studied on fresh sputum and are described in detail. These studies show that *S. bronchialis* is a separate species, distinct from the spirochætes of the alveolo-dental arch.

Concerning the Efficacy of Preventive Quinine in the Prophylaxis of Malaria (J. Legendre).—Quinine as a preventive of malaria has been used for over fifty years, since the discovery by Maillot of the specific rôle of quinine in the treatment of the disease. Preventive quinine at one time rarely exceeded doses of 0·25 gr., but nowadays as much as 0·40 and 0·50 gr. per dose is taken. The author is convinced that quinine as a preventive of malaria is not efficacious, and that given in large doses may often do more harm than good.

Intestinal Coccidiosis of Vipera berus due to Cyclospora babauli nov. sp. (Mme. Phisalix).—Three vipers, *Vipera berus* Lin., captured in the province of the Yonne, were found to harbour numerous coccidia in the intestine, showing the two forms of multiplication which are described in this paper. The coccidia of *Vipera berus* is very similar to the one found in *Vipera aspic* and named *Cyclospora viperæ*. In this case the coccidia is named *C. babauli*, after M. Guy Babault, who captured the vipers.

THREE CASES OF CASTELLANI'S ENDEMIC FUNICULITIS IN KENYA COLONY.

By N. P. Jewell, F.R.C.S I., M.D.
European Hospital, Mombasa.

Endemic funiculitis was first described as a separate disease by Castellani in Ceylon some years ago. According to him the condition was known, though very imperfectly, to the local practitioners for many years, and considered to be of venereal origin or of malarial origin. Cases have been recently recorded from Southern India and Egypt. So far as I know, the present three cases are the first to be recorded from Eastern Africa. I am of opinion that this disease is endemic to this part of Africa.

That the disease is one *sui generis* there can be no doubt in the mind of anyone operating on one of these suppurative cases. The appearance of the spermatic cord is quite characteristic, and, on cutting into it, the pus wells out of the veins in a way that, once seen, is never forgotten.

The ætiology of the disease is, at present, uncertain, but in one of my cases (the Mombasa one) I found the diplo-streptococcus mentioned by Castellani. In none of my cases was bilharzia known to exist, nor was there any sign of micro-filaria. It would seem from the sudden acute severity of the disease, that a streptococcal origin was most likely, but I am informed by Dr. Nair, of Mombasa, that he had a case corresponding to the description of endemic funiculitis in which he was able to obtain micro-filaria in the blood, and he further stated that he had seen several similar cases, but had been unable to obtain filaria in the blood, although he regarded the cases as filariasis. These cases must have been of the mild variety mentioned by Castellani, as none of them were treated surgically and all recovered under medical treatment.

It would seem that there are two definite varieties of the disease. *One*, a mild type in which the causative organism is the micro-filaria and which is capable of cure without surgical aid. *Two*, a severe type, with septicæmia and destruction of the cord, the cause of which appears to be a diplo-streptococcus. It may be that these two types represent two separate diseases, i.e., the mild type being a manifestation of filariasis, and the severe form of endemic funiculitis proper.

It will be seen that the three cases recorded fall at once into two groups, one, the Kisumu case—mild in comparison to the other two, treated medically and going on to recovery without suppuration. This was probably a filariasis case. The other two are of the severe type, probably both diplo-streptococcal, both suppurative and requiring immediate operation.

As regards the diagnosis in the severe form, the condition is not at all unlike a strangulated inguinal hernia—the sudden onset, with tense swelling in groin coming on quickly, with no impulse on coughing, and marked shock, and, as in one of my cases, a history of inguinal hernia on that side, suggest strongly the latter condition, more especially as the history to be obtained from natives is generally very unreliable.

Case 1.—*At Kisumu, in* 1918.—My own personal boy, a Kikuyu native, aged about thirty years, was suddenly taken ill with rigor, vomiting and great pain along the right spermatic cord. The cord rapidly enlarged to about one inch in diameter and the temperature rose to 103° F., the pulse was fast and of low tension.

There was a history of gonorrhœa several years ago, but no recent history of infection. There was no history of injury, and no signs of filariasis.

I was puzzled by the case and could not classify it at all. On looking up a text-book on tropical medicine I found a reference to endemic funiculitis, and, on comparing the description with the case in point, I was satisfied that I was dealing with a case of that disease.

I treated this case with boracic foments two-hourly and, later on, local applications of iodine. Internally, urotropine and acid. sol phosp. gr. 10 of each, four times daily, and saline purges each morning. The condition gradually subsided in about ten days and left no after-effects.

Case 2.—*At Kismayu in* 1922.—The patient was an elderly man, who was under treatment in hospital by Dr. Davison for ankylostomiasis and was very debilitated. He had suddenly developed a swelling, either the previous night or the early morning, over the left inguinal canal and into the scrotum. The swelling was tense and very painful, with no impulse on coughing. The overlying skin was normal. The temperature was normal, but the pulse was fast and thready. There was a history of inguinal hernia on that side. I made the provisional diagnosis of strangulated hernia and suggested immediate operation, which was agreed to. On making the usual incision over the inguinal canal, pus came into the wound on division of the subcutaneous tissue. Mixed with the pus was material that looked like, and smelt like, semen. On gently feeling in the wound I found the cord greatly enlarged and gangrenous, and the examining finger passed readily through the disintegrated tissue down to and into the epididymis and testis. The wound was enlarged and freely opened up and the dead tissue gently cleared away and free drainage established, but the patient died the same day.

Case 3.—*At Mombasa*, 1923.—This case was seen in consultation with Dr. Massey at the Native Civil Hospital. The patient was a young man of thirty years, with a swelling from the testis into the inguinal canal. His temperature was 100° F., the skin over the swelling was freely movable, the testis was at the bottom of the swelling and was normal, there was a little fluid in the tunica vaginalis, his bowels had worked the previous day. We could not obtain any history of hernia.

History.—The history obtained from the boy was as follows: Three or four days before coming

in he had had a sudden attack of fever and vomiting, there was pain and swelling along the spermatic cord on the left side. The pain was very severe. There was no history of venereal disease, but he suffered from constipation, although, as already noted, the bowels had worked the previous day. The swelling was tense and dull on percussion. The condition resembled a strangulated omental hernia into a patent vaginal process. As we were not certain of the diagnosis and there was a possibility of the condition being a strangulated hernia, it was considered wise to operate at once, and this was done. On cutting through the skin and subcutaneous tissue, one came at once on the greatly inflamed spermatic cord, which was about one and a half inches in diameter. An opening was made into the cord from the inguinal ring to the epididymis, and about one inch deep. On cutting into the cord pus welled out from the cut veins and connective tissue. The whole wound was cleaned out with dioxide and left open. A boric fomentation was used as dressing, and this dressing was repeated two hourly during the next few days, at each dressing the wound was irrigated with dioxide. Recovery was uneventful.

LIGHTNING STROKE AND ELECTRIC STORMS IN THE TROPICS.

By H. A. SPENCER, M.R.C.S., L.R.C.P.Lond.

DURING a long residence in the Transvaal, South Africa, with its continental climate some hundreds of miles from the seaboard, it has been my experience to witness, and far too often to be involved in, the often terrific displays of electric storm which occur every summer with unfailing regularity. The man whose duties constantly take him far away over the bare veld at this time of the year, where there are few trees to act as possible lightning conductors, himself runs great risk of acting in this manner during storms which come up so quickly, appearing in a previously cloudless sky with scant warning, as he travels about, for he cannot avoid exposure to their fury. It is just this risk which is apt to make him ponder, as he travels, upon the source, vagaries and general conduct of atmospheric electricity, to turn over in his mind the possible means of avoiding being struck and the various methods of resuscitating those who have been so unfortunate.

ATMOSPHERIC ELECTRICITY

is, as we all know, resident in the upper altitudes of the atmosphere even in the clearest and brightest of skies; when humidity is driven higher and higher by the up-rushing heat from the baked earth, and reaches the heights of condensing cold it becomes visible cloud, which, driven still higher, becomes electrified. Now the condensing action of electricity upon water vapour is well illustrated by approaching an electric current to a playing fountain of water, issuing so finely divided that it can only be seen but falls noiselessly into the basin like soft rain falling without splash; each time the current is approached, however, the spray is at once seen to become denser, more coarse, and falls into the basin with a loud splash, whilst each time it is removed the spray returns to its vaporous form. What happens is that the molecules of water when they collide in the air rebound from each other, but in the presence of electricity they at once coalesce whenever they touch, forming larger and larger drops, which are of course far heavier than mist. In this manner the electrified cloud in the upper atmosphere becomes heavier and heavier and rapidly falls to earth with its contained electricity. I think this electrical action upon water vapour fully explains the sudden appearance of these electric storms in the heat of summer; at one moment the atmosphere with its invisible water vapour is clear and bright, at the next, almost, a lowering cloud is seen rapidly descending earthwards filled with potential "lightning."

Applying what happens to one cloud to enormous quantities of water vapour over a particularly hot spot of the ground, it is easy to see what further happens: that clouds, above others, becoming overcharged are constantly forced to off-load into contiguous clouds within their reach, this going on from above keeping up the supply of lightning from the higher altitudes to earth. An overcharged and very heavy cloud which has dropped away from contact above is a source of terrible danger to life and property under certain conditions, when it discharges its whole content of electricity at one contact with enormous force in one impulsive rush! Terrible injuries are then produced upon men and animals; lightning conductors are practically useless against it!

CONDUCTION OF LIGHTNING BY OBJECTS AND HUMAN BEINGS.

Falling rain is the commonest conductor of the lightning from cloud to earth, and the most anxious time on the veld is that preceding the fall of rain, when heavy thunder-clouds are lowering and lowering overhead and a flash may come at any moment; for the lower surface of the cloud is surcharged with positive electricity, as it passes over the earth's surface, held there by the attraction of the negative electricity following beneath it on the ground, flowing across the veld, up hill and down dale, up trees it meets in its path or any object travelling along—ever trying to rise high enough to make connection with that ever-falling-lower above, and to thus complete the circuit. Whenever the jump becomes short enough between the two for this to occur, the cloud sparks to the earth—a flash of lightning falls—and whatever assists the contact of the electricity above with that below will receive the full force of the discharge and conduct it to earth. Under these circumstances the flash is short, the streak of lightning no more than an instant's blinding light, and human beings or animals which may have assisted to complete the circuit are instantly electrocuted! When rain does fall, however, the flash may be very long indeed, often appearing to be from dome to zenith, for there is no dependence under these circumstances

upon such conductors, the falling rain conducts from above and from below, from cloud to ground and vice versa, and though casualties do occur during rainfall they are more in the nature of accidents.

It is during "dry storms" that most of the casualties from lightning stroke occur upon the road, carts and horses and travelling ox-wagons being fairly frequently struck, killing some, stunning others of the occupants as well as the horses, or running along the trek-chain of the wagon, killing or stunning the oxen on each side of it. In other cases, when rain has left the cloud but not yet reached the earth, lightning appears to outrun its conductor when near the earth and will then strike along the current of heated air left behind by the sweating horses or oxen, finding this warm current a better conductor to earth than the surrounding air.

Only one instance of a travelling motor-car being struck by lightning has come to my notice, though they leave a long and more highly-heated current of air behind them as they travel. I think it possible that they more often conduct lightning to earth than their occupants are aware of, as, being of iron or steel, the body of the car may, especially if wet, distribute the electric fluid to earth upon its external surface unnoticed by those travelling in it. In the instance which came to my notice, a car was travelling in a rather crowded street during a thunder-storm, when a flash of lightning fell in the vicinity and appeared to splash off a neighbouring house veranda on to the car just above the wind-screen; the driver holding the wheel was aware of no sort of shock, but upon stopping the car at once and making an examination evidence was found in a fresh streak over the varnish, running down the wind-screen, front and bonnet of the car to the wheel on that side. In view of the large numbers of motor-cars now on the roads and the extreme rarity of any reported instance of a car being struck, it is probable, I consider, that motor-cars are far safer to travel in, during a thunder-storm, than any other vehicle. In the same manner is the lightning distributed over the corrugated iron roofs of our houses and conducted to earth by the water-pipes connecting with the guttering. Though I have seen house roofs struck, and examined several others which had recently been struck, I am not acquainted with any instance where more than trivial damage was done, and probably for this reason.

It is wiser when walking over the veld—perhaps with a gun—or travelling in a cart and overtaken by a thunder-cloud which refuses to precipitate its contained rain, to lie flat upon the ground so as not to offer conduction of earth electricity to the cloud; but such is the indifference bred of familiarity with these storms, and by perhaps long immunity, that few travellers will take this trouble, rather risking the possibility of being struck and getting along. Flammarion, in his book upon lightning, mentions just such an instance. A number of peasants were hoeing in a large field when they observed thunder-clouds arriving overhead, and as rain did not begin to fall all hurriedly left the field, except one old man who was lame; knowing that it would take him some time to reach safety, he dropped to his knees where he stood, and knelt in prayer while the storm passed over him, and in this position was struck by a flash of lightning. When the storm had passed the labourers returned to find the old man still kneeling in the same position, but upon one of them laying a hand upon his shoulder he fell forward, and was found to be dead.

When a man is struck the lightning is readily conducted to earth by his clothes if they are thoroughly soaked and streaming with water, but if he is sheltering beneath a tree, for instance, and his clothes not really wet, the moisture on the surface of his skin and the fluid blood in the capillaries of the skin offer the next best ready conduction to earth; in the latter case streaks and arborescent patches in the track of the electric fluid to the ground, caused by charring of the epidermis and slight scorching of the cutis vera beneath, are very characteristic of lightning stroke; the clothes, socks and boots are invariably burst off from his body, and have the appearance of having had a very blunt knife inserted and its edge dragged through from within out with considerable force. The streaks are red at first, upon a white skin, but soon become brown, the parts feeling stiff and sore for some days but healing without scarring before long. The arborescence is of course much more readily appreciated upon a white than upon a black skin.

A native convict was discharged from jail one morning early, and dressed in a coat and trousers, carrying a stick and a rolled blanket, blithely started for his kraal about two days away. Next morning his body was found beside a path about eight miles from the town, it was thought with appearances of a struggle about him. Totally unaware of the cause of death, and forgetful of a smart thunder-storm which had passed over the town the previous afternoon, I visited the body, to find the coat ripped from his back and trousers from his legs in characteristic manner, whilst a mere glance at the surface of his skin revealed the arborescent burns down one side of the face and at intervals down his trunk and limbs. He had been struck by lightning the afternoon before.

But rarely there are other and far more severe injuries produced by the terrific discharges emanating from overcharged clouds; thus the dome of the skull is sometimes driven in and a gaping aperture with great disorganization of the brain produced, as with a blow of tremendous and concentrated force; other parts of the body have been described similarly broken up and destroyed where struck by this form of lightning.

A man ploughing in heavy rain was struck on the back of the head by lightning whilst thus engaged and, though rendered insensible for many hours and permanently deafened in one ear, recovered otherwise completely *because his clothing was soaked and streaming with wet at the time* and conducted the electric fluid quickly over its surface to the ground. He fell insensible when struck, the horse with the plough wandering back to the homestead alone; carried to the house, after some six hours he was given gr. v. of calomel—shaken dry between his teeth

and washed down with a few spoonfuls of water—the bowels acting vigorously an hour or so later, and in a few minutes he opened his eyes and looked around. It was some time before he spoke, but when seen some hours later still he was able to talk coherently. The back of the hat he wore showed an irregular break, the edges of which were slightly burned, and from the back of the head in this situation a streak of superficial burn was seen to run down the back of his neck, but from here the electric fluid mostly ran down outside his clothes, conducted by the water streaming down them at the time; they were not burst or broken, as usually seen when lightning travels beneath them upon the sweating surface of the body, but wherever metals were worn or carried in the pockets the electric fluid appeared to have struck in through the clothes and produced superficial burns immediately beneath them, e.g., beneath each metal stud and button worn, the buckle of his belt and of each brace, the catch of his sock-suspenders, a knife in one pocket and a key in another. He was somewhat somnolent and stupid for some twenty-four hours more but appeared to recover, with the exception of the hearing referred to and which remained the same many years later, though his brother declared that he was never quite the same as before the stroke.

Remedial Measures.

No more than has already been said can be recommended as a preventive measure for the guidance of those anxious and willing to avoid the risk of lightning stroke, but it should never be forgotten that in most cases it is possible to resuscitate an insensible person who has been struck, by ordinary artificial respiration and brisk rubbing of the body and limbs to set the circulation going again; for the heart, like other muscles, is instantly contracted very firmly by the electrification, and may so remain for a considerable time until *forcibly* distended by the blood again being pumped into it from the lungs and body. A condition of stasis of the circulation exists at this time, and during the period of insensibility there is much suffusion of the face, pointing to feebleness of the circulation from an exhaustion which is probably both nervous and muscular. Many times those struck and apparently quite dead have been thus revived, and excellent work achieved by volunteers in numerous relays. It is recognized treatment also to give a few grains of calomel during the insensibility stage; it acts satisfactorily, probably by stimulating rather violent peristalsis, and in some such way assisting in the recovery of the circulation in the abdomen, for the suffusion of the face diminishes soon after the calomel has acted well.

The Extraordinary Effulgence of Lightning.

Travelling home one night, in a cart with mules, it became pitch dark from an impending thunder-storm; some eight miles had still to be travelled, and anxiety was felt as to whether the distance would be covered before the storm fell; suddenly the road was lit up by a distant but exceptionally vivid flash of lightning, which so illuminated the country-side that the mules stopped dead as though blinded, and it was some minutes before I was able to proceed. That flash had come to earth over thirty miles away and was the first flash seen before the storm broke. Where it fell seven men were crowded into a bell-tent, to the pole of which, high up, was lashed a bicycle; the tent was struck at its point, bursting a large hole in it and running down its pole to the ground, the electric fluid creating terrible havoc; some of it splashed off the bicycle into the faces of the men, immediately and totally blinding some of them by burning their corneæ, killing three instantly and burning them all severely about the body; mercifully most of them were dead when found next day, but one man survived who is totally blind and has remained so now for a number of years.

During the Boer War, and whilst resting in a tent one afternoon, the nearness of an impending thunder-storm was advertised by the thump of a few great drops of rain upon the canvas; hastily kneeling up to the canvas I was about to let down the lower fringe of curtain when a very vivid flash of lightning came to earth about 200 yards away and exactly opposite me as I knelt; in the second or less during which the incandescence of the flash lasted the side of the tent was perfectly transparent, as though swept from before me, and I saw through it the flash fall amongst a group of soldiers, throwing them apart like chaff! Upon hurrying straight to the spot, three of the soldiers lay insensible, whilst one, who had been standing, leaning upon a rifle with fixed bayonet, and who was seen to be struck, was killed. Artificial respiration resorted to at once resuscitated the three after a considerable time and many relays of men; they all ultimately recovered completely, but no less than nine other soldiers were more or less splashed and burnt by the electric fluid. There was evidence that the rifle held by the man killed was struck first, and that the lightning travelled from it along his arms and entered his chest, for his injuries in this region were very severe.

The extraordinary effulgence of lightning, its extreme brilliance whilst it lasts, is seldom so astonishingly brought home to one as in this instance; it is produced by the instant incandescence of the air through which the electric fluid speeds at such terrific momentum and, owing to particles of dust in the air, is always most vivid when it falls, before the rain descends, through comparatively dry air.

Mycetoma. Report of four Cases (E. D. Lovejoy and R. W. Hammack, *Arch. of Dermat. and Syph.*, January, 1925).—Mycetoma is more common in the south-west of the United States than in other parts. It occurs most often in Mexicans, probably because of habits and occupation. There is comparatively little variation in the clinical and pathological picture, in spite of the fact that the causative fungi vary greatly. These four cases bring the number of mycetoma cases reported in the United States up to nineteen.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings** per annum, may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these,** with remittance, **is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 ,, ,, ...	1	3	3
200 ,, ,, ...	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 ,, ,, ,,	2	6	0
200 ,, ,, ,,	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

A WHITE AUSTRALIA: IS IT A POSSIBILITY?

By SYDNEY J. SKERTCHLEY, J.P.

(*Continued from page* 114.)

CHAPTER IX.

Australia.

(167) We must now apply the results of our investigation to the land of our adoption, Australia. We have reviewed the story of the human race from prehistoric times to the present day, looking upon it from an anthropological and not a political point of view, and have been driven to a remarkable conclusion. It has been shown that there is no evidence that either the Fair Whites (who alone concern us) or the Dark Whites, have ever succeeded in permanently establishing themselves on any foreign soil, with the doubtful exception of Canada. It is puerile to prattle about there not having been time enough to adequately test the question—we have been testing it from those dim ages when the elephant trumpeted in the glades that overlooked old Father Thames, in whose waters the hippopotamus wallowed, and where our forebears attacked the monsters with stone axes. We have seen the power of Imperial Rome succumb to the Fair White till all Europe owned his sway, and we have found in each and every case the autochthonous race—the man of the soil—come to his own again. This cry of "Give Australia time enough" is but the cuckoo-babble of ignorance. He who will not learn from experience can learn from nothing.

(168) In North America we have the finest object lesson of the age, and it is some four centuries old. In that great land, the land of splendid distances and splendid achievements, we see that the Fair White has not held his own, and that the future of the United States is by no means a certainty along the Anglo-Saxon lines that have led to greatness. The old Puritan and Dutch blood which gave the initial stamina is dead or decaying, and is being fast replaced by the less virile blood of the Dark White and the Slav, who, themselves, if we may judge by their history in the south, will in turn become enfeebled. I had been driven to this conclusion independently, and was surprised to find how keenly alive some of the best Americans were to the unpleasant fact. I had seen moribund Spain in the Far West and the Far East—the problem was not merely academic with me, though my studies had led me into academic grooves. My professional work had lain for years along anthropological lines, and in addition a longish line has been spent wandering to and fro upon the earth—like another great personage. The result was painful, but that I could not help. Had I been able to come to any other conclusion I would have gladly done so; but facts were too many for my patriotic belief in my race. The case of the United States determined me to review in detail the whole of the evidence, with the results now being set forth. The climax was, of necessity, the application of my studies to Australia.

(169) Through the kindness of Mr. Thornhill Weedon, the Queensland Government Statistician, I was enabled to work out the details of that State, and I had completed this—my last article—when the "Official Year Book of the Commonwealth of Australia" for 1901-8 appeared. I found Mr. G. H. Knibbs, the Commonwealth Statistician, had dealt with the question of the population of Australia in a masterly manner, and curiously had taken the United States for comparison of the natural increase. This welcome and independent addition to my subject

necessitated the re-writing of my article, and hence the delay in publication. It is no pleasant task to cry "Woe, woe to the city," or even "Wolf," and I suppose Priam and Hecuba snubbed Cassandra as a vapouring schoolgirl—yet Troy fell. I don't wish to be a trousered Cassandra, but I needs must show that "Australia for the Australians" is rather an aspiration than a probability.

(170) I will deal with Australia under three aspects. First, the natural rate of increase; second, Tropical Australia; and third, Urban Australia, that is, the effect of centralization.

Chapter X.

Components of Australian Population.

(171) The census of 1901 gave the population of Australia, with Tasmania, as 3,773,801, of which 2,908,801 were of Australian birth. The percentage of population according to birthplace for the Commonwealth was:—

	Per cent.
Australia	77·23
New Zealand	0·68
United Kingdom	18 03
Rest of Europe	1·98
Asia	1·25
Africa	0·08
America	0·33
Polynesia	0·28
At Sea	0·14
Total ...	100·00

We have therefore in the Commonwealth, a typically Australian population, the British-born numbering 679,159, as against 2,908,303 "Australian natives," as they proudly and justly dub themselves. But we have more than this: the population is essentially Fair White, and so eminently adapted for our investigation. As Mr. Knibbs puts it, "For the Commonwealth as a whole 98 per cent. of the population were from Australian or European birthplaces." (All quotations in this article, unless otherwise specified, are from Mr. Knibbs' "Official Year Book.") The Dark White population is so insignificant as to be negligible, amounting only to 0·008 per cent. Australia is, therefore, an even better test case than the United States in the investigation of the problem as to whether the Fair White race can permanently occupy a region foreign to that of their origin.

(172) The increase of the population of the Commonwealth since records have been kept is as follows:—

1788	857
1800	7,707
1810	15,063
1820	52,505
1830	70,039
1840	190,408
1850	405,356
1860	1,145,585
1870	1,647,756
1880	2,231,531
1890	3,151,355
1900	3 765 339
1907	4,197,037

Annotations.

The Treatment of Psoriasis by Intravenous Injections of Salicylate of Soda (J. Ferguson Smith, *Brit. Jour. of Dermat. and Syph.*, January, 1925).—Intravenous injections of sodium salicylate caused the disappearance of the eruption in sixteen per cent. of fifty-seven cases of psoriasis, its almost complete disappearance in eighteen per cent., and its distinct amelioration in fourteen per cent. Fifty-two per cent. were either unimproved or worse. Provided the dose did not exceed 3·0 gm. no unpleasant effects were noted. Exfoliative dermatitis ensued in six per cent. of the cases. Its connection with the treatment is uncertain. Several difficult cases, including one which had resisted a great variety of measures, were cleared by this means. While unsuited by the high percentage of failures and the necessity for frequent attendance for routine use, the method seems worth a trial in selected difficult cases. No evidence has yet been obtained as to its power of preventing relapse. It is advisable to combine the injections with local treatment, which was omitted in this series solely in order to evaluate the injection method.

Granuloma Inguinale: Including a Series of Cases illustrating some Points in Prognosis and Treatment (A. R. Fraser, *Brit. Jour. of Dermat. and Syph.*).—Eighteen cases of granuloma inguinale are summarized. Of these tartar emetic was employed in sixteen. Six cases healed completely. In ten cases there was no benefit from the intravenous use of the drug. In one case tartar emetic was not employed, and in another the condition healed after the administration of sulfarsenol. In no case was the rapid healing following intravenous tartar emetic, reported by some workers, observed. The prognosis in this condition is always grave as regards prospects of healing. There is no danger to life, and little impairment to general health. Intercurrent disease frequently makes headway on account of lowered resistance on the part of the patient. If the lesion is confined to the penis there is always a serious risk of the whole organ being completely destroyed. When this unfortunate state is reached the disease invariably becomes quiescent, and, although further spread does not occur, complete healing never takes place. The statement that the disease tends to spontaneous healing is without foundation. Treatment is most unsatisfactory.

Amœbiasis Cutis. With a Survey of the Medical Literature to Date (L. F. Heimburger, China, *Arch. of Dermat. and Syph.*, January, 1925).—Amœbic infection of the skin is extremely rare; few cases have been recorded in the literature. An interesting case is described by the author, in a Chinese farmer, aged 39. Patient first complained of a large ulcerated area in the right loin, painful; discharged large quantity of brownish-coloured

pus with a putrid odour. An interesting factor in this case is the rupture of the abscess externally through the abdominal wall. The growth of the ulceration was comparatively slow. The marvellous rapidity with which the emetin acted when given in sufficient dosage, is worthy of note, even in tissues in which the blood supply is greatly interfered with by the embolic action of the amœba. With drastic treatment with ordinary antiseptics (forty-nine per cent. liquor formaldehydi) the viability of the amœbæ was not noticeably affected. Emetin treatment by hypodermic injection in sufficient quantities is a specific for this disease.

Leprosy in New York City (J. A. Fordyce and Fred Wise, *Arch. of Dermat. and Syph.*, January, 1925).—Cases of leprosy in New York are not few; being a seaport town, many persons with leprosy gain access to the country and the disease is not always detected by the port authorities on account of its long incubation period. In the majority of cases the incubation period is a matter of years. The disease is evidently a contagious one. A table is given showing some data on forty-seven patients with leprosy. There are thirty-seven males and ten females. Youngest, a girl of seven; oldest, a woman aged fifty-five. There were twenty-nine white persons, eleven mulattoes, six Chinese, and one negro. Only three gave their birth-place as the United States, the rest were from different parts of the world. Fourteen patients had maculo-anæsthetic leprosy; eleven the nodular type, and twenty-two the mixed type. The photographs which accompany the article illustrate the early or more active phases of the disease.

A Study of the 1923 *Epidemic of Anterior Poliomyelitis in Kansas. Preliminary Report* (R. L. Diveley, *Jour. Amer. Med. Assoc.*, January 10, 1925).—From the study of this epidemic of anterior poliomyelitis, the cases over a period of one year having been followed, the following conclusions seem justifiable. If an early diagnosis is made, and proper treatment instituted during the febrile stage, the resulting cord involvement is not only lessened, but in a great percentage of cases prevented. If proper treatment is carried out during the second or convalescent stage, from seventy-five to eighty-five per cent. of the cases will show marked improvement or complete recovery, against forty to forty-five per cent. of partial recovery if proper treatment is not carried out. If proper treatment is carried out during the first and second stages, fully ninety per cent. of the deformed limbs and backs can be prevented. Many cases recover spontaneously without treatment, while others still show signs of paralysis after one year of careful supervision.

Some Morphological Features of Plasmodium falciparum (J. W. W. Stephens, *Annals of Trop. Med. and Parasitology*, April 30, 1924).—Microscopical examination of stained films, from a case admitted to hospital in West Africa, showed numerous *P. falciparum* parasites and a very scanty crescent infection. The red cell infection rate was approximately one per cent., and the relative numbers of single and multiple infections were: single, sixty-nine per cent.; multiple, thirty-one per cent. A more prolonged examination of these films revealed many peculiar forms, some of which are figured diagramatically in this paper. These forms were somewhat uncommon, but could always be found by systematic search through the films with a mechanical stage. They are arranged in four groups: (*a*) those in which there is a cytoplasmic connection between two adjacent parasites; (*b*) those in which there is a nuclear connection between two adjacent parasites; (*c*) symmetrical parasites; (*d*) miscellaneous forms.

The Crescent and the Red Cell (J. W. W. Stephens and R. M. Gordon, *Annals of Trop. Med. and Parasitology*, August 2, 1924).—The observations described were made on a series of thin blood films from a case of malaria in the Federated Malay States. Attention is drawn to the variable relationship existing between the crescent and the red cell. Illustrations of the forms accompany the paper, and are divided into four groups, i.e.: (*a*) those in which the red cell stains uniformly, presenting a solid appearance; (*b*) those in which the red cell is partly decolorized; (*c*) those in which the greater part of the red cell is decolorized and in which part of the circumference of the red cell takes the form of a loop, usually corrugated and generally subtending the concavity of the crescent; (*d*) miscellaneous forms.

On "Orchidoma" or "Orchidoblastoma" of the Horse (Tetsuji Kimura, *The Sei-I-Kwai Med. Jour.*, December, 1924).—The occurrence of tumours among the slaughter cattle in Japan is chiefly observed in horses, and melonoma and tumour of the testis are the most frequently met with. Tumours of the testis among horses are almost all so-called "orchidoma" or "orchidoblastoma," being found mostly in stallions of fifteen or more years of age, and usually only one testicle is involved. From the results of the macroscopical and microscopical examinations it can be seen that these tumours arise from the cell-proliferation in the seminiferous tubule, and belong to the epithelial new-growths (epithelioma). Metastasis in spermatic cord, inguinal and lumbar lymph-nodes is frequently to be seen, and always occurs through the lymph vessels.

Tuberculosis Incidence and Climate in India: Rainfall and Wet Winds (Sir Leonard Rogers, *Brit. Med. Jour.*, February 7, 1925).—The direction, steadiness, and strength of the rain-bearing winds appear to be the most important factors, in addition to high rainfall and absolute humidity, in influenc-

ing the prevalence of pulmonary tuberculosis in Indian jails. These observations are in accordance with the well-known observations of Dr. W. Gordon, of Exeter, on the relation between exposure to humid winds in Devonshire and the incidence of phthisis, and afford them strong support on a very large scale, since the monsoon-influenced Ganges and Upper Indus valleys extend over 1,400 miles. Their bearing on the choice of a residence for an actual or potential phthisical patient, and on the choice of sites for sanatoriums, is obvious.

Cutaneous Gonococcal Infection (A. Neave Kingsbury, *Brit. Med. Jour.*, February 7, 1925).—A medical man consulted Dr. Kingsbury on account of a curious dermatitis of the elbow. A slight abrasion was caused by a fall while playing football, and a week later the lesion became acutely inflamed and painful. On examination the abrasion was found to have become a shallow ulcer. Encircling the ulcer were a number of bullæ. The axillary glands were large and tender. Serous fluid was obtained by the aspiration of one of the bullæ, and films showed a few pus cells with intracellular Gram-negative diplococci morphologically resembling gonococci. A few Gram-positive cocci were also present. From cultures on blood agar *Staphylococcus aureus* and a Gram-negative diplococcus were obtained. Colonies of the latter on serum agar developed the scalloped edge characteristic of gonococcal colonies after four days' incubation. No history of gonorrhœa. Fermentation tests proved the organisms to be the gonococcus. Inquiries as to the probable source of infection elicited the fact that three days before the elbow became painful the patient had operated on a female for elephantiasis. At the time of operation there was vaginal discharge, but subsequent examination failed to detect any gonococci.

The Relative Number of Male and Female Crescents (J. W. W. Stephens and R. M. Gordon, *Annals of Trop. Med. and Parasitology*, April 30, 1924).—In this case, observed by the authors on nine separate days, female always outnumbered male crescents, the average ratio being three to one.

On Orchitis of the Rabbit, Experimentally produced by Inoculation with the Spirochæte of Rat-Bite Fever (S. Takenaka, *Acta Dermatologica*, November, 1924).—This paper gives a brief report of the clinical and histological features of the orchitic change in the rabbit induced by the injection of the spirochæte of rat-bite fever into this organ, whereby the specific inflammation takes place in each instance without fail, running a much shorter but much more regular course than that of the experimental syphilitic affection of the same animal. The spirochæte originated from a human case of rat-bite fever, and was transmitted from mouse to mouse in succession through many generations—passage virus. The process affects the testicle tissue uniformly. The course, being quite regular, can be divided into four stages: first week, incubation; second week, the stage of active progression; third week (or a few days more; the process may be prolonged into the fourth week), the stage of regression; fourth-fifth week, the œdematous swelling of the prepuce (and the perianal region) is a syndrome frequently observed.

The Production and Significance of Cutaneous Allergy to Pneumococcus Protein (G. M. Mackenzie and S. T. Woo, *Jour. of Exper. Med.*, January 1, 1925).—Intracutaneous injection of guinea-pigs with an alkaline extract of pneumococcus produces in about two-thirds of the animals an allergy with a skin reaction similar to the allergic skin response of tuberculosis. Continuance of the intracutaneous injections after the appearance of allergy results in its disappearance. The skin ceases to react. Neither of the animals manifesting skin allergy, nor those which fail to develop it, show any significant alteration in susceptibility to pneumococcus infection by intraperitoneal inoculation. Similarly, animals desensitized by continuing the intracutaneous injections after the appearance of allergy show an unaltered susceptibility.

The Significance of Anaphylaxis in Pneumococcus Immunity (G. M. Mackenzie, *Jour. of Exper. Med.*, January 1, 1925).—Intraperitoneal injections of killed and living broth cultures of a virulent pneumococcus produce in guinea-pigs a high degree of active immunity and a serum with strong protective power. Despite the protective power of such serum, no agglutinins for the homologous organism and no precipitins for soluble derivatives were demonstrable. Guinea-pig immunity to pneumococcus infection produced by the method described is not attended by cutaneous allergy to derivatives of the pneumococcus used for immunization. During the course of an artificially produced active immunity, anaphylaxis may at times be present, and at times absent, without any measurable effect upon the resistance of the animal to infection by intraperitoneal injection. In the particular instance studied, the experiments indicate that anaphylaxis to pneumococcus protein has no important effect upon the resistance of the animal to infection. It appears to be a concomitant without any significant rôle in the immunity mechanism.

Encephalitozoon Cuniculi as a Kidney Parasite in the Rabbit (T. Smith and Laura Florence, *Jour. of Exper. Med.*, January 1, 1925).—A spontaneous epidemic of nephritis among rabbits, associated with a protozoan parasite, has been observed in a certain breeding stock since 1918. It is regarded as a nest

infection. The parasite is tentatively classed among the microsporidia and the stages encountered are regarded as vegetative, which may, perhaps, pass through several generations in the same host. It is a parasite of the epithelial cell, provoking no immediate host reactions. These are supposed to follow injury, such as the destruction of the epithelium and denudation and plugging of the tubules. The localizations in the brain are also without cell reaction, except under special conditions, and the many cell foci present are attributed to coccidia and perhaps to bacteria and other intestinal parasites. The kidneys are looked upon as the normal habitat and the brain parasites as aberrant and outside the normal cycle, unless it can be shown that the spores discharged into the circulation may again multiply in some organ like the kidneys in direct communication with the exterior. It is highly probable that many reported cases of nephritis among older rabbits used in experiments had their origin in an early invasion of the parasite described.

Serological Relationships among and between the Streptococci and Pneumococci (C. H. Hitchcock).—Using the complement-fixation reaction with whole bacterial solutions as antigens, it has been possible to confirm the existence, within the non-hæmolytic streptococcus family, of two great groups. One of these groups, that which may be designated as of the left side, is related in an orderly way to the hæmolytic streptococci; the other, of the right side, is similarly related to the entire pneumococcus family. In addition, the hæmolytic streptococcus family shows a reactive range which relates it, though less closely, to the non-hæmolytic streptococci of the right side, and to the pneumococci. The existence of these cross-relationships is not associated with the precipitable substance of either family, but may tentatively be presumed to be dependent upon the properties of the protein or lipoid-protein fraction of the bacterial cell.

Malaria in Suriname (C. Bonne, *Nederl. Tijdschr. v. Geneesk.*, August, 1924).—In Dutch Guiana all three species of malarial parasites are found and ten known species of anopheles. Subtertian malaria is the commonest form in the hills, and the chief insect host is *A. argyrotarsis*. This parasite is not found on the coast, but *A. tarsimaculatus* may be seen. Fifty-four per cent. of the nigger children and twenty-four per cent. of adults are infected. Fifty-six per cent. of the black miners are infected. Malaria was much less prevalent in 1922 than 1921. Ten cases of blackwater fever have been recorded during these years.

Factors concerned in the Polycythemia produced by the Subcutaneous Injection of Epinephrine (C. W. Edmunds and E. E. Nelson, *Jour. of Exper. Med.*, January 1, 1925).—The subcutaneous injection of epinephrine in doses of 1 mg. per kilo brings about a polycythemia, an increase in reticulocytes, and an increase in young forms of polymorphonuclear leucocytes. The polycythemia is no doubt in part a concentration phenomenon, but the presence of these young cells in increasing numbers is believed to be evidence that there is at the same time a discharge of cells from the blood-forming organs, due to the effect of the drug upon them. A similar effect is obtained by continued stimulation of the peripheral ends of the cut sciatic nerves in the curarized animal.

The Alleged Rôle of Lactic Acid in Arthritis and Rheumatoid Conditions (F. A. Cajori and C. Y. Crouter and R. Pamberton, *Arch. of Internal Med.*, October 15, 1924).—The lactic acid contents of the blood, urine and sweat of patients suffering from arthritis and rheumatic disabilities has been determined, and the results have been compared with the respective lactic acid contents from non-arthritic persons. The lactic acid was determined also in the synovial fluid from a case of joint effusion. In no case have abnormal quantities of lactic acid been observed in the arthritic patients. These findings, therefore, lend no support to the idea that arthritis, at least of the types studied, is caused or characterized by abnormal production or disposal of lactic acid. Lactic acid has been found to be present in sweat in considerable quantities, making up about fifty per cent. of the organic acids of sweat. Its presence in this secretion may be referable to the chemical changes occurring in the sweat glands during their activity. The benefit accruing to arthritic patients from sweating measures cannot, in the light of these results, be ascribed to the elimination of lactic acid in the sweat.

The Concentrating Capacity of the Kidney (T. Addis and M. G. Foster, *Arch. Internal Medicine*, October 15, 1924).—Experiments on normal human subjects are reported in which the conditions were adjusted with a view to the production of urine which would contain the highest possible concentration of urea, chlorids and phosphates. It was found that the highest concentration of each of these substances was attained when it was given in considerable amount and in high concentration to subjects whose fluid intake had been restricted. Experiments on rabbits deprived of water and given large amounts of a mixture of urea and sodium chloride showed that it was possible to obtain urine in which there was a high concentration of both these substances. No evidence was found which would suggest that the height to which the osmotic pressure of the urine might rise is restricted by virtue of any limitation in renal capacity. The widely accepted hypothesis that the kidney is unable to excrete urea, chlorid or phosphates at more than certain maximum concentrations is shown to be

untenable. The assumption that concentrations of urea, chlorid and phosphates, which approach the highest levels found in the urine, have approximately the same osmotic pressure is shown to be contrary to observed facts. It is suggested that changes in the concentration of urea, chlorids and phosphates in the urine are produced by changes in the relation between the concentration of these substances in the blood and the concentration of free water in the blood. It is difficult to obtain very high concentration of the urine because a marked increase in the concentration of urea, chlorid or phosphate in the blood is associated with a concomitant increase in the concentration of free water in the blood.

On the Accuracy of Measurement of Small Volumes of Fluid with a Capillary Pipette (A. Fleming, *Brit. Journal Exper. Path.*, 1924, vol. v, page 148).—It has been shown that measurements of five and ten cubic millimetres can be made with ordinary capillary pipettes with more than sufficient accuracy for use in the ordinary serological work of a bacteriological laboratory. The wash—that is the amount of fluid which adheres to the inner wall of the pipette—amounts to, at the ordinary rate of working, about three per cent. of the volume measured. In making a series of dilutions in the ordinary way, the fact that a wash about three per cent. remains in the tube introduces a progressively increasing error of about 1·5 per cent. with each dilution, so that at the eighth dilution the theoretical error would be about 13 per cent. A pipette is described whereby a series of dilutions can be made rapidly, and in which the error due to the wash can be eliminated.

The Reaction of the Liver to Phenol-tetrachlorphthalein in Early Obstructive Jaundice (W. Bloom and W. H. Rosenau, *Arch. of Internal Medicine*, October 15, 1924).—In the absence of the liver and kidneys, phenol-tetrachlorphthalein continued to circulate in the blood-stream. The intravenous injection of phenol-tetrachlorphthalein in the early stages of obstructive jaundice in dogs caused an early appearance of both the indirect and the direct Van den Bergh reactions that was noticed in control animals. All attempts to recover the dye from the liver in obstructive jaundice were unsuccessful. Dog liver decolorized phenol-tetrachlorphthalein less than the heart, lung and spleen *in vitro*. In early obstructive jaundice phenol-tetrachlorphthalein appeared in minute amounts or not at all in the lymph of the thoracic duct. In chronic obstructive jaundice, however, the dye was present in large amounts in the lymph of the thoracic duct. The intravenous injection produced in the human being a transient hyperbilirubinemia, as evidenced by the Van den Bergh test. The high incidence of thromboses and other untoward reactions after the injection of phenol-tetrachlorphthalein is a serious objection to the execution of this test as a clinical method. In no case of long standing complete biliary obstruction have we noticed a greater dye retention than four per cent. in the blood-stream. A new method is given for the accurate determination of small amounts of phenol-tetrachlorphthalein in blood-serum.

Detection of Traces of Alkali or Soap in Refined Coconut Oil (W. L. Brooke, *Philippine Journal of Science*, August, 1924).—Less than 0·02 per cent. sodium carbonate can be detected in twenty-five grammes of coconut oil by ashing and testing with phenolphthalein. As small an amount as 0·00065 per cent. sodium hydroxid can be detected in twenty-five grammes of coconut oil with certainty by ashing. A nickel crucible is preferable to a porcelain crucible for ashing.

Chemotherapeutic Experiments with Chaulmoogra and Allied Preparations (Otto Schobl, *Philippine Journal of Science*, August, 1924).—The degree of unsaturation of vegetable oils which stimulate the growth of acid-fast bacteria and of those which inhibit the growth of acid-fast bacteria has no relation to their growth-stimulating or growth-inhibiting activity. The growth-stimulating effect of certain vegetable oils is due to the glyceryl and not to the acid part of the oil. The condition of the unsaturation of the oils containing the acids from the chaulmoogra series and of the oils which stimulate the growth of acid-fast bacteria is paramount. Saturated chaulmoogra oil lacks the growth-inhibiting activity toward acid-fast bacteria which is possessed by the unsaturated oil. The growth-inhibiting activity of chaulmoogra oil depends on the structure of the ring of the fatty acids. When the structure of the ring is changed by saturation with hydrogen the oil loses this biologic property. There are indications that, due to physical properties, acids from the chaulmoogra series containing a short side-chain are more effective *in vitro* than are those having a long side-chain. Acid-fast bacteria adapt themselves to the acids from the chaulmoogra series in due time and then withstand larger doses than they did originally.

The Concentration of the Plasma Proteins in Nephritis (G. C. Linder, C. Lundsgard and D. D. Van Slyke, *Journal of Experimental Medicine*, vol. xxxix, No. 6, June, 1924).—In nephrosclerosis (Volhard and Fahr classification of nephritis) there was no decrease in the plasma proteins. With heart failure the ratio of albumin to globulin fell from the normal 1·7-0·3 to about one.

There is a sharp difference between the two types of glomerulonephritis in the effect on plasma proteins. In the vascular-interstitial type the effect was

the same as in nephrosclerosis. There was no decrease in the plasma proteins until shortly before death.

In the glomerulo-tubular or nephrotic type, active or recently active, the total plasma proteins were less than 5 gm. per 100 c.c. This decrease from the normal 5·5 to 7·5 occurred whether œdema was present or absent. The decrease chiefly affected the albumin, the globulin being usually diminished but little, and sometimes slightly increased. Consequently the ratio of albumin to globulin was reduced to less than one, and occasionally to 0·6.

In nephrosis similar conditions were found in the protein concentration, but in severe cases the decrease in albumin was greater than in nephrotic glomerulonephritis, while the globulin was either very slightly reduced or was increased. The albumin globulin ratio was therefore lower than in nephrotic glomerulonephritis, ranging down to 0·26.

With the disappearance of œdema there was usually an increase in the plasma protein concentration, but this was not invariable, and concentrations of 4·5 per cent. or less were compatible with the persistent absence of œdema. The ratio of albumin to globulin showed an irregular tendency to rise. Whenever the total concentration was less than four per cent. there was œdema present, but it was sometimes slight in amount.

With recovery in acute cases, and remission with decrease of proteinuria in chronic cases, normal concentrations were regained. The albumin-globulin ratio remained low in some instances for a longer period on account of an absolute increase in globulin concentration.

In " functional proteinuria " no change in plasma proteins was found.

Low plasma protein concentrations were always associated with considerable losses of protein in the urine, but these losses did not provide an explanation for all the observations. A disturbance in the production of the plasma proteins appears probable.

A New Liver Function Test (G. D. Delprat, M. N. Epstein, William J. Kerr, *Archives of Internal Medicine*, October 15, 1924).—In normal persons, following the injection of a given amount of rose Bengal into the circulation, the concentration of the dye computed under standard conditions of dosage and blood volume does not exceed certain limits at four and eight minutes after the time of injection. In abnormal cases, where evidence of liver disease can be demonstrated clinically, the concentration of the dye in the circulation computed under standard conditions of dosage and blood volume at four and eight minutes from the time of injections, exceeds the limits of concentration of the normal cases. Complete biliary obstruction which can be determined by other clinical tests, causes a retention in the blood-stream. When it can be shown that the rate of elimination of rose Bengal from the circulation, after injection is reduced, or, in other words, when the concentration of the dye at four and eight minutes after injection exceeds the normal limits, a certain degree of liver dysfunction may be assumed to exist in the absence of complete biliary obstruction. A rough estimate can be formed from the concentration of the dye remaining in the circulation at four and eight minutes after injection, of the extent of the liver disease.

Multiple Electrical Stethoscope and Electrical Filters as Aids to Diagnosis. Phonograph Records of Heart Murmurs (C. J. Gamble, M.D., *Journal of American Medical Association*, October 18, 1924).—Further improvements have been made in the multiple electrical stethoscope. Electrical filters permit selection of the components of a sound above or below a chosen pitch, a procedure not possible in other methods of auscultation. This is of advantage in the magnification of lung sounds and murmurs, and the detection of pericardial rubs and fœtal heart tones. Phonograph records of heart murmur and breath sounds, of a quality satisfactory for teaching, have been made and demonstrated to a large audience. With a small attachment they may be reproduced on an ordinary phonograph. Marked progress has been made in the reproduction of chest sounds by a loud speaker.

Report on the Investigation of a number of Cases of Leprosy at Nauru, Central Pacific (F. G. Morgan, *Commonwealth Department of Health Service Publication*, No. 25).—Nauru is a small, very isolated island in the Central Pacific Ocean. The Nauruans are an attractive, happy people, well nourished and well developed. Their food is mainly raw fish and coconuts. The climate is equable, extremes of heat and cold do not exist, and there are no seasons. Since 1920, thirty-nine known cases of leprosy have occurred upon the island. Of this number, thirty-seven were Nauruans, one a Chinese, and one a Caroline Island native for many years resident on Nauru. A few sporadic cases have occurred amongst the Chinese labourers from time to time previous to 1920. A Gilbertese woman, Etsio, was probably the source by which the disease was introduced to the Nauruans between the years 1911 to 1914. Since leprosy has a prolonged incubation period, it is to be expected that further recognizable cases will appear as the disease develops, while at present they show no recognizable signs of the malady. The recently introduced method of regular medical inspection of the total population, combined with prompt segregation of lepers, will do much towards stamping out the disease. Routine nasal swabbing was of little value in detecting incipient cases of leprosy. Acid-fast bacilli were detected in the nasal secretions in two cases out of twenty-nine known lepers, and were not found in any case not otherwise demonstrated to be leprous. It appears that smears made from tissue excised from suspicious lesions is the best method of demonstrating acid-fast bacilli.

This is by no means infallible, but supplies useful confirmatory evidence. Most of the patients were in an early stage of the disease. A point of interest was the frequency with which the various lesions appeared in different parts of the body, and the frequent and early appearance of macules upon the upper limb, especially between the elbow and the shoulder.

The Wassermann Test. The Effect of Intramuscular Injection of Neo-arsphenamin on the Wassermann Reaction (D. L. Belding and R. H. Holmes, *Arch. Dermatology and Syphilology*, vol. 10, No. 5, November, 1924).—This is the third of a series of papers that discuss the effect of certain antisyphilitic remedies on the Wassermann reaction. The conclusions are that the strength of the Wassermann reaction in congenital syphilis, as a rule, is greater than in acquired syphilis of the same duration. Apparently it is stronger in early than in late congenital syphilis. Children with clinical evidence of syphilis have a stronger reaction than children with only serum-positive syphilis. Children who have received treatment have weaker reactions than the untreated children. Intramuscular injections of neo-arsphenamin appreciably lower the strength of the reaction, at least for sixteen weeks, the period of observation in the authors' cases. Children who give past or present clinical evidence of syphilis and resultant malnutrition respond less readily to treatment than those in whom the disease is latent. Untreated or slightly treated children respond more readily to treatment than those who have received thorough previous treatment, suggesting the development of a treatment-fast condition.

Works on Rabies During the Last Ten Years (P. Remlinger).—The author has condensed the most important papers published within the last ten years on the subject of rabies. The clinical diagnosis of human rabies is not always easy; many of the symptoms may also be seen in other affections and for this reason there have been several erroneous diagnoses.

Effects of Non-Specific Protein Therapy in Syphilis (S. S. Greenbaum, L. Carrol, S. Wright, *Arch. of Dermatology and Syphilology*, vol. 10, No. 5, November, 1924).—This series of cases shows that non-specific protein therapy favourably influences the course of syphilis. In what manner it exerts this favourable influence or what value it has in the treatment of syphilis, the authors are not prepared to say. They emphasize that it is not their purpose to intimate that injections of foreign protein are in any way a cure for syphilis. Their experience, however, would indicate that there is a definite influence on the course of the disease following their use; and this influence, in chronic syphilis at least, appears to be a favourable one. If the effect of the injections is to stimulate the natural protective forces of the body, the use of non-specific protein therapy as an adjunct to specific therapy may be of decided value.

Universal Leukæmia Cutis (H. L. Keim, *Arch. Dermatology and Syphilology*, vol. 10, No. 5, November, 1924).—A case of universal leukæmia is presented with clinical histopathologic and hæmatologic evidence of lymphatic leukæmia From a study of this patient and other cases of leukæmia, mycosis, fungoides, lymphosarcoma and Hodgkin's disease it would seem that these diseases are genetically related pathologically and may be grouped under the head of the "lymphoblastoma." If such a classification is justifiable, then the cutaneous pictures associated with these diseases must be regarded as the variable cutaneous expressions of the "lymphoblastomas."

Scrofuloderma Gummosa (Tuberculosis Colliquativa) (H. A. Michelson, *Arch. Dermatology and Syphilology*, vol. 10, No. 5, November, 1924).—From a review of the literature and his own observations on tuberculous colliquativa (scrofuloderma gummosa) the author is convinced that this is a distinct type of true cutaneous tuberculosis which does not necessarily arise from tuberculous glands or bones, but may begin in the cutis or sub-cutis.

The Calcium Content of the Blood in Various Diseases of the Skin (H. J. Schwartz and O. L. Levin, *Arch. of Dermatology and Syphilology*, vol. 10, No. 5, November, 1924).—These studies are based on an analysis of over 300 cases, which are given in tabulated form, and which show that examination of the blood from patients suffering from various dermatoses does not reveal any positive relationship between the calcium content of the blood and the skin disease. The presence of calcium deficiency was revealed in several cases of acne vulgaris, eczema, furunculosis and folliculitis. The administration of calcium and parathyroid by mouth seemed to produce clinical improvement in some of the patients and enhance the calcium content of the blood. Although normal figures were obtained in urticaria and allied conditions, it is possible that in such instances the tissues may have been unable to take up and use the blood calcium or that there may have been a disturbed colloidal chemistry of the cells. The clinician who is anxious to establish a relationship between abnormal calcium metabolism and skin diseases must, according to the authors, wait for more improved laboratory methods and a better understanding of the whole subject of calcium metabolism.

Diagnostic Errors Leading to Uncalled for Appendectomy (Henry Wald Bettmann, *Journal of the American Medical Association*, October 18, 1924).—Operations for chronic appendicitis do not yield a satisfactory proportion of cures owing to errors in diagnosis. The term chronic appendicitis expresses a pathological rather than clinical condition. The relapsing form of appendicitis necessitates prompt surgical intervention, and yields a very large proportion of permanent cures. Aside from the relapsing type, a particular group of symptoms suggests chronic appendicitis, but not with reasonable certainty. Right iliac pain is a most deceptive sign. In from forty to fifty per cent. of the unsuccessful operations it remains for months or years after the operations. Two thirds of the failures are in cases that have not been adequately studied before operation. Roentgen-ray examinations are usually not to be depended on for clinical diagnosis, and are often misleading. Urinary disorders are far too often mistaken for appendicitis. In general, too many constitutional disorders are overlooked, and appendectomy often has serious after-results

Current Literature.

The Indian Medical Gazette. January, 1925.

The Problem of Epidemic Dropsy and Beriberi (H. W. Acton and R. N. Chopra).—Epidemic dropsy and beriberi are different clinical aspects of a toxic syndrome caused by the ingestion of poisonous bases formed in rice under certain conditions; although similar poisons can be formed in other foods under storage, e.g., tinned provisions, dried fish, &c. This disease in the rice can readily be detected by the water test, and moreover these two clinical entities are associated with two different grades of rice. A spore-forming proteolytic bacillus of the *B. vulgatus* group is commonly found in such diseased grains. Highly polished grain is more easily attacked owing to the loss of the aleurone layer and embryo, and the consequent exposure of the delicate cells of the fruit. The bacteria and their spores as well as their effects on the structure of the fruit, can be demonstrated by microscopical sections and cultural tests. Experimentally by spraying rice or inoculating sterile rice media under certain conditions of temperature and humidity, the same poisonous bases are formed from the proteids. These bases pharmacologically produce all the signs of the disease, viz.: œdema, heart effects, and para-sympathetic paralysis, and they are not present in the non-inoculated control rice media. Individual susceptibility plays an important part when the amount of poison ingested is small in amount, e.g., the small incidence sometimes seen in a jail population. When the quantity ingested is very large, e.g., in a whole family attacked by epidemic dropsy, it then determines the mortality. Hypo-adrenia in particular, and hypothyroidism to a lesser extent, increase the susceptibility towards these bases, and this in turn is closely correlated with coloration of animals. Rice polishings contain bases that are antagonistic to the bases found in diseased rice. Polished parboil rice is the most dangerous of all rices, and can be protected only by preservatives and proper storage. Adrenalin in small doses, two minims intramuscularly twice a day, diminishes cell permeability and so relieves the œdema, and also antagonizes the action of the water-soluble bases. To a lesser extent it protects the para-sympathetic.

Serum Reactions in Syphilis (R. B. Lloyd).—In this paper no finality has yet been reached; the following is the summary of the present position: While there are material differences amongst some of the leading workers regarding the value of flocculation tests, there is a general consensus of opinion that the Wassermann reaction remains for the present the best test for the detection of syphilis, though one or more of the flocculation tests may be done in addition. The great advantage of the Wassermann test is its high degree of sensitiveness, combined with an almost total absence of false positives. While the earlier flocculation tests have not proved as satisfactory as was expected, the more recent developments are much more promising. Improvements in technique may very possibly enhance the value of Sachs-Georgi test. The Kahn test is simple and apparently very serviceable. The former of these tests, however, is not quantitative. The Dreyer-Ward test is valuable and quantitative, and the technique should admit of simplification. It is probable that some form of flocculation test will eventually attain to extended use; although the difficulty in reading intermediate grades of positive reaction is at present considerable. The occurrence of non-specific reactions in flocculation tests needs further examination. Before any particular flocculation reaction can be accepted as the standard test, it must be clearly shown to be capable of yielding satisfactory results with cerebrospinal fluid; since this is the direction in which syphilis therapy is concentrating.

A Preliminary Note on the Successful Treatment of Kala-azar with "Stibamine Glucoside" (L. E. Napier).—Stibamine glucoside, an aromatic compound allied to sodium-amino-phenyl-stibiate with an antimony content of about 30 per cent. and a minimum lethal dose of about 500 mg. per kilo, has proved successful in the treatment of kala-azar cases at the Carmichael Hospital for Tropical Diseases in Calcutta. The compound, an easily soluble powder, was dissolved in distilled water to make a 4 per cent. solution and was injected intravenously. The initial dose given was 0·1 grm. and 0·2 grm, the maximum dose for patients weighing over 50 lb. The cure was confirmed by direct and

cultural examination of the spleen puncture material, in cases where the spleen was palpable, and of the liver puncture material where it was not, taken about one week after the last injection had been given. It is obvious that this compound is far superior to the antimony tartrates in the treatment of kala-azar.

A Case of Typhoid Septicæmia without Typhoid Ulcers (W. Fletcher and J. E. Lesslar)—Two strains of *B. typhosus*, the one smooth and agglutinable, the other rough and non-agglutinable, were isolated from the blood of an old Chinese labourer, whose serum agglutinated a stock of emulsion of *B. typhosus* in high dilutions. *B. dysenteriæ* Flexner, type X, was isolated from his fæces on each of four occasions when they were examined. The patient died about six weeks after the commencement of his illness. There was no marked thickening or inflammation of the gall-bladder, but an agglutinable strain of *B. typhosus* was cultivated from it There were two old pigmented scars just above the ileocæcal valve, but there were no typhoid ulcers. It is an open question whether the patient was a chronic carrier and the septicæmia the result of infection from an old focus in the gall-bladder, or whether, on the contrary, the gall-bladder had become recently infected as a result of the general septicæmia.

BULLETIN DE LA SOCIETIE DE PATHOLOGIE EXOTIQUE.
January 14, 1925.

Coccidium persicum, *nov. sp. Parasite of the Biliary Tract of* Tropidonotus natrix, *var.* persa *Pallas* (Mme. M. Phisalix).—The coccidium described was found in the biliary tract of a number of snakes of Bologna. The complete development of the parasite has been followed by the author, and a full description is given. It belongs to the same genus *Coccidium* (syn.: *Eimeria*) discovered by Debaisieux, but varies in some of its characters, especially the merozoites and microgametes. To distinguish this parasite from the others of the biliary tract the author has named it *Coccidium persicum.*

Chytridial Parasites of the Amœbæ of Man Possibility of their Utilization as Biological Means of Fight against Amœbic Dysentery (A. Lwoff).—This parasite was found in the stools of a patient. It appears to be fairly common in *E. coli* and *E. dysenteriæ*, but up to the present it has not been minutely described. In three amœbæ, out of 400 examined, the parasite was seen in the form of spherical masses made up of a large number of small corpuscles. No nucleus could be detected in their interior. Two of these amœbæ contained only one parasite, the other contained three. The parasite is *Sphærita endogena;* it is minutely described.

The Use of Quinine in the Treatment of Malaria (Ed. and Et. Sergent, L. Parrot, H. Foley and A. Catanei).—This paper is divided into three parts, viz.: The Therapeutic Use of Quinine, The Preventive Use, and The Use of Quinine to Improve the Reservoirs of Virus. Quinine given therapeutically can only be administered according to the condition of the patient and the result of the microscopical examination. As a general rule, the dose for an adult should not exceed 2 gr. pro die. Children generally tolerate proportionally larger doses than adults. Intravenous injections should be given in pernicious attacks of malaria; intramuscular injections in grave cases, in cases of stomachal intolerance and in cases where the doctor wishes to be sure of the absorption of the medicament. Administration *per os* can be given in most cases. In the case of quinine as a preventive of malaria, it cannot be said that quinine absolutely protects one from the malady, but should a person be affected with malaria, in spite of taking quinine, it never takes on the pernicious form. As quinine is rapidly eliminated, daily administration is necessary. Results of the Anti-malarial Service in Algeria prove the efficacy of quinine as a preventive of malaria.

Clinical Observations on Multiple Oriental Sore (M. Neveu-Lemaire).—These observations were carried out in the course of a journey in Syria and Mesopotamia during last autumn, from which the following conclusions may be gathered. All the lesions of this disease appear at the place of an insect bite, very probably the *Phlebotomus*. It is pointed out by the author that in nearly all books on the subject one reads that Oriental sore, in the beginning, resembles an insect bite; he thinks it would be more exact to say that it is on the level of an insect bite that the first lesion appears and this is very probably produced by the inoculation, at the moment of the bite, of the infectious germ. The period of incubation is generally eighteen days. A longer incubation period is exceptional, except in cases of experimental disease. In a patient suffering from Oriental sore there seems to be, during the evolution of the lesion, a marked hypersensibility which has already been described by various authors. The number of cases met with in this series is fifteen. Treatment so far has been unsatisfactory. The application of aseptic dressings has been quite as good as eight injections of emetic, each of 10 cg.

Leprosy in New Caledonia (J. Genevray).—This paper confirms the works on leprosy previously published by several authors during the last ten years or so. The natives of New Caledonia in 1924 numbered 26,857, and of these, 578 were isolated as lepers. The affection is unequally distributed throughout the colony. Cases of nervous leprosy are very common. The diagnosis of suspected cases is not easy; the numerous diseases which are met with such as Raynaud's disease, ainhum, scleroderma, &c., are often cases of error in diagnosis, but 300 to 350 of the suspected cases may be considered as true lepers. This brings the number of lepers up to nearly 900, and to these may be added a percentage of ten, which repre-

sents lepers who get away from observation. Among the Europeans inhabiting New Caledonia 158 cases (0·95 per cent.) of leprosy existed on May 1, 1924, most of which were cases of cutaneous leprosy; nervous cases were rare. There were only eight suspected cases. The men generally are more frequently attacked than the women, both natives and Europeans. The paper is to be continued.

Tests of Treatment of Leprosy at Martinique (R. Baujean).—Twenty cases of leprosy, all of different stages, have been treated with various medicaments, of which chaulmoogra oil, and especially ethyl ethers, have proved to be the most efficacious. Eleven of these cases were ameliorated after treatment, in different degrees, the other nine cases remained stationary during and after treatment.

Piroplasmosis of Bovidæ in the Government of Petrograd in 1923, *Preliminary Note* (W. L Yakimoff, Mlle. W. Z. Wassilewsky and B. Zawialoff).—Bovine piroplasmosis is very common in Petrograd, as it is in all the north-west region of Russia. The ætiological agent of piroplasmosis in Russia is *Babesiella bovis*, and not *Piroplasma bigeminum*, as has been stated by several Russian authors. The latter exists, however, in the south. The two piroplasmoses can be differentiated. The period of incubation is twelve days. The most characteristic feature of this malady is the hæmoglobinuria.

Details of the Transmission of European Recurrent Fever by Lice (C. Chapcheff).—The investigations reported were carried out in North Africa, on *Spirochæta berbera*. During the first series the spirochæte was found in only 13 of the 138 lice collected from cases of recurrent fever during the course of the second to the eighteenth day of the illness. The spirochætes are particularly found in abundance in the hæmolymph of the insects and less often in other parts of the organism. Both male and female lice, of the head and of the body, are equally infected by visible forms of the parasite. None of the lice nourished on patients in the apyrexial stage showed presence of spirilla. These investigations prove that both European and North African recurrent fever are transmitted to healthy subjects by the excrements of lice, and not by the bite of the louse as is commonly believed. Another point of interest is that to contaminate man with exanthematus typhoid one louse bite is sufficient, but to infect recurrent fever a large number of lice is necessary. This difference explains certain epidemiological facts observed in Russia during the epidemic of 1918-20.

Avitaminosis and Infection in Experimental Disease of the Young Pig due to Bacillus asthenogenes. *Investigations on Beriberi* (P. Noel Bernard).—The conclusions which may be gathered from these investigations are that rice-bran, in which vitamin B has been destroyed by heating at 135° for one hour does not cause the beriberi syndrome in young pigs in 110 days. The syndrome is seen in less than 110 days, by infection due to *B. asthenogenes*, in young pigs which have absorbed cultures of the infectious germ and fed with polished rice or rice-bran, heated at 100° for twenty minutes, which is generally considered insufficient to destroy vitamin B. Polished rice is one of the essential causes of the production of the experimental disease. The bran exercises a protective action against the infection by its nutritive value and other qualities. The experimental disease of the young pig is a toxi-infection, the beginning of which is the alterations in the gastro-intestinal functions under the influence of an alimentation which favours the infectious germ, its multiplication, and the production of its toxin, and in which the evolution, which begins with the beriberi syndrome, depends on the absorption of this toxin by the organism.

Apropos Ganglionic Substance Particularly Rich in Trypanosoma gambiense (R. Guillet).—From this article there is reason to believe that sleeping sickness constitutes a great danger in certain regions of Senegal. A native, forty-five years of age, was sent to the Pasteur Institute for microscopical control of the diagnosis of trypanosomiasis. He complained of having become thin and of fatigue. A very clear cervical polyadenitis was present, and a characteristic, large, soft ganglion on the right was observed. Puncture of the ganglion showed a true culture of trypanosomes; in one field fourteen flagellates were counted. This case is interesting inasmuch as it is apparently the first during the three years' investigation of the author, in which the ganglionic substance has been so rich in trypanosomes.

Medical News.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

Examination Results.

Division of Tropical Medicine and Hygiene.

The following Medical Officers passed the School Examination at the termination of the 77th Session (January-March, 1925):

Passed with Distinction.— Craighead, A. C. (winner of "Duncan" Medal); Haworth, A. N.; Klaber, R.; Goldsworthy, N. E.; Mohammed, A. S.

Passed.—Lumsden, K.; Vickers, W. J.; Garnham, P. C. C.; Campbell, A. H.; Cook, E. N.; Banks, J. N.; Graham, J. W.; Monks, A. B.; Fraser, E. M.; Struthers, E. B.; Grant, P. F. A.; Brown, H. H.; Bowyer, J. H.; Ali, M.; Gordon, J.; Manley, J.; Speirs, R. C.; Goodwin, T. S.; Read, F. C.; Lal, M.; More, H. J.; Enzer, J.; Wilde, O. G.; Thambiah, R. W. C.; Coomarasamy, A. N.; Moffatt, G. M.; Maclean, A. H.; Stuart, J. L.; Mumford, R. H.; Pan, T. C.; Chan, V. F. T.

March 31, 1925.

New Preparations, Inventions, &c.

A NIGHT TRAP FOR GNATS, MOSQUITOES, AND TSETSE FLY.[1]

Dr. F. W. ALEXANDER, Medical Officer of Health for Poplar, has designed a simple device to trap insects which fly by night. In the centre of a wooden base a well-protected night-light or electric bulb is fixed. This is surrounded by vertical sheets of ground glass arranged in wooden sockets, so as to be placed in any desired position. The glass sheets are smeared with honey or some other sticky substance, which can easily be washed off and replaced. The whole apparatus can be fixed on a pole and placed where the insects are most likely to be found. Dr. Alexander points out that this device can be made for a few shillings, apart from any storage battery or accumulator if an electric lamp is used.

"SOLOID" URINE-SUGAR TEST CASE.

THIS case combines simplicity with utility and has been specially designed by Messrs. Burroughs Wellcome & Co. for those diabetics who are under insulin treatment at home. The case is made of stout cardboard and contains a liberal supply of tests, twenty-four in all.

The full contents are two tubes of "Soloid" Alkaline Citrate, one tube of "Soloid" Copper Sulphate, one medicine dropper with rubber bulb, two test-tubes graduated, one wire test-tube holder, one small square of asbestos, and one bottle of twenty-five "Soloid" Hexamethylenetetramine (one of these placed on the asbestos square will burn for three minutes, sufficiently long to conduct one test.)

The test is very reliable, and amounts as low as 0·1 per cent. of glucose are read with ease. The introduction of a simple heating medium, obviating the employment of methylated spirit, is a feature which will be readily appreciated. The flame is smokeless and therefore there is no tendency for the reading to become obscured.

The case is very compact, measuring 5 in. by 4¼ in. by 1⅛ in. and may easily be carried in the pocket.

BOVRIL LIMITED.

ANOTHER RECORD YEAR.

PRESIDING at the twenty-eighth annual general meeting of Bovril Limited, held in London on March 4, Sir George Lawson Johnston (Chairman) congratulated the shareholders on having had a successful year. He said:—

"The gross profit on trading, less advertisements, stands at £639,123, as against £571,491 for the year 1923. This gross profit, of course, constitutes a record, whilst the expenditure on advertising, which has already been deducted from the gross profit, also reached record figures. The debtor side of this account shows us the nett profit of £390,992, as against £351,898 in the previous year. As indicated in the report, this increase is the result of a very gratifying expansion in the home and export sales of Bovril during the year 1924."

The Selling Value of a Smile.

Referring to recent advertising schemes, Sir George Lawson Johnston emphasized how the display of some of the series of Bovril posters brought back advertising memories of the last quarter of a century, and many were surprised to see how long a slight tinge of humour had been a feature of these posters, which otherwise depict a serious food fact.

It is rather surprising that it is only in recent years that a touch of humour in posters has become prevalent.

Sir James Crichton-Browne on Food and Physical Efficiency.

Sir James Crichton-Browne said the Company was constantly receiving testimony to the sterling value of Bovril from all quarters of the globe and under the most diverse conditions. Bovril had been used largely by the enterprising Oxford University Arctic Expedition, by which, for the first time in history, an aeroplane had been employed in arctic exploration; it had been carried by Mr. Simpson, of the *Daily Telegraph* Expedition, which twice crossed the Continent of Australia in a Bean motor-car; and supplies of Bovril had been laid down at ten selected depot points for the use of the great Cape to Cairo motor expedition, now in progress under the leadership of Captain Court Treatt. These were emergency uses of Bovril. The extent of its routine and habitual consumption was best shown by the figures which had been submitted to the shareholders. Bovril was of firmly established reputation and world-wide acceptance, and he ventured to predict for it a still growing popularity. It represented in an agreeable and easily assimilable form that animal protein upon which all the great nations of the world had been built up, and the amount of which, as a food constituent—as Lieut.-Colonel McCarrison, a very high authority, had just shown—might be taken as a measure of the physical efficiency and power of resistance to disease of the different races of India.

On the nutrient properties of Bovril, Sir James said he need not enlarge, but he would claim for it what might be called a vitaminic virtue also. The vitamins, which were now becoming household words, were not in themselves foods, and did not nourish, but were essential to nutrition, and gave a fillip to certain metabolic changes in the system. Bovril did that also, as Prof. Thompson's experiments had conclusively proved, and at the same time it did what the infinitesimal vitamins could not do—it renewed the tissues and yielded energy. Bovril was a food in itself, and promoted the assimilation of other foods.

A STUDY OF INTENSIVE ANTIMONY-THERAPY IN SCHISTOSOMIASIS JAPONICA.[1]

By Henry Edmund Meleney, M.D., Ernest Carroll Faust, Ph.D., and Corydon McA. Wassell, M.D.

Introduction.

In spite of the extensive use of tartar emetic in the treatment of vesical and rectal bilharziosis since the first successful trial by Christopherson in 1917 (1918), it has been felt by careful practitioners coming in contact with cases of Oriental schistosomiasis that the drug is still on trial with respect to treatment of this latter infection. In Egyptian bilharziosis thousands of cases are treated annually with intravenous injections of tartar emetic, the greater majority in out-patient clinics, and the symptoms of toxæmia following the administration of the drug are so negligible as to have little effect on the willingness of the patient to submit to a full course of treatment. While Sanders and Priston (1921), Tyau (1922), Tootell (1923), and Faust and Meleney (1924) have reported favourably on the effect of this drug in incipient or moderately advanced cases of schistosomiasis japonica, it has been administered only on in-patients, the majority of whom were persuaded only with difficulty to complete a full course of treatment. Furthermore, Libby (1923, 1924) has called attention to the apparently marked toxic symptoms attendant on the administration of small quantities of the drug to advanced cases with ascites.

It was with these facts in mind and with the idea of giving tartar emetic a careful test in several closely observed cases before advocating its use unreservedly for all persons found to harbour *Schistosoma japonicum* that this study was undertaken. Since incipient cases as such seldom appear in the clinics in the endemic areas in China, it was believed that moderately advanced cases, either quiescent or mildly active, should be selected for the study. They were to be carefully observed and examined from all aspects of the disease, but were to be especially tested with respect to (1) their reaction to intravenous injections of tartar emetic administered in moderately heavy doses; and (2) the potency of the drug in killing the parasite.

It was found advisable to select Wuchang, in the centre of the endemic area of the mid-Yangtze region, where, in the clinics of the Church General Hospital, suitable patients could be found for the investigation. The method of procedure was based on past experience with reference to the difficulty in securing patients to take a full course of treatment with antimony.

[1] Contribution from the Department of Medicine and from the Parasitology Laboratory, Pekin Union Medical College.

Outline of Procedure for Intensive Treatment of Schistosomiasis Japonica.

(1) A series of cases was to be studied, being kept in the hospital under direct observation for a period of about six months.

(2) The cases selected were to be favourable for treatment, the infection in each one being moderately severe, but not advanced to the stage of marked ascites. Males between the ages of fifteen and thirty years were to be chosen if possible.

(3) The patients were to be employed by the hospital as coolies with slight compensation in order to keep them under observation.

(4) The patients were to agree to stay in the hospital for six months, not returning to their homes during that time. This precaution was to be taken in order to avoid the possibility of re-infection.

(5) Patients were to be provided a hospital bed or its equivalent in a "convalescent hostel" for the whole period of six months. While acutely ill or while under intensive treatment patients were to be kept in bed. At other times they might be given light work to do about the hospital.

(6) Careful clinical and laboratory records were to be kept of each patient. These included:

(*a*) On admission: (1) Detailed history and physical examination. (2) Complete blood count—red blood cells, hæmoglobin, white blood cells, differential; search for blood parasites. (3) Globulin precipitation test. (4) Total serum proteins. (5) Wassermann. (6) Routine urinalysis. (7) Stool examination, gross and microscopic.

(*b*) During treatment, daily: (1) Urine for albumin. (2) Stool for schistosome eggs, washed and hatched for viability of eggs.

(*c*) During treatment, weekly (or as frequently as advisable): (1) Globulin precipitation test. (2) Differential blood count. (3) Measurement of size of liver and spleen.

(*d*) After treatment, weekly: (1) Stool for schistosome eggs, washed and hatched for viability of eggs.

(*e*) After treatment, monthly (or as occasion permitted): (1) Complete blood count. (2) Globulin precipitation test. (3) Total serum proteins. (4) Measurement of size of liver and spleen.

(7) *Treatment.*—With chemically pure potassium antimony tartrate intensively, similar to treatment of American naval officer at Peking Union Medical College in 1923 (Faust and Meleney, 1924).

Treatment in each case should cover not over one month. Thereafter further treatment was to be given only if evidence appeared that patient was not cured (i.e., that the worms were not yet dead). This was to be determined by: (*a*) Reappearance of viable eggs in fæces. (*b*) Reappearance of positive globulin test.

It will be seen from the protocols and data which follow that this ideally thorough intensive course of treatment was not entirely feasible. However, we believe that the data in hand have a direct bearing on the inquiry initiated and should be placed in written form.

TABLE I.—REACTION OF SCHISTOSOMIASIS

Day	Case 1					Case 2					Case 3

[1] Urine examination throughout the treatment was consistently negative for albumin

Protocol of Cases.[1]

Altogether ten cases were examined[2] for this study, of which seven are reported in this paper.

Case 1.—L. K. S., age 25, farmer from Hupeh Province, was admitted to the Men's Department of the Church General Hospital on March 4, 1924, complaining of respiratory trouble and skin infection on the scalp. On examination he was found to be in a fair state of nutrition, but under-developed. Weight, 86¼ lb.; height, 4ft. 10½in.; muscles undeveloped, slight atrophy and extreme weakness in legs and arms. Examination of the head showed a dry scaly skin with favus on the scalp. Coarse moist râles at right hilus of lungs both front and back. The heart gave a rough systolic murmur in pulmonic area. Abdomen had the shape of an inverted gourd, irregularly barrel-shaped; circumference at costal margin 75 cm., at umbilicus 67·5 cm. Small amount of free fluid in abdomen. Liver hard, 7 cm. below xiphoid cartilage, 4·5 cm. below costal margin in right mid-clavicular line. Spleen edge 7 cm. at greatest distance perpendicular to left costal margin. Descending colon appreciably thickened.

Laboratory Findings.—R.B.C., 2,790,000; hgb., 37; W.B.C., 5,500; neutrophiles, 72 per cent.; basophiles, 1·5 per cent.; eosinophiles, 14 per cent.; lymphocytes, 9 per cent.; large mononuclears, 1·5 per cent.; transitionals, 2 per cent. Urine, negative. Fæces, eggs of *Schistosoma japonicum*, hookworm. Serum globulin, + +; Wassermann negative. Total serum proteins, 9·06 per cent.; albumin, 3·29 per cent.; serum globulin, 5·77 per cent.

Diagnosis.—Schistosomiasis japonica; bronchitis.

Therapy.—Potassium antimony tartrate treatment was begun on March 7 with an initial dose of 5 c.c. (one per cent. sol.). First reaction on the third day, when a total dosage of 0·225 grm. had been given. Following this initial reaction, the time interval for administering the drug was governed in part by the condition of the patient. However, no marked reaction was observed until the twenty-ninth day of treatment, when 1·375 grm. of the drug had been given. From this time on, both nausea and coughing were common reactions to the drug. On the thirty-third day, when 1·650 grm. had been administered, it seemed advisable to discontinue treatment for a time. On the fortieth day, just as treatment was to be reinstituted, the patient ran away. The study was, therefore, incomplete, although daily laboratory records (see Table II) showed that eggs appeared for the last time in the fæces on the ninth day and miracidia were hatched from total fæcal samples for the last time on the twenty-sixth day. Likewise the temperature chart, which was extremely variable preceding and during treatment, appreciably improved during the last week of observation. It seems likely that a sufficient amount of the drug had been administered to

[1] Reaction of patients to tartar emetic is indicated in Table I.

[2] Three of these cases left the hospital before treatment was initiated.

Table II.

No.	Primary diagnosis	Complications	Physical findings	Laboratory findings							Treatment—pot.-antim.-tart.				Effect
				Eosinophils per cent.	Hb. (Sahli)	Serum globulin precipitation		Protein			Wassermann	Amount	Period	Positive for	
								Total per cent	Albumin per cent	Serum globulin per cent				Eggs	Hatched Miracidium	
												grm.	days	days	days	
1	Schistosomiasis japonica	Ankylostomiasis; bronchitis	Retarded growth, pallor and emaciation, bronchitis, enlarged liver and spleen, ascites; descending colon thick	14	37	++	(1)	9·06	3·29	5·77	–	1·65	33	9	26	Incomplete (ran away)

							(2)	9·15	5·82	3·33						
5	Schistosomiasis japonica	Scabies	Retarded development, enlarged liver and spleen	15	48	++	(1)	9·72	3·17	6·55	–	2·030	56	26	31	Cured (?)
							(2)	8·55	4·23	4·32						
6	Schistosomiasis japonica	None	Retarded development, enlarged liver and spleen	10	40	++	(1)	8·76	4·31	4·45	–	2·050	62	33	45	Cured (?)
							(2)	8·20	3·96	4·24						
7	Schistosomiasis japonica	Ankylostomiasis	Retarded development, enlarged liver and spleen	18	43	+	(1)	8·92	4·20	4·72	Anti-comp.	2·005	60	28	39	Cured (?)
							(2)	8·38	4·50	3·88						

effect a cure, although time would be required to repair the damage to the liver and intestinal tract brought about by the infection.

Case 2 (fig. 1).—C.S.N., age 21, farmer from Hupeh Province, was admitted to the Church General Hospital on March 28, 1924, complaining of abdominal discomfort and slight fever and chills. On examination he was found to be under-developed but with a fair degree of nutrition. Weight, 60 lb.;

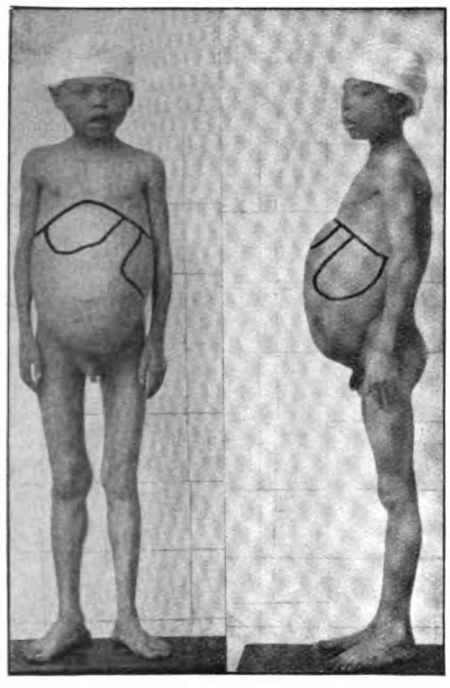

Fig. 1.—Patient of Case 2, front and left profile view, showing outline of liver and spleen.

height, 4ft. 3½in.; body fairly strong. Lungs normal; heart normal. Abdomen barrel shape; circumference at costal margin 70 cm., and at umbilicus 69 cm. No free fluid. Liver hard, nodular, 6 cm. below the xiphoid cartilage and 6 cm. below costal margin in right mid-clavicular line. Spleen edge 22·5 cm. at greatest distance perpendicular to left costal margin. Colon appreciably thickened; abdominal veins visible. Anæmia.

Laboratory Findings.—R.B.C., 2,800,000; hgb., 48; W.B.C., 1,200 (?); neutrophiles, 77 per cent.; basophiles, 2 per cent.; eosinophiles, 10 per cent.; lymphocytes, 6 per cent.; large mononuclears, 3 per cent. Urine negative. Fæces, eggs of *Schistosoma japonicum*, hookworm, *Ascaris*, *Trichuris*. Serum globulin, + + +; Wassermann negative. Total serum proteins, 9·13 per cent.; albumin, 3·97; serum globulin, 5·16 per cent.

Diagnosis.—Schistosomiasis japonica.

Therapy.—Potassium antimony tartrate treatment was begun on April 3 with an initial dose of 5 c.c. (one per cent. sol.). Slight nausea after administration of first dose; further reaction after 0·3 grm. of the drug had been administered. Cough not marked until twenty-ninth day, when 1·05 grm. had been given. Treatment continued at intervals until fifty-sixth day, when it was deemed advisable to discontinue administration due to marked reaction. Total drug given, 1·825 grm. Eggs last found on the thirteenth day and miracidia on the thirty-seventh day after treatment was instituted.

Examination at end of period of treatment as follows: R.B.C., 2,246,000; W.B.C., 1,600 (?). Eosinophiles, 6 per cent. Total serum proteins, 8·80 per cent.; albumin, 4·67 per cent.; serum globulin, 4·13 per cent. Weight, 68 lb. Liver, 9 cm. below xiphoid cartilage, not palpable at right mid-costal margin. Spleen edge 9 cm. at greatest distance perpendicular to left costal margin. General improvement marked. Sixty days after treatment was begun the patient was dismissed as probably cured.

Case 3 (fig. 2).—M.P.I., age 18, a farmer from Hupeh Province, was admitted to hospital on April 10, 1924, complaining of abdominal discomfort. On examination he was found to be under-developed, but in a fair state of nutrition. Weight, 78 lb.;

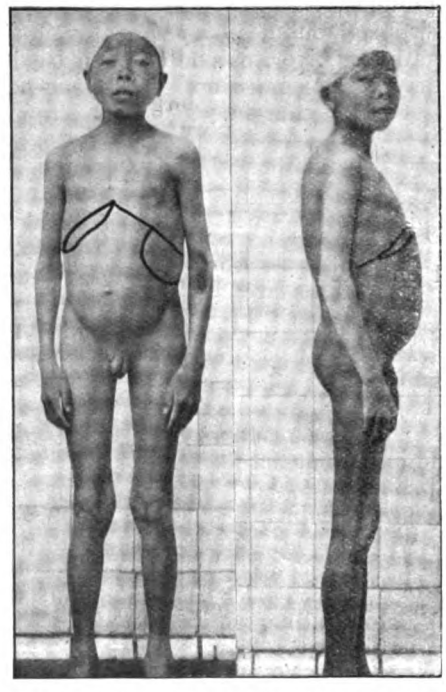

Fig. 2.—Patient of Case 3, front and right profile view, showing outline of liver and spleen.

height, 4ft. 11¾in. Muscles weak. Lungs and heart normal. Abdominal girth at costal margin 74 cm.; at umbilicus, 72 cm. No free fluid. Liver soft, extending 4 cm. beyond the right costal margin, but not palpable at midline. Spleen extending as a discoidal mass 9 cm. perpendicular to left costal margin.

Laboratory Findings.—R.B.C., 3,328,000; hgb., 44 per cent.; W.B.C., 9,200; neutrophiles, 30 per cent.; basophiles, 0; eosinophiles, 23 per cent.;

lymphocytes, 31 per cent.; large mononuclears, 13 per cent.; transitionals, 3 per cent. Urine, negative. Fæces, eggs of *Schistosoma japonicum*, hookworm, *Ascaris*. Serum globulin + + ; Wassermann + +. Total serum proteins, 8·67 per cent.; albumin, 4·27 per cent.; serum globulin, 4·40 per cent.

Diagnosis.—Schistosomiasis japonica and syphilis.

Therapy.—Potassium antimony tartrate treatment was begun on April 12 with an initial dose of 5 c.c. (1 per cent. sol.), and was continued at intervals until the thirty-sixth day of treatment, when the first marked toxic symptoms were observed. Two days later, when 1·571 grm. of the drug had been administered, treatment was terminated.

The last eggs were found in fæces on the fourteenth day and the last miracidia were hatched thirty days after treatment was begun. It must be noted that a year previously 0·67 grm. of tartar emetic had been administered to the patient, so that the total amount which he had received within the year was 2·24 grm.

Examination at end of period of treatment showed the following: Weight, 86 lb.; R.B.C., 3,392,000; W.B.C., 4,200; eosinophiles, 6 per cent. Total serum proteins, 9·16 per cent.; albumin, 4·63 per cent.; serum globulin, 4·53 per cent.; precipitation test negative. Liver, extending 5 cm. below right costal margin; spleen, 8 cm. in line perpendicular to left costal margin. General improvement marked.

Seventy days after admission the patient was dismissed as probably cured.

Case 4 (fig. 3).—M.I.L., age 15, herder and farmer from Rupeh Province, was admitted to the hospital on March 21, 1924, complaining of heatstroke. On examination he was found to be well developed physically. Height, 4ft. 10in.; weight, 72½ lb. Lungs and heart normal. Abdomen 68 cm. in circumference at costal margin; somewhat enlarged between umbilicus and symphysis pubis. Liver 4 cm. below xiphoid cartilage; 5 cm. below right mid-clavicular line; soft in consistency. Spleen not palpable.

Laboratory Findings.—R.B.C., 4,040,000; hgb., 66; W.B.C., 9,000; neutrophiles, 62 per cent.; basophiles, 0 per cent.; eosinophiles, 31 per cent.; lymphocytes, 5 per cent.; large mononuclears, 2 per cent. Urine negative. Fæces, eggs of *Schistosoma japonicum*. Serum globulin, negative; Wassermann negative. Total serum proteins, 9·66 per cent.; albumin, 5·88 per cent.; serum globulin, 3·78 per cent.

Diagnosis.—Schistosomiasis japonica (secondary stage).

Therapy.—Potassium antimony tartrate treatment was begun on March 27 with an initial dose of 5 c.c. (1 per cent. sol.), and was continued forty-nine days, during which time 2·15 grm. of the drug were administered. The reaction to the drug was very slight, being noted most conspicuously on the fourth day of treatment, when a total dosage of 0·235 grm. had been given. The total amount was finally increased to 2·376 grm.

The last eggs were found in the fæces on the twenty-ninth day and the last miracidia were hatched on the forty-first day after treatment was begun.

Examinations made from time to time until June 18, when the patient was dismissed, showed urine negative for albumin, and the fæces negative for hatched miracidia during the last five weeks of observation. On June 9 a second examination showed: total serum proteins, 9·15 per cent.; albumin, 5·82 per cent.; serum globulin, 3·33 per cent. The liver was in practically the same position as on initial examination, and the spleen was just palpable on inspiration. Weight, 77 lb. General condition excellent. Ninety days after admission the patient

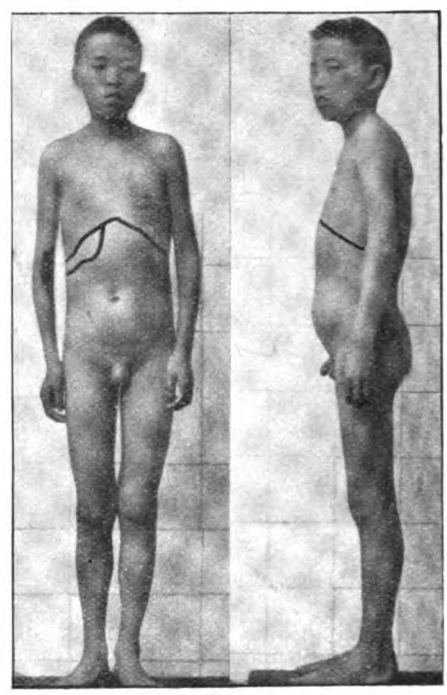

Fig. 3.—Patient of Case 4, front and left profile view, showing outline of liver and spleen.

was dismissed with the belief that he was cured. Two months later he returned for examination, which showed an increase in weight, diminution of the liver, and general improvement.

Case 5 (fig. 4).—M.C.P., age 22, farmer from Hupeh Province, was admitted to the hospital on March 28, 1924, complaining of general abdominal distress. On examination he was found to be under-developed, with poor nutrition and moderate pallor. Height, 4ft. 6½in.; weight, 65 lb. Lungs and heart normal. Abdominal girth 72 cm. at costal margin and 74 cm. at umbilicus. Free fluid in abdomen. Liver 10 cm. below xiphoid cartilage, 3 cm. below costal margin in left mid-clavicular line and 4 cm. below costal margin in right mid-clavicular line; hard, nodular. Spleen 11 cm., perpendicular to left costal margin. Colon and omentum thickened.

Laboratory Findings.—R.B.C., 3,664,000; hgb., 48 per cent.; W.B.C., 6,400; neutrophiles, 58 per cent.; basophiles, 0 per cent.; eosinophiles, 15 per cent.; lymphocytes, 27 per cent. Urine negative. Fæces positive for eggs of *Schistosoma japonicum*, hookworm and *Trichuris*. Serum globulin, + +; Wassermann negative. Total serum proteins, 9·72 per cent.; albumin, 3·17 per cent.; serum globulin, 6·55 per cent.

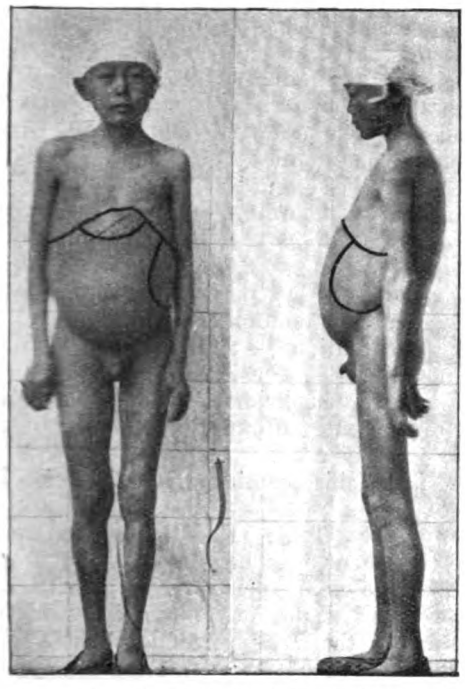

FIG. 4.—Patient of Case 5, *ibid.*

Diagnosis.—Schistosomiasis japonica.

Therapy.—Potassium antimony tartrate treatment was begun on April 2 with an initial dose of 5 c.c. (1 per cent. sol.) and was continued over a period of 56 days, during which time 2·03 grm. of the drug were administered. No reaction was observed until the thirteenth day of treatment (0·625 grm.), but was not marked until 1·555 grm. had been administered. From this time on until the full dosage had been given it was constantly present. The last eggs were found on the twenty-sixth day and the last miracidia hatched on the thirty-first day after treatment was begun. Treatment was therefore continued for twenty-five days following the last positive laboratory diagnosis.

On examination on June 1 the liver had receded two centimetres in the mid-frontal line, while the spleen had receded three centimetres toward the left costal margin. The weight had increased to 70 lb. The total serum proteins amounted to 8·55 per cent.; albumin, 4·23 per cent.; serum globulin, 4·32 per cent. R.B.C., 3,128,000; W.B.C., 3,400; neutrophiles, 56 per cent.; basophiles, 2 per cent.; eosinophiles, 14 per cent.; lymphocytes, 13 per cent.; large mononuclears, 1 per cent. On August 5, when the patient returned for re-examination, the spleen had further receded, so that it was palpable only 5 cm. beyond the costal margin. Weight, 76 lb.; R.B.C., 3,760,000; hgb., 52 per cent.; W.B.C., 5,420; neutrophiles, 37 per cent.; eosinophiles, 15 per cent.; small mononuclears, 18 per cent.; large mononuclears, 20 per cent. The patient showed a marked improvement and gave all indications of being cured.

CASE 6 (fig. 5).—L.T.Y., age 18, farmer boy from Hupeh Province, was admitted to the hospital on March 28, 1924, complaining of slight pulmonary discomfort and abdominal fullness. On examination he was found to be in a fair stage of nourishment but under-developed. Height, 4ft. 1½in.; weight, 59 lb. Left lung slightly duller than right; moist râles at right bases. Heart normal. Abdomen barrel-shaped ("pot-belly"), with a girth of 74 cm. at costal margin and 72·3 cm. at umbilicus. Free fluid and shifting dullness. Liver palpable 6·8 cm. below xiphoid cartilage, 6·5 cm. below costal margin in left mid-clavicular line, and 5·5 cm. below costal margin in right mid-clavicular line. Consistency hard, nodular. Spleen extending 15·5 cm. at great distance perpendicular to left costal margin. Colon and omentum thickened. Abdominal veins visible.

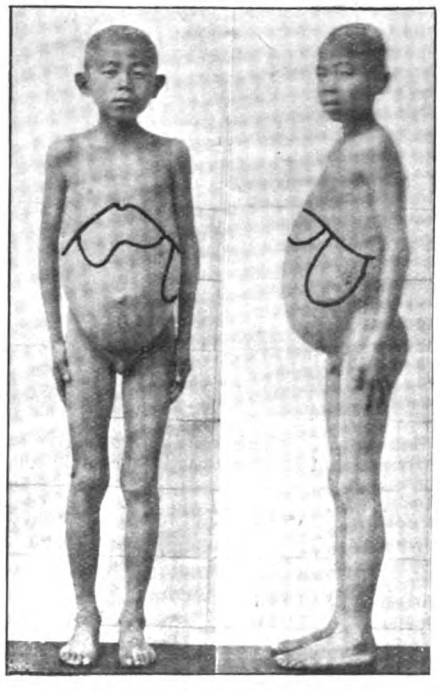

FIG. 5.—Patient of Case 6, *ibid.*

Laboratory Findings.—R.B.C., 4,120,000; hgb., 40 per cent.; W.B.C., 4,000; neutrophiles, 64 per cent.; basophiles, 1 per cent.; eosinophiles, 10 per cent.; lymphocytes, 13 per cent.; large mononuclears, 12 per cent. Urine negative. Fæces, eggs of *Schistosoma japonicum* and hookworm. Serum globulin precipitation + +; Wassermann negative.

Total serum proteins, 8·76 per cent.; albumin, 4·31 per cent.; serum globulin, 4·45 per cent.

Diagnosis.—Schistosomiasis japonica.

Therapy.—Potassium antimony tartrate treatment was begun on April 5 with an initial dose of 5 c.c. (1 per cent. sol.), and continued for a period of 62 days, during which time 2·05 grm. of the drug were administered. The first reaction was observed on the tenth day, when 0·525 grm. of the drug had been administered. After 1 grm. of the drug had been given it became necessary to increase the interval between injections due to the low tolerance of the patient. The patient was kept under direct observation for two weeks following completion of the treatment and then dismissed as materially improved and probably cured. The eggs were found for the last time in fæcal smears on the thirty-third

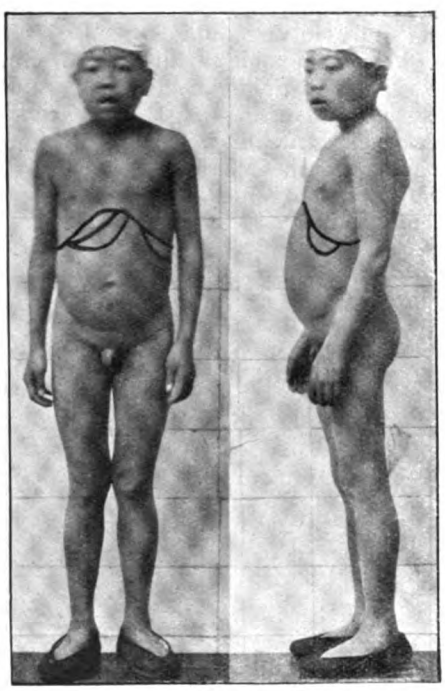

FIG. 6.—Patient of Case 7, *ibid.*, also shows liver margin after treatment had been partially completed.

day and miracidia were last hatched forty-five days following the initial dosage. Before dismissal physical examination showed the liver to have remained in about the same position as at admission, while the spleen had receded 3 cm. toward the costal margin. Weight 62½ lb. The total serum proteins amounted to 8·20 per cent., of which 3·96 per cent. was albumin and 4·24 per cent. serum globulin. R.B.C., 3,032,000; W.B.C., 3,000; eosinophiles, 13 per cent. Two months later the patient returned for re-examination. The weight had reached 70½ lb. The liver was palpable only in the midline. The spleen had receded another 4 cm. R.B.C., 4,848,000; hgb., 60 per cent.; W.B.C., 5,600. Serum globulin precipitation +. Eosinophiles 15 per cent. General appearance and nutrition excellent.

CASE 7 (fig. 6).—S. H. C., age 20, farmer boy from Hupeh Province, was admitted to the hospital March 28, 1924, complaining of " itch " and abdominal discomfort. On examination he was found to be under-developed, with noticeable anæmia and pallor. Height, 4ft. 5in.; weight 67½ lb. Eczema of scalp; eyelids œdematous. Heart normal except for slight systolic murmur at apex. Lungs normal. Abdomen barrel-shaped (" pot-belly "), with a girth of 70·5 cm. at costal margin and 72 cm. at umbilicus. Liver palpable 8 cm. below xiphoid cartilage, 2 cm. below costal margin in left mid-clavicular line and 5 cm. below costal margin in right mid-clavicular line. Consistency, soft. Spleen palpable 5 cm. at greatest perpendicular to left costal margin. Abdominal veins visible.

Laboratory Findings.—R.B.C., 1,832,000; hgb., 43 per cent.; W.B.C., 11,700; neutrophiles, 68 per cent.; eosinophiles, 18 per cent.; lymphocytes, 7 per cent.; large mononuclears, 7 per cent. Serum globulin precipitation +; Wassermann negative. Urine negative. Fæces, eggs of *Schistosoma japonicum* and hookworm. Total serum proteins, 8·92 per cent.; albumin, 4·20 per cent.; serum globulin, 4·72 per cent.

Diagnosis.—Schistosomiasis japonica, hookworm, eczema of scalp.

Therapy (see Table I).—Potassium antimony tartrate treatment was begun on April 7 with an initial dose of 5 c.c. (1 per cent. sol.) and continued for a period of sixty days, during which time 2·005 grm. of the drug were administered. Reaction to the drug began on the third day, when a total of 0·225 grm. had been administered. It became so marked when the total dosage had reached 1·025 grm. that a period of eighteen days was allowed to elapse before further treatment was attempted. During the latter half of the treatment reaction was marked, although the general condition of the patient improved from day to day. The last eggs were found in fæcal smears on the twenty-eighth day and the last miracidia were hatched on the thirty-ninth day following first dose of the drug. The patient was continued under observation until the eighty-third day, when he was dismissed, greatly improved and apparently cured of the infection. Physical examination before dismissal showed a slight increase in weight, 72 lb. General shape improved. Liver and spleen barely palpable on inspiration. Total serum proteins, 8·38 per cent.; albumin, 4·50 per cent.; serum globulin, 3·88 per cent.; R.B.C., 3,064,000; W.B.C., 5,400; neutrophiles, 31 per cent.; basophiles, 1 per cent.; eosinophiles, 43 per cent.; lymphocytes, 2 per cent.; large mononuclears, 20 per cent.; transitionals, 3 per cent. Serum globulin precipitation negative. Fæces positive for hookworm.

DISCUSSION OF DATA PRESENTED.

With the possible exception of Case 4, which represents a slightly earlier stage of infection than the other cases in this series, all of the cases studied denote a single stage of schistosomiasis japonica, a moderately advanced pre-ascitic condition, in which

both liver and spleen are markedly enlarged, in which there is an appreciable secondary anæmia and in which eosinophiles still constitute a considerable fraction of the white blood cells. In this respect they correspond to the majority of Tootell's twenty-six cases from Changteh, Hunan, twelve of which received a course of tartar emetic treatment sufficient to justify Dr. Tootell in the belief that cures had been effected. These are summarized in Table III by the side of the Wuchang cases. They correspond in some degree to certain cases studied by one of us (H.E.M. in Faust and Meleney, 1924, p. 224) in Kashing, Chekiang, in 1923. The case of the American naval officer (Faust and Meleney, *l.c.* p. 236), and the case of a Roumanian gipsy under the care of Dr. C. U. Lee in the Peking Union Medical College Hospital in 1924 (see Table III) both represent incipient infections. Libby's cases of both series (Libby 1923, 1924) constitute groups of advanced schistosomiasis japonica with severe cirrhosis of the liver, usually accompanied with marked ascites. While there are differences in presentation of data of these several groups of cases which do not make a detailed comparison in the symptomatology and treatment of them possible, on the whole they constitute a progressive series from the early incipient type to the last stage of the disease. Some of the data as presented in Table III, if taken out of the case histories, are in conflict with similar data from other groups. However, they represent the only cases treated with tartar emetic in China of which there are sufficient data for comparison. It will therefore be useful to keep this fact in mind in considering the Wuchang cases.

Table III.—Comparative Data on Tartar Emetic Treatment of Schistosomiasis Patients in China.

	American Naval Officer (incipient)	C. U. Lee's case (incipient)	Wuchang cases (moderately advanced)	Tootell's cases (moderately advanced)	Libby (2) (4 advanced cases)	Libby (1) (3 advanced cases)
Rationing of drug used ...	0·1-0·2 grm. each time	0·04-0·1 grm. each time	0·05-0·1 grm. each time	0·01-0·1 grm. each time	0·033-0·156 grm. each time	0·033-0·1 grm. each time

* A few non-viable eggs were passed ten days after miracidia were hatched. Note comment in text.

Physical Findings.

The Wuchang series consists of cases of young male Chinese of approximately the same age (15-25 years) coming from the same region, of the same occupation, and having about the same amount of exposure to this and to other infections. With the exception of Case 4 they represent a similar stage in the infection; and with the exception of Case 4 they were all under-developed. They all had enlarged palpable livers, and all but Case 4 had enlarged spleens.

Careful plotting of the livers and spleens of all seven cases on a diagram chart (fig. 7) after they have been reduced to a common standard shows a marked diversity in size and shape of these organs. The distribution of the palpable liver areas is much more irregular than those of the spleens, although the apices of the latter are much more dispersed than Christophers has found to obtain in malaria spleens in Indian children (Christophers, 1924, p. 109). It is realized that an index based on distance palpable below the costal margin is somewhat variable, depending materially on the chest and abdominal development of the patient and in no less a degree at times on the enlargement of the liver in this disease. Yet the shape and size of liver and spleen differ so considerably in schistosomiasis japonica in cases of the same stage and supposedly of the same degree of infection, that the value of attempting to utilize such an index in this infection is questionable. If we take the livers and spleens of different stages of the disease, and plot them on a common chart (fig. 8) we do not get the simple curve which Christophers secured for his malaria series, but a very greatly dispersed and uncorrelated graph. In other words, although in general there may be some correlation between the size of the liver or spleen and the severity of the infection, such a correlation does not necessarily follow. In fact, Faust and Meleney have shown (*l.c.*, p. 222) that there is frequently an inverse relationship between the sizes of liver and spleen in advanced cases, "which does not vary with the degree of ascites nor with the apparent duration of the disease." They consider "that it is probably related to thrombosis of the portal or splenic vein, and to a combination of other indefinite factors, including the toxæmia of the infection and the early plugging of many portal venules by the eggs of the parasite."

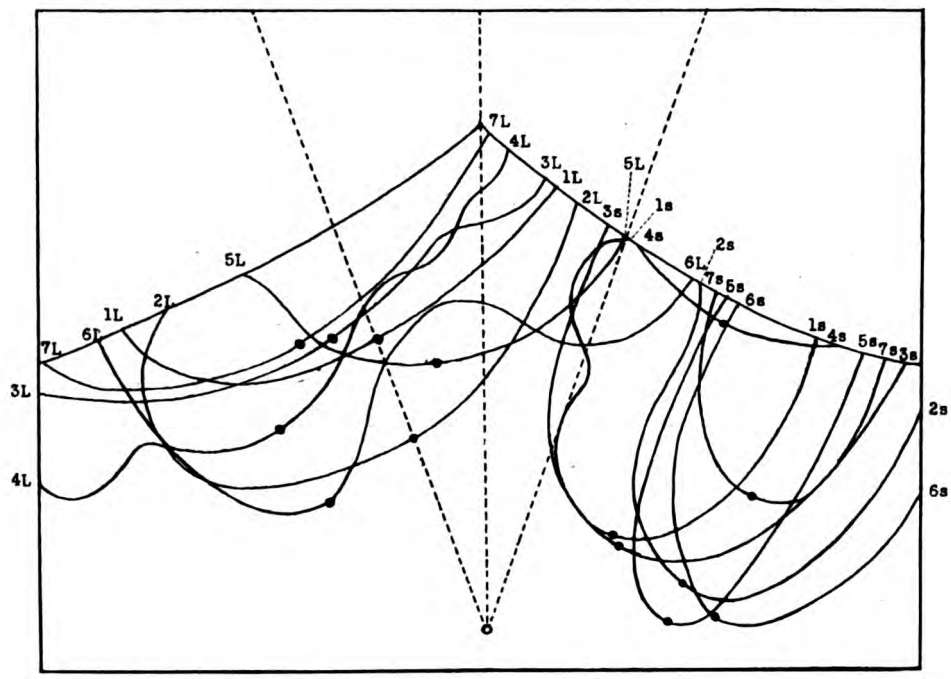

FIG. 7.—Outline of livers and spleens in Wuchang series of seven cases of schistosomiasis japonica. 1L—1L, liver outline of Case 1; 1s—1s, spleen outline of Case 1.

In other words, although ascites represents a late stage in schistosomiasis japonica, the factors involved in the enlargement of the liver and spleen in this disease are so many and at times so complicated that they cannot be expressed in any simple formula or curve.

In all cases, except those with marked ascites, improvement occurred after antimony therapy. There was considerable evidence afforded that in such patients a certain amount of tartar emetic is lethal for the worms in the portal system. However, the destruction of the vital tissues of liver and spleen and replacement by fibrous connective tissue is another matter. If destruction has not been too great, a recession of liver and spleen under the costal margin begins before or soon after the minimum lethal dose for the parasite has been initiated and continues until these organs approach their prediseased normal condition. If, on the other hand, destruction and replacement of vital tissue with fibrous tissue have been profound, little improvement from the condition of cirrhosis resulting from the infection can be expected. *Such patients may be cured of the infection but not of the disease.*

LABORATORY FINDINGS.

(1) *Blood.*—When we turn from the physical finding in schistosomiasis japonica to the laboratory findings, we are confronted with data much more readily correlated.

In the early active stage of the disease in man the percentage of eosinophiles is usually very high. In the case of the American naval officer (*l.c.*) it ranged from 52 to 29 per cent. In Lee's Roumanian

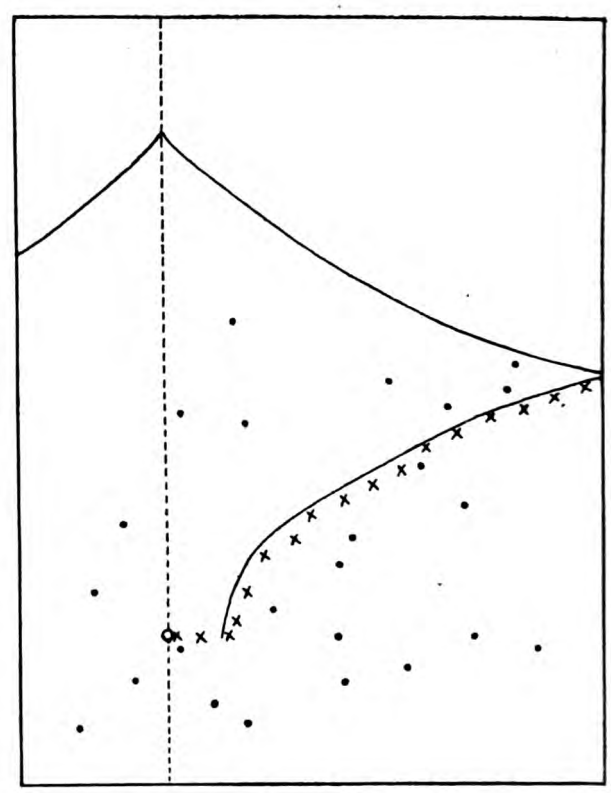

FIG. 8.—Graph showing spleen size in schistosomiasis japonica in comparison with mean average of malaria spleens in Indian children (Christophers' data). •, greatest distance of schistosomiasis spleen from left costal margin; X, *ibid.* for malaria spleens; O, umbilicus.

case it was likewise exceptionally high (from 72 to 27 per cent.). The Wuchang cases, which represent a more advanced stage of the infection, ran from 43 to 10 per cent., with an average of 23·1 per cent. Tootell's cases from Changteh showed from 30 to 9 per cent. eosinophilia, with an average of 13 per cent. The Kashing series (Faust and Meleney, *l.c.* p. 224) had an average eosinophilia of 16·8 per cent. for the early members of the series and 4·3 per cent. for the late ascitic cases. Libby's cases (1924, 386) had an average eosinophilia of 6·4 per cent. Furthermore, while the percentage of these cells may be reduced somewhat as treatment progresses, it remains high for a considerable period after a full course of treatment has been administered. Five members of the Wuchang series, examined three months after treatment was instituted and a month or more after it was completed, had an average eosinophilia of 16·8 per cent. as against 21·2 per cent. before treatment.

While the number of red blood cells and the hæmoglobin percentage are frequently rapidly reduced in schistosomiasis japonica, with attendant clinical signs of secondary anæmia, once the disease has run a course of several months the red blood cells bear little relationship to a particular stage of the infection.[1] The Wuchang series had a R.B.C. ranging from 1,832,000 to 4,120,000, and a hgb. percentage from 37 to 66 (average 46·6 per cent.). The hgb. in Tootell's cases averaged 60·2 per cent.; in Libby's advanced cases it averaged 57 per cent. Nor is the percentage of hæmoglobin necessarily correlated with the number of red cells. In treated cases however, if we may judge from the Wuchang series, the hæmoglobin percentage rises appreciably before the number of red cells increases.

(2) *Serum globulin* (Table II).—Ray's precipitation test for serum globulin (Sia, 1924) varied in the Wuchang series from + + + to negative, although the majority were + +. The total serum proteins of the seven patients on admittance varied from 8·67 to 9·72 per cent., and the serum globulin from 3·78 to 6·55 per cent., with averages for the series of 9·13 and 4·98 per cent. respectively. If we compare these percentages with the Kashing series (Meleney and Wu, 1924, 358) we find somewhat similar figures. It seems more justifiable, however, to divide this latter series of cases into two equal groups: (*a*) moderately early, and (*b*) late. The average total serum proteins for the first half of the series is 8·01 per cent. that for the second half 8·73 per cent. Similarly the serum globulin averages 4·89 per cent. and 6·19 per cent. The highest serum globulin in the case of the American naval officer (Meleney and Wu, *l.c.*, 360) was 3·68 per cent., a lower figure than any member of the Wuchang series and lower than all but three of the Kashing series. On the other hand, the total serum protein of this case was practically the same as that of the average for the Kashing series. On the whole, therefore, but not necessarily in each individual case, the data support the view that there is no important change in the total serum proteins in untreated cases during various stages of the infection, although there is an increase in the serum globulin.

In the case of the American naval officer referred to above there was a marked decrease in the serum globulin on the seventh day of treatment with tartar emetic, but a return later to the original percentage. In our Wuchang series estimates of the total serum proteins in six cases for an average period of sixty-four days following the initial administration of tartar emetic showed a slight diminution in all cases except Case 2. Likewise, a similar estimate on the serum globulin showed a more or less marked decrease in percentage except in Case 2. It seems possible that the condition in this single case can be explained by the positive Wassermann reaction. As improvement takes place in schistosomiasis patients following tartar emetic treatment, there are indications of a reduction in the serum globulin.

(3) *Urine.*—Throughout the series urinalysis was consistently negative for albumin and sugar.

(4) *Fæces.*—The eggs other than those of *Schistosoma japonicum* found in the fæces indicated no heavy infection which could essentially alter the physical condition of the patients or cause marked deviation from normal of the blood picture. In no case was the fæces bloody, as in initial or terminal dysentery or in spontaneous eruptions of a large number of eggs bursting through the intestinal wall. The relationship of the presence of eggs in the stool and of viable miracidia will be discussed under the subject of treatment.

Treatment.

The result of tartar emetic therapy in the Wuchang series was both a success and a disappointment. It was successful in that under carefully controlled conditions it showed that *moderately advanced cases of schistosomiasis japonica can probably be cured.* It was unsuccessful in that it demonstrated clearly that *two grammes of the drug cannot be administered to patients in this stage of the infection within the limit of one month.* In fact, under most favourable financial arrangements for the patients the tedium and discomfort of a complete treatment caused almost as many patients to run away from treatment as actually stayed through a complete course. In Tootell's twelve cases (1924), which he designated as "cured," he gave an average dosage of tartar emetic of 1·2 grm. administered on the average in 15·6 injections; the number of doses covered an average period of 37·3 days. He determined his dosage and spacing of injections in the usual manner by observing the tolerance of the patients and the signs of reaction, and the end point in the treatment by examining stools for five or more successive days and finding them to be negative. Comparison of Tootell's data with similar items in our series (Table III) shows certain points of agreement. We started with a larger initial dosage of the drug,

[1] It is to be expected, of course, that on the average late cases have a more pronounced anæmia than early cases.

but Tootell's cases soon caught up with ours in amounts administered each time. Tootell's treatment of 1·2 grm. covered a slightly longer period than we took to administer a similar amount to our patients (30 days). Our series showed an average last egg recovered by fæcal examination on the twenty-second day after beginning treatment, or at a time when 0·98 grm. of the drug had been administered. *But our hatching of miracidia as a check on the recovery of eggs consistently showed* (compare Table II) *that the absence of eggs in routine smear examinations is an unsafe method of diagnosing "cures."* An average additional dosage amounting to 0·34 grm. covering a period of fourteen more days was administered before hatched miracidia were negative as well as the eggs. *In none of our series have eggs been found after miracidia became negative in washed fæces*, although daily routine examinations were continued until the treatment was completed.

In this connection Dr. C. U. Lee's case (Table III) needs a word of explanation. It appears as if the data relative to the appearance of the last egg and the last hatched miracidia were reversed. The miracidia were hatched in the standard way advocated by Faust and Meleney (1924, p. 218). However, the eggs were examined each time in a more careful way than the ordinary smear method, in case that proved negative. Larger samples of fæces were centrifuged and the sediment carefully examined for eggs. This more thorough search revealed eggs not found in the ordinary way. It may be added, however, that no viable eggs were found after the miracidia failed to hatch. It is evident, therefore, that eggs filter through the intestinal tissues in small numbers after the miracidia have been rendered non-viable. Unfortunately, we cannot state from our present information whether these non-viable ova filtered through the tissues following or preceding the death of the parent worms in the portal system. We *are* able to state, nevertheless, that the "hatched miracidia test" is a much more reliable laboratory method of determining the apparently lethal amount of the drug for the worms than that of searching a fæcal sample for the eggs by the smear method.

It is possible that Tootell's average dosage of 1·2 grm. constitutes a sufficient amount of the drug to kill the worms in incipient or moderately advanced cases. In the five patients of his series which he re-examined a month later, and the one which he re-examined six months later, that would appear to be a correct inference. If such is the case, then the worms are killed before the last viable ova filter through to the intestinal lumen. However, we are inclined to believe that safety lies in a somewhat longer treatment and the administration of a greater amount of the drug. Yet it seems hardly likely that two grammes is required to effect a cure in such cases. If it can be shown by the study of a sufficient number of cases that cures can be effected by the administration of 1·5 grm. of tartar emetic covering a period of about forty-five days, either according to our suggested method of administration or any other feasible one, the patient would be relieved of many of the intoxicating symptoms of the treatment most prominent during the administration of the last 0·5 grm. of the drug.

We believe that Libby's cases (Table III), representing, as they do, an advanced type in which hepatic cirrhosis (with ascites) has proceeded beyond a period of functional recovery of the liver, have little hope from tartar emetic treatment. The marked toxic effects exhibited by the patients during treatment, the reduced dosage necessitated, except in one instance, where grave antimony poisoning resulted in death, and the prolonged interval necessary between injections, all contra-indicate tartar emetic therapy in this stage of the disease. In such cases there is little hope for recovery, even if it were possible to administer enough of the drug to kill the worms. These advanced cases undoubtedly represent a type more grave than any of the cases of schistosomiasis hæmatobia or schistosomiasis mansoni and must be recognized as such. In fine, even in moderately advanced cases of schistosomiasis japonica, tartar emetic is not as simple a procedure as in early cases, and they are surely not as amenable to simple treatment as either vesical or rectal bilharziosis. As schistosomiasis japonica develops the patients tolerate a smaller and smaller amount of the drug at one time, a condition differing from that in kala-azar patients, whose tolerance for the drug is fairly comparable to that of bilharzia patients. A probable explanation for the greater severity of this disease is the far greater fecundity of the female worm, with the correspondingly larger number of eggs extruded into the tissues. It may be that the liver is so severely and extensively damaged by these eggs, even in moderately advanced cases, that poisoning by the drug is induced more readily. It will require longer courses of treatment with smaller doses and longer intervals between doses to cure these cases than is necessary to cure very early ones.

This treatment cannot feasibly be carried on at the present time in China in out-patient clinics on account of the marked reaction of the patient to the drug. However, we are not in a position to advocate the use of other therapeutics in schistosomiasis japonica, since no other drug has been given ever the trial to which tartar emetic has been subjected. The fact that tartar emetic has been proved specific in early and secondary stages of the disease makes it possible to treat such cases as in-patients, but the drug needs to be used with great caution in advanced cases.

Summary and Conclusions.

(1) This study was undertaken: (*a*) To test the reactions of patients suffering from schistosomiasis japonica to intravenous injections of tartar emetic administered in moderately heavy doses; and (*b*) to determine the potency of the drug in killing the parasite responsible for the infection.

(2) A series of seven young males suffering from moderately advanced schistosomiasis japonica was selected and treatment instituted on them as in-patients in the Church General Hospital, Wuchang, China. The data secured embodied (*a*) detailed history and physical examination, (*b*) detailed blood, urine and fæces examinations on admission and throughout the study, (*c*) treatment with tartar emetic up to about 2 grm. or until they were believed to be cured; reaction to the treatment and effect of the drug on the patient, as determined by clinical and laboratory findings.

(3) Although it was proposed to administer the entire amount of the drug within one month, practical experience, based principally on the tolerance of the patient, showed that such a programme was not feasible. About sixty days was found to be necessary for the full treatment.

(4) The hatching of miracidia for an average period of fourteen days after the last eggs of the parasite were found in the fæces by routine smear examination showed that the former method is preferable in estimating the minimum amount of the drug lethal for the parasite. Even this method, however, is not an absolute check, since the parasites in the portal system may still be viable after the laboratory tests are all negative.

(5) In the Wuchang series eggs ceased to appear in routine fæcal smears after an average of twenty-two days, with an average administration of 0·98 grm. of tartar emetic. Miracidia were hatched up to the thirty-sixth day, or until an average of 1·32 grm. of the drug had been given. It is felt that 2 grm. of tartar emetic may be an over-dosage in incipient or moderately advanced cases of schistosomiasis japonica. If 1·5 grm. is found by experience to be sufficient, much of the discomfort of the patient, due to the administration of an additional 0·5 grm., can be avoided.

(6) The series treated gave evidence that tartar emetic treatment in moderately advanced cases of schistosomiasis japonica caused marked improvement and probably cure, as indicated by clinical and laboratory examinations. The blood picture improved, the liver and spleen began to recede, and the general physical condition of the patient showed a decided improvement. Tartar emetic is advocated, therefore, for incipent cases and those of the secondary stage of the infection, but caution in the use of the drug is recommended in cases with advanced cirrhosis and ascites.

ACKNOWLEDGMENTS.

We wish to express our appreciation to the house staff of the Church General Hospital, Wuchang, for their co-operation in our study, and to Dr. C. U. Lee for permission to use some of his data before they are in published form.

Experimental Amœbiasis in Cats from Acute and Chronic Human Cases (Edna H. Wagener and Margaret D. Thompson, *University of California Publications in Zoology*, Vol. 26, No. 15, 1924).—Attempts have been made to infect kittens with motile amœbas from acute and chronic cases of amœbiasis. One acute dysenteric fæcal specimen produced infection in three kittens, which was carried through six transfers in thirty-three cats. Fourteen attempts to infect kittens with motile amœbas from chronic cases resulted in only one infection which was transferred only once to a young kitten. Amœbas have been found to appear intermittently in the stools from cats with chronic or subacute experimental amœbiasis. Kittens which have been previously injected with motile amœbas were more difficult to infect than normal animals of the same age and size, thus suggesting a possible immunity. No cysts were found in the fæces of infected cats at any time. It has been found impossible to infect guinea pigs and rats by the rectal injection of actively motile amœbas obtained from acute cases of experimental dysentery in kittens. No infections resulted in guinea-pigs which were fed on cysts from human fæces.

Notes on Ocular Epidemiology in Libia (E. Bartolotta, *Arch. Ital. Scienze Med. Coloniali*, February-March, 1924).—The conjunctival diseases occurring in Libia may be classified into: (*a*) catarrhal, (*b*) muco-purulent, (*c*) fibrino-purulent. The catarrhal are of bacillary origin, the muco-purulent are due to staphylococci, and the fibrino-purulent to pneumococci. These never appear in epidemic form at the same time; the catarrhal are observed in spring and early summer, the muco-purulent in summer, and the fibrino-purulent in the autumn and early winter. In the very cold and rainy months these infections do not appear at all. It is interesting to note that fair people are more susceptible than dark, but no race is exempt from the disease.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these,** with remittance, **is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 ,, ,, ...	1	3	3
200 ,, ,, ...	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 ,, ,, ,,	2	6	0
200 ,, ,, ,,	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

A WHITE AUSTRALIA: IS IT A POSSIBILITY?

By SYDNEY J. SKERTCHLEY, J.P.

(*Continued from page* 142.)

CHAPTER XI

Natural Rate of Increase.

(173) By the natural increase of a population is meant the excess of births over deaths. Where immigration is not a factor, this represents the numbers given in census returns, but where, as in Australia and the United States, immigration is a considerable item, it must be carefully and separately dealt with. It has, I trust, been overwhelmingly demonstrated that no land can hold its own if it depend solely on immigration. The East and West Indies show this unmistakably, and we have seen that even in the United States immigration has not had the effect so fondly anticipated by the early statisticians. Moreover, no country can stand the continual strain of immigration, and we have shown how the European source of supply shows strong signs of depletion, and has only been maintained of late by the artificial stimulus of interested advertisement. It behoves us, then, to examine carefully both our rate of natural increase and our immigration returns. These last can only be approximately estimated by taking the excess of arrivals over departures, but the resulting figures are sufficiently near the truth for our purpose.

(174) Now the natural increase depends not only upon the birth-rate, but upon the death-rate also. Where the death-rate is low (that is when the country is healthy, or otherwise conducive to longevity) we may have a high rate of increase with a low birth-rate. This is what happens in the Commonwealth. "Notwithstanding its comparatively low birth-rate, Australia has a high rate of natural increase, owing to the fact that its death-rate is a very low one."

(175) This is a most important fact, and we must deal with it in some detail. For various reasons it is only possible to deal with what is technically called the crude birth-rate, that is, the number of births per 1,000 of the mean annual population. This rate for the Commonwealth has been as follows:—

1901	27·14
1902	26·66
1903	26·23
1904	26 33
1905	26·12
1906	26·81
1907	26·55

This birth-rate is lower than that of any European countries, except Scandinavia, Belgium, and France; the rate for England, for example, is 27·1, while for Russia it is as high as 47·9. But this is to some degree compensated by the low Australian death-rate, which in 1907 was only 10·9, as against 15·6 for the United Kingdom.

(176) The result of the combined low birth-rate with a low death-rate is to give the Commonwealth a natural increase of 15·0, as against 12·13 for England and Wales. The actual increase varies between 18·4 for Western Australia and 12·67 for Victoria, that for Queensland being 15·63. So far, then, as natural increase is concerned we seem to have nothing to complain of. But, alas, this is a misreading of the evidence. Hear what Mr. Knibbs has to say upon the matter. Under a special heading he calls serious attention to the "unsatisfactory nature of the Commonwealth rate."

(177) "The annual rate of increase in the Commonwealth population for the quinquennium 1901-6 was

practically identical with the annual rate for Germany, the figures being respectively 1·49 per cent. and 1·47 per cent. In view of the sparsity of the population of Australia and the recency of its settlement, this rate of increase, equal only to that of such a densely populated country as Germany, cannot be regarded as satisfactory. When contrasted with the growth of population in the United States the comparison is even less favourable, since the annual rate of increase of that country for the period 1901-6 was 1·62 per cent. Further, if the increase in the population of the Commonwealth be compared with that of the United States under comparable conditions as to density of population, it will be seen that whilst during the seventy years 1790-1860 the population of the United States increased at a rate of slightly more than 3 per cent. per annum, that of the Commonwealth has, in the past ten years, grown at less than half that rate. The full significance of the difference between these two rates of increase will be seen on comparing the figures shown in line (*a*) below with those appearing in line (*b*). The former represent the population of the Commonwealth in the years specified, on the assumption that the rate of increase experienced in the Commonwealth during the past ten years remains permanently in force, while the latter show what it would be in the same years if the rate of increase experienced in the United States during the seventy years, 1790-1860, were in force.

SIGNIFICANCE OF PRESENT RATE OF GROWTH OF COMMONWEALTH POPULATION.

	Dec. 31 1907	Dec. 31 1908	Dec. 31 1909	Dec. 31 1910	Dec. 31 1920	Dec. 31 1930	Dec. 31 1940	Dec. 31 1950
(*a*)	4,197,037	4,260,000	4,324,000	4,388,000	5,091,000	5,906,000	6,852,000	7,949,000
(*b*)	4,197,037	4,324,000	4,454,000	4,588,000	6,176,000	8,321,000	11,188,000	15,058,000

(*a*) On basis of Commonwealth rate of increase, 1898-1907.
(*b*) On basis of U.S.A. rates of increase, 1790-1860.

"These are not predictions as to the probable future population of the Commonwealth, but computations showing what the population will be if only the present rate of increase is maintained, and what it would be if the increase were as rapid as in the United States at a comparable period."

(178) Now this is one of the most remarkable and important official statements ever made with respect to the population of Australia. It is the deliberate finding of an accomplished statistician who has at command the most complete details. I confess my own investigations, though pointing to a similar general result, hardly led me to see the problem in so grim a light.

(179) But the amazing point is that Mr. Knibbs should have selected the United States for comparison, as I had done in the previous article (pars. 138-166). But, whereas Mr. Knibbs saw in the United States an increase that, he grieves, seems hopeless for Australia. I, from the same evidence, proved that the rate in the United States was a falling one, and threatened the extinction of the Fair Whites. Now, if the case of the United States is so alarming to her own people, and if the case of the Commonwealth is so much worse that our cousins' condition looks rosy in comparison, what in all sober earnest becomes of the cry "Australia for the Australians"?

(180) Nor is this putting the case at its strongest. It may be argued that after all we may rely upon immigration to keep our ranks full, even if our cradles are comparatively empty. We will see how this works out in practice. It has already been shown that no country can stand a continual drain of its populace, and that the tide of emigration, though bolstered up by artificial stimuli, is ebbing rapidly. But we will cede these points and ask whether Australia has proved, and is proving, the tempting lure that many conscientiously believe to be the case.

(181) There is plenty of room for expansion in Australia—the land is by no means overcrowded. Again let Mr. Knibbs speak. "From one aspect population may be less significant in respect of its absolute amount than in respect of the density of its distribution. The Commonwealth of Australia, with an area of 2,974,581 square miles, and a population on 31st December, 1907, of 4,197,037, has a density of only 1·41 persons to the square mile, and is, therefore, the most sparsely populated of the civilized countries of the world. For the other continents the densities are approximately as follows: Europe, 111; Asia, 55; Africa, 13; America, 10. The population of the Commonwealth has thus about 14 per cent. of the density of that of America, about 11 per cent. of that of Africa, about 2½ per cent. of that of Asia, and about 1¼ per cent. of that of Europe." This mode of stating the case is a just one. It cannot be claimed as a set-off that much of Australia is uninhabitable desert, for the same is true of Africa and Asia, and to a lesser degree of America. How, then, have our immigrants fared?

(182) During the forty-seven years, 1861-1907, there was a net excess of arrivals amounting to 784,982 persons. That is 26 per cent. of the increase has been due to net immigration, and 74 per cent. to natural increase. The immigrant increase has not been equally spread over the States of the Commonwealth, for during the period in question, the departures from Tasmania and Victoria have exceeded the arrivals, in the former case by 12,488, in the latter by 26,713. Indeed in all the States there have been quinquennial periods in which the departures have exceeded the arrivals; in New South Wales and Queensland in 1881-5; Victoria in 1886-90; South Australia in 1876 80; in Western Australia and Tasmania in 1896-90. Again let me cite Mr. Knibbs.

(183) "During the twenty-six years, 1881-1907 the annual rate of increase in the population of the

Commonwealth has exhibited a marked decline, falling from an average of 3·86 per cent. for the five years 1881-6 to an average of 1·49 for 1901-6, the rate for the latter period being also the average for the five years 1891-6. A slight improvement took place in 1907."

(184). Now what do these fluctuations of immigration show? There seems to me to be but one answer. In spite of the mining and other booms that have done so much for Australia, in spite of her exquisite climate, in spite of her fertile and cheap lands, Australia has not been able to attach her immigrants to her soil as firmly as America has done. There we have no parallel to the fluctuating wave across the sea. Victoria and Tasmania, the most home-like of the States, have sent more people from their shores than they have received, and so slender is the hold of the remaining States that at the touch of drought or commercial depression the new comers take flight. The native Australian cannot keep up the natural increase; the immigrant does not.

(185). Even this does not fully represent the seriousness of the result of this investigation. We have still to consider the effects of our tropical regions upon the stamina of the people, and the truly alarming and unparalleled tendency of the Australian to congregate in towns instead of diffusing over the wide and life-giving country, in which alone lies, in my belief, the possibility of there being a permanent white Australia at all. This will be the subject of my next, and last, article.

Annotations.

Treatment for Tapeworms (H. Iacobaeus, *Ugeskrift f. Laeger*, 1924).—The writer has been in charge of an 85-bed hospital in Copenhagen for twenty-one years, during which time 132 cases of tapeworms have been treated, most of which were due to infection with the *Tænia mediocanellata*. There was no case with *T. solium* and only seven with *Bothriocephalus latus*. Up to 1869 *T. solium* was very common in Denmark, but it has since gradually died out. In one case three large specimens of the *B. latus* were found in the same host, and in another case there were two specimens of *T. mediocanellata* in the same host; the latter is a very rare occurrence. In several of the writer's cases of *T. mediocanellata* there were none of the classical symptoms of tapeworm infection, and in only a few was there some emaciation. Bothriocephalus may cause severe anæmia and should be treated immediately; it is easily expelled. In the case of *T. mediocanellata* active treatment is not urgent, and if there are complications such as pregnancy, treatment should be deferred till the complications no longer exist. About 100 cases have been reported of serious impairment of vision following administration of filix mas; mostly observed in South Germany and Switzerland. Although this drug is used extensively in Scandinavian countries, especially in Finland, no cases of amaurosis have been recorded. Negative results with the treatment of filix mas are generally due to inferior quality of the drug.

Malaria in Rural Settlements in Palestine. Incidence and Etiology of Malaria (I. J. Kligler, *Journal of Hygiene*, December, 1924).—Statistical and laboratory data are presented, which bear on the incidence and epidemiology of malaria in rural Palestine. These data indicate that the annual incidence of malaria ranged between 50 and 100 per cent., and that in the areas where no control was effected in 1922 it was always considerably higher than the minimum figure. They also show that malaria is both endemic and epidemic and that there are two epidemic periods, one in the summer and one in the fall of the year. In the winter and spring there is little or no primary malaria. The parasites most frequently encountered are *P. vivax* and *P. falciparum; P. malariæ* is uncommon. The *P. vivax* is found throughout the year, but constitutes about ninety-eight per cent. of the total malarias in February to June and only fifty to sixty per cent. during October to December.

The Treatment of Multiple Sclerosis with Silver-Salvarsan (H. Schafgen, *Deut. Med. Woch.*, 1924).—The author has found silver salvarsan the most effective remedy in cases of multiple sclerosis. Twenty-one typical cases with a negative Wassermann have been treated. The first dose was 0·05 grm. twice a week; this was gradually increased to 0·15 or 0·2 grm., the average total dose being 2·5 grm. In thirteen of these cases definite objective improvement was observed. During the past twenty years the author has treated 135 cases of multiple sclerosis with various remedies in his hospital, and the results obtained with silver salvarsan are by far the best.

Original Communications.

STUDIES OF YELLOW FEVER IN VERA CRUZ IN 1920-1921.

By THOMAS J. LEBLANC, A.B., M.S.P.H., C.P.H., Sc.D.

Associate Professor of Preventive Medicine, University of Cincinnati; formerly Assistant Statistician, U.S. Public Health Service and Special Member Field Staff, International Health Board.

I.—ISOLATION OF LEPTOSPIRA ICTEROIDES.

During the epidemic of yellow fever which occurred in Vera Cruz in 1920-21, the opportunity presented itself to carry out some experiments on the transmission of yellow fever from human cases to guinea-pigs and the isolation of *L. icteroides*, which had been obtained from cases of yellow fever in Guayaquil, Ecuador, by Noguchi in 1919 [1], in Merida, Mexico [2], and in Northern Peru [3] by Noguchi and Kligler in 1919-20, and by Pérez Grovas [4] in Vera Cruz in the summer of 1920. The experiments extended over the period from December, 1920, to April, 1921. The Federal Department of Health of Mexico co-operated in the work, furnishing a laboratory for the purpose of the experiments. Special acknowledgments are due Dr. G. Cassasús, representative of the Federal Department of Health, for his co-operation in the matter of immediate laboratory facilities and assistants, and to Dr. M. Loyo, head of the Hospital Beneficia Español, for his unfailing interest and generous assistance on the clinical aspect of the cases studied. The writer is deeply indebted to Dr. Hideyo Noguchi, of the Rockefeller Institute for Medical Research, for his kind assistance and wise counsel, without which this work would have been impossible. The necessary laboratory materials and animals (young guinea-pigs weighing 250 to 300 grm.) were brought from New York.

Upon arrival in Vera Cruz it was found that the epidemic was about at an end, and there remained few suitable (i.e., early) cases of yellow fever for use in transmission experiments. In all, seven cases were used for transmission experiments. Of these one (Case 9) was indefinite as to the stage and questionable as to diagnosis; two others (Case 1 and Case 3) were in the fourth and fifth day of the disease respectively. Of the remaining four cases, three (Cases 2, 5, and 8) were in the third day and one (Case 4) in the second day. If we consider the third day after the date of onset as the limit of time during which the case is favourable for transmission, it is seen that out of the seven cases studied, four may be considered as in that class. Of these four, Case 1 gave an encouraging reaction in one guinea-pig injected with blood from the case, and Case 2 resulted in a positive transmission with the recovery of a culture (Chart I). These two cases will be reported in some detail.

Case History, Case 1, D.B.M. (Chart III).

Male, 32 years of age. Nationality, Mexican. Occupation, civil engineer. Home, Jalapa. Arrived in Vera Cruz on or about November 20, 1920. Sickness began on the evening of Saturday, November 27, with violent pains in back, head and calves, attended by a temperature of 104° F. Was seen by Dr. Loyo on Sunday, November 28, at 6.30 p.m., at which time he prescribed calomel in ten doses of one centigram each, a dose taken every half-hour, and the ten doses to be followed by two ounces of castor oil. The patient had violent fits of vomiting all day Sunday. The material expelled was a yellow, bitter, foul-smelling fluid. No food was taken from the beginning of the illness.

On Monday, November 29, at 8.30 a.m., the face was flushed and congested, the conjunctivæ injected, and jaundice was beginning to appear. The patient experienced some difficulty in breathing, and the breath was foul-smelling. He seemed restless, with shining eyes, and appeared very alert, mentally. On Monday, at 3 p.m., he seemed worse.

The shutters had been drawn at the request of the patient, who had exhibited some photophobia. At this time it was deemed advisable to remove him to the hospital. The case was clear, and was diagnosed as yellow fever by Dr. Loyo and confirmed by Dr. Cassasús. Blood was withdrawn for use in transmission experiments. At the same time 5 c.c. of Noguchi serum was given. The small amount is explained by the attending physician's fear of a reaction. No reaction followed. On Tuesday, at 3 a.m., an additional 30 c.c. of serum was given, and at 7 p.m. of the same date another dose of 40 c.c. There was an apparent improvement. The vomiting lessened and the soreness left the abdomen. The pulse became regular and well defined, and the pains in the head and back lessened. The general appearance of the patient seemed much improved. Later the patient became weak and had periods of delirium. At the hospital the urine collected in twelve hours was 100 c.c. Previous urine collections were impossible because of bowel movements, which had occurred about one per hour; the stools were green, greenish-yellow, or yellow in colour. Albumin in the urine was marked from the beginning of observation; there was no pigment. On Tuesday afternoon the pulse became weak, and an injection was given of 100 c.c. of 0·9 per cent. saline containing 1·0 c.c. of 1:1,000 adrenalin. The heart responded temporarily. The same procedure was repeated on Wednesday p.m., with a response from the heart that lasted for about two hours. The pulse then became fainter and fainter. At 6 a.m. on Thursday the pulse was undefined, and the patient died in a coma at 8 a.m. Permission for autopsy was not granted.

At the time blood was withdrawn it was realized that the case was by no means favourable for transmission purposes, since it had reached too advanced a stage, but since the epidemic was nearing an end it was thought necessary to take advantage of every opportunity that presented itself.

Case History, Case 2, L. S. (Chart III).

Male, age 19 years. Nationality, Spaniard. Residence in Vera Cruz for one year. Occupation, waiter in a canteen, which was next door to the rooming house where Case 1 developed. Illness began after the evening meal on the night of December 7 with a chill, followed by fever, severe pains in the head and general malaise. On the eighth the pains had extended to the back and legs, and on the ninth he was removed to the hospital. The pains had decreased somewhat, the face was flushed and congested, especially in the region about the mouth, conjunctivæ injected, patient restless and excited. At 6 p.m. on the ninth he was seen by Dr. T. C. Lyster. At this time the breathing was catchy and irregular. Diagnosis of yellow fever was made by Dr. Lyster and confirmed by Drs. B. Caldwell, M. Loyo and G. Cassasús. All agreed that it was a very severe case. At this time blood was withdrawn for transmission experiments, and 20 c.c. of Noguchi serum given. There was a slight reaction indicated by scratching of the face and neck and persistent sneezing. The serum produced a favourable change in the pulse and temperature. Eight hours later an additional 20 c.c. was given, with no reaction as in the first dose, but a like favourable reaction on the temperature and pulse. At this stage there appeared tenderness in the epigastrium. The general condition of the

patient had improved, the breathing was regular, and the state of excitement had passed. On the afternoon of the tenth a third dose of 20 c.c. was given, which was followed by a still greater improvement in the pulse and temperature.

Upon entering the hospital there was a trace of albumin in the urine with nitric acid. On the second day the albumin was pronounced in 200 c.c. of urine voided during the night. The routine of the hospital called for only a qualitative test with an estimation of the quantity by the doctor in charge. On the third day there was an increase in albumin, about the same amount of urine being voided. On this day there was a severe black vomit and bleeding from the nose and gums. After the third day the urine increased steadily with a decrease in the amount of albumin present, as well as a decrease in the bile pigments that had been present at this time. His condition steadily improved, and he was discharged as cured on December 24.

Experiments with Blood from Case 1.

While the guinea-pigs inoculated with blood from Case 1 were very promising, as the protocols show, on subsequent passage to new animals the latter either succumbed to bacterial infection or showed no noteworthy reaction. A third passage gave entirely negative results.

Guinea-pig 3.—Inoculated intraperitoneally on December 1, 1920, with 2 c.c. of blood from Case 1. Temperature 105° F. on December 6 and 104·2° F. on December 8. No further symptoms developed, and the animal was killed for examination and passage on December 8. The lungs were slightly congested and contained a few scattered but well-defined hæmorrhagic foci, the liver was markedly pale, showing some icterus, the spleen normal, the kidney enlarged and congested. The blood-vessels of the stomach were congested, especially near the cardiac end. The subcutaneous tissues had a faint yellow tinge. There was considerable albumin in the urine. No leptospira could be demonstrated either in the heart blood or in suspension of liver and kidney.

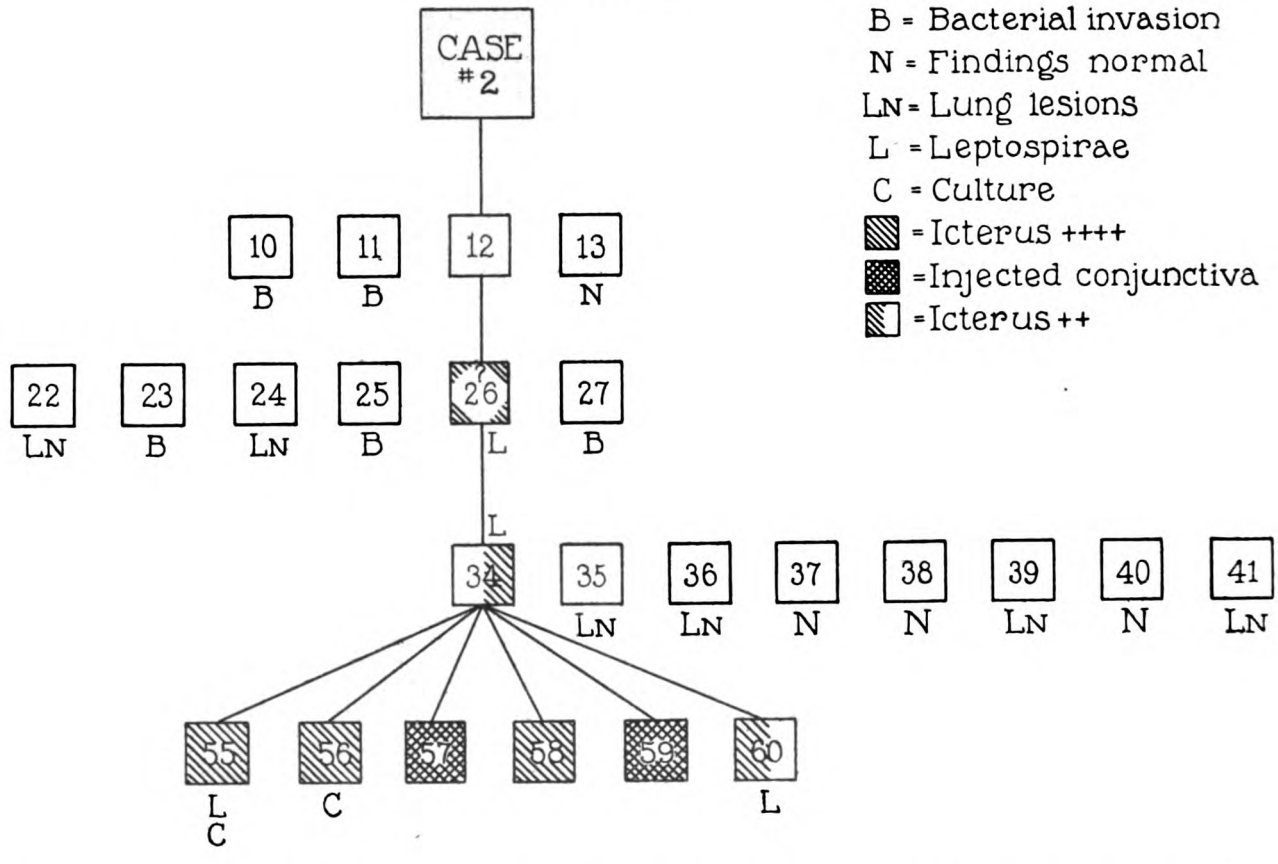
Guinea-pig 4.—Duplicate of foregoing experiment. No fever or other symptoms. When killed December 30 for examination, a few old hæmorrhagic foci were found in the lungs.

Guinea-pigs 9, 10 and 11 were inoculated December 9, 1920, each with 4 c.c. of liver suspension from guinea-pig 3. Guinea-pig 9 died within twenty-four hours of secondary bacterial infection. The others showed no reaction.

Experiments with Blood from Case 2.

While guinea-pig 12, inoculated with material from Case 2, did not present nearly so promising a picture as had guinea-pig 3 from Case 1, and a comparatively long period elapsed before a reaction was evident, passage to guinea-pig 26 gave encouraging results. The animal was undoubtedly sick and the autopsy findings were clearer and more evenly distributed, i.e., more organs were involved in the changes. Because of the dark brown colour of the animal, there was some doubt whether the yellow tint observed was a true jaundice. Passage was made from this animal to a white guinea-pig, No. 34, which showed undoubted jaundice. Of the seven

CHART 1.



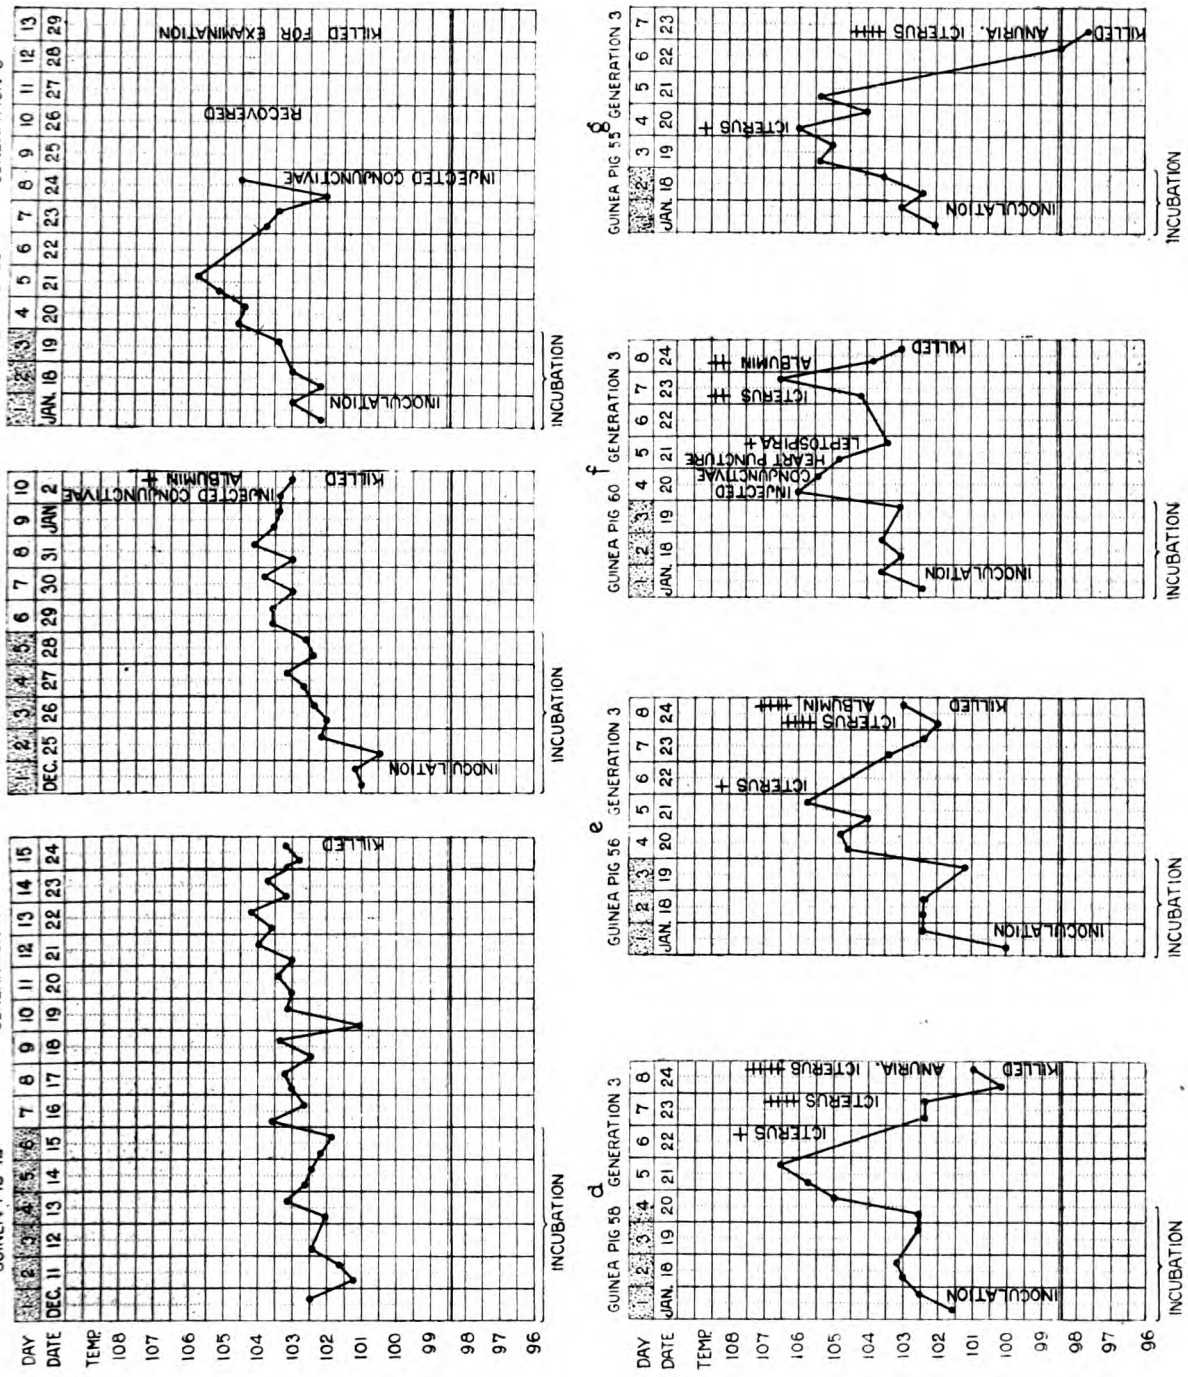


CHART II.

TRANSMISSION WITH BLOOD OF CASE 2

other animals similarly inoculated, four apparently passed through extremely mild infection, as evidenced by the presence of foci of hæmorrhage in the lungs on later examination, while three were entirely negative. On the third passage (transfers from guinea-pig 34), all the animals inoculated developed typical yellow fever, some showing more pronounced jaundice than others. The reaction was prompt, clear cut, and unmistakable. The icterus is noted on the chart as + + + + (Chart I), meaning that the animal was intensely jaundiced, eyes, skin, ears, and paws being the colour of butter.

Subsequent passages gave typical reactions in every instance, and while the minimum lethal dose was not determined, the strain attained a fair degree of virulence for guinea-pigs. In the instances in which demonstration of *L. icteroides* was not successful in the third passage, failure was undoubtedly due to the fact that the animals were allowed to live too long. This was done for the benefit of visiting physicians, that they might see the marked pathological picture of experimental yellow fever in guinea-pigs, the essential features of which are: fever (104° to 106° F.) after an incubation period of three to six days, occasionally two days' jaundice, appearing usually at the height of fever, three to five days after onset, an abrupt fall of temperature succeeding the jaundice, decrease in the amount of urine, accompanied by the presence of albumin and casts in the urine, often complete anuria. Autopsy reveals hæmorrhages of the gastro-intestinal tract and in the lungs, and fatty degeneration of liver and kidney. The spleen is never enlarged in uncomplicated infection.

Guinea-pig 12 (*a* Chart II), inoculated intraperitoneally December 9, 1920, with 3 c.c. citrated blood from Case 2 on the second day of illness. The animal had no reaction for six days, then the temperature rose to 103° F. in the afternoon; the animal was quiet in the cage and did not eat. As the chart shows, the temperature took the form of a gradually ascending curve, reaching a maximum of 104·2° on December 22, when the animal was killed for examination and transfer.

Autopsy.—Clear-cut hæmorrhagic foci in the lungs, with well-defined borders, usually triangular in shape, averaging about 2 mm. on a side. There were seven such hæmorrhages in the left and five in the right lung, and in addition numerous small pin-point hæmorrhages. The liver was markedly congested, the stomach congested, with blood-vessels injected, and the wall near the cardiac end appearing darker than normal. The intestines presented somewhat the same picture as the stomach, but less marked. The kidneys were swollen and congested, spleen normal, bladder empty. No leptospira could be demonstrated. Heart blood was sterile in control broth cultures. Passage was made to guinea-pigs 22 to 27.

Guinea-pig 13. — Duplicate experiment. This animal had no reaction.

Transfers from Guinea-pig 12. I Passage.

Guinea-pig 26 (*b* Chart II), inoculated intraperitoneally December 24, 1920, with 1·5 c.c. citrated blood from guinea-pig 12. At the end of five days the temperature rose to 103·8° F., the next day to 104·2°. The animal was quiet and had no appetite. The temperature began to fall at this point, and the animal was killed for examination.

Autopsy.—Liver pale, especially near the edges of the lobes, making them sharply demarcated. Stomach filled with undigested food; vessels injected; one small hæmorrhagic area near the cardiac end. Intestines congested but with no macroscopic lesions. Kidneys swollen and apparently degenerated; adrenals congested. Lungs pale and contained fifteen to twenty characteristic hæmorrhagic areas, especially near the bases. Urine scanty; what could be recovered contained casts and albumin. A noticeable characteristic of both liver and kidney was their friability; both were easily broken or torn.

No leptospira could be demonstrated in the heart blood, which, however, was sterile in broth control cultures. Three leptospiras were found in the suspension of liver and kidney. The preparations were shown to Dr. Iglesias, head of the laboratories of the Campaña contra la Fiebre Amarilla, who confirmed the finding. Fifteen tubes of leptospira medium were inoculated with the material, but at the end of three days twelve of them showed bacterial contamination, and the remaining three contained neither leptospiras nor bacteria. Passage was made to guinea-pigs 34 to 41.

Of the other animals inoculated with material from guinea-pig 12, one (guinea-pig 22) probably had a mild attack of yellow fever. It had received 1 c.c. of blood intraperitoneally on December 24. On January 3 its temperature was 104·4° F., and on January 7 it was 104° F. There were no other symptoms, but when the animal was killed on January 22 for examination, four old hæmorrhagic foci were found at the base of the left lung, about 2 mm. in diameter, and numerous pin-point hæmorrhages scattered through the right lung. Guinea-pigs 23 and 27 were lost through secondary bacterial infection. Guinea-pig 24 had no reaction, and guinea-pig 25 had a period of irregular fever and died in the night; *post-mortem* changes made it impossible to determine the cause of death in this animal.

Transfers from Guinea-pig 26. II Passage.

Guinea-pig 34.—Inoculated intraperitoneally January 2, 1921, with 1 c.c. citrated blood from guinea-pig 26. At the end of four days the temperature rose to 103·8° F., and continued high until three days later it reached 104·4°, and icterus was noted. Icterus increased for two days, until the eyes were fairly yellow, and the soles of the feet had begun to lose their pinkness, when it began to decrease, and the animal was apparently recovering. It was killed on the thirteenth day after inoculation for examination and transfers.

Autopsy.—Subcutaneous tissue slightly tinged with yellow. Liver friable and the colour of caramel. Kidneys swollen and about one and a half times normal size; tissue easily broken. Adrenals enlarged and markedly congested. Lungs pale, with a yellowish tint, and filled with characteristic hæmorrhagic areas in the wall, irregular in shape, and about 3 mm. in diameter. Stomach filled with dark fluid, viscous and foul-smelling; wall showed three irregular hæmorrhagic areas, about 3 mm. in diameter. Intestines intensely congested, filled with dark contents, and having many pin-point hæmorrhages in the wall. No urine available. Leptospiras were demonstrated in the heart blood and in the suspension of liver. Twelve tubes were inoculated with heart blood, but after four days they all showed the presence of molds.

Guinea-pigs 35 and 36 showed no fever or other symptoms, but when they were killed later for examination, a few hæmorrhagic foci were found in the lungs. Guinea-pigs 37, 38 and 40 had no reaction

and were negative when killed for examination. Guinea-pig 39 had fever (104° F.) for one day but no other symptoms; the lungs showed the characteristic hæmorrhagic foci when the animal was killed two weeks later. A similar picture, but less characteristic, was seen in guinea-pig 41.

Transfers from Guinea-pig 34. *III Passage.*

Guinea-pig 55 (*g* Chart II).—Inoculated intraperitoneally January 17, 1921, with 2 c.c. liver suspension from guinea-pig 34. Temperature 105·4° F. on the third day, 106° F. on the fourth day, after inoculation. Icterus developed on the fourth day and increased in intensity until the seventh day, when it was very intense (+ + + +). At this time the temperature fell to 97·6° F., and the animal was killed.

Autopsy.—Subcutaneous hæmorrhagic areas over the abdominal wall. Pectoral muscles on the right side intensely hæmorrhagic. Liver coffee-coloured, with mottled appearance. Kidneys about twice normal size and brownish-grey in colour. Adrenals swollen and congested. Stomach contained some undigested food, and the contents were dark greyish brown in colour; hæmorrhagic foci in the wall, especially in posterior part. Intestines filled with material much like that of the stomach; walls showed a number of hæmorrhagic foci about the size of a pin-head. Spleen normal. Lungs light cream colour and peppered with reddish brown, irregular hæmorrhagic foci extending throughout both lungs and up into the apices. No urine available. Leptospiras were demonstrated in the heart blood, and twelve tubes of culture medium were inoculated. Six of these escaped contamination, and after eight days five of them showed leptospiras.

Guinea-pig 56, inoculated intraperitoneally January 17, 1921, with 1·5 c.c. of liver suspension from guinea-pig 34. On the fourth day the temperature rose to 104·8° F. and on the fifth day to 105·8°. Icterus appeared on the sixth day and was intense (+ + + +) by the eighth day. At this time it was killed for examination.

Autopsy.—Subcutaneous tissues hæmorrhagic. Liver yellowish brown; mottled. Kidneys double the normal size; adrenals congested and enlarged. Stomach and intestines presented the same picture as guinea-pig 55. Spleen normal. The small amount of urine available was filled with casts and gave a heavy precipitate of albumin with Esbach's reagent. Lungs light yellow, filled with hæmorrhagic areas. No leptospiras could be demonstrated in the heart blood or in suspensions of the liver and kidney. Twelve tubes of leptospira medium were inoculated with heart blood, and at the end of seven days four of the eight tubes remaining free from bacteria showed leptospiras. The other four were negative.

Guinea-pig 57.—Duplicate of foregoing experiment. On the third day the temperature rose to 104·4° F., on the fourth to 105·4° F., on the fifth to 106° F. The conjunctivæ became injected on the seventh day, and were in the same condition on the eighth day, but no icterus could be observed. From this time the condition of the animal improved, and after twelve days observation it was killed for examination.

Autopsy.—Two characteristic foci of hæmorrhage in the right lung and three in the left. All other organs normal.

Guinea-pig 58 (*d* Chart II).—Duplicate of foregoing experiment. Temperature 105·4° F. on the fourth day, 106·6° on the fifth day. Icterus + + on the sixth, + + + + on the seventh day (eyes, ears, paws, and skin over abdomen all intensely yellow). Icterus still intense on the eighth day, temperature 101° F., animal killed for examination.

Autopsy.—Everything typical of an intense infection, the picture being essentially the same as that in guinea-pig 56. Bladder empty. No leptospira could be demonstrated in the heart blood nor in suspensions of liver or kidney. Broth control cultures of heart blood remained sterile. Six tubes of leptospira medium were inoculated with heart blood, but no growth of leptospira appeared in any of them.

Guinea-pig 59 (*c* Chart II), received 1·5 c.c. kidney suspension from guinea-pig 34 intraperitoneally on January 17. Temperature 104·6° F. on the fourth day, 105·6° F. on the fifth day, after inoculation. During the following two days it dropped, then rose to 104·6° F. At this time the conjunctivæ became markedly congested, but no icterus was observed. The animal was killed for examination January 29.

Autopsy.—Lungs showed characteristic hæmorrhagic foci, especially near the bases, averaging 3 to 4 mm. on a side. No gross evidence of change in other organs.

Guinea-pig 60 (*f* Chart II), received 2 c.c. kidney suspension from guinea-pig 34 intraperitoneally on January 17. At the end of the fourth day after inoculation the temperature rose to 106° F., and the conjunctivæ became injected. The temperature remained high for four days, and icterus developed to an intensity of + +. Heart puncture made on the fifth day revealed the presence of numerous leptospiras (one in every three or four fields). The finding was confirmed by Drs. Loyo, Cassasús, Iglesias, and Morfín. On the eighth day the animal was killed for examination.

Autopsy.—Everything typical of a moderately severe infection. Skin yellow, with some subcutaneous hæmorrhages. Liver pale, greyish brown, and easily broken. Kidneys enlarged, yellowish grey in colour. Adrenals hyperæmic. Stomach congested and showing two hæmorrhagic areas. Intestines congested; fairly numerous pinpoint hæmorrhages. Lungs yellowish pink, peppered with hæmorrhages. Bladder contained small quantity of urine, in which casts were found, and albmuin was demonstrated by Esbach's reagent. No leptospiras could be demonstrated in the heart blood or in suspensions of liver, kidney, or adrenals, notwithstanding they had been numerous in the heart blood on the fifth day, and cultures remained negative.

The culture obtained by inoculation of leptospira medium with heart blood of guinea-pig 55 was inoculated into guinea-pigs 62, 63 and 64. Although there was a concomitant paratyphoid infection in two of these animals, as shown by enlargement of liver and spleen, the *icteroides* infection was predominant, and in only one instance did the changes due to the paratyphoid bacillus obscure those caused by the leptospira. The leptospira was recovered from two of the three animals.

Guinea-pig 62, inoculated with 1 c.c. culture intraperitoneally on February 11, 1921. February 15, temperature 104·6° F. February 16, temperature 103·4° F. a.m., 102·6° F. p.m., icterus +. February 1, icterus + + + +; animal killed for examination.

Autopsy.—Skin and subcutaneous tissues canary yellow, vessels injected, some small hæmorrhagic areas over thorax and abdomen. Lungs peppered with small characteristic

hæmorrhagic spots, dark brown in colour, remainder of lung cream colour. Liver greatly enlarged, friable, and reddish brown in colour. Stomach mucosa hæmorrhagic, especially near cardiac end; vessels injected. Intestines markedly congested; no hæmorrhagic spots. Spleen normal. Kidneys about twice normal size, icteric, especially near hylus. Adrenals enlarged and apparently degenerated. Urine contained casts and a considerable amount of albumin. Leptospiras were found in suspensions of the liver and kidney in small numbers, none in the heart blood, notwithstanding thorough examination. Cultures of heart blood, however, yielded a growth of the organism.

Guinea-pig 63, inoculated February 11, 1921, with 0·5 c.c. culture. February 15, temperature 104·2° F.; February 17, temperature 106° F. No further symptoms. February 27, found dead. Autopsy showed enlarged dark-coloured spleen, also enlargement of liver and kidneys, and hæmorrhages in in the lungs. This animal undoubtedly recovered from a mild attack of yellow fever and succumbed to paratyphoid.

Guinea-pig 64, duplicate of the foregoing experiment. Temperature 104·6° F. on the afternoon of February 16, 104° F. on February 17. Icterus + + + +. Killed February 18 for examination.

Autopsy.—Skin and subcutaneous tissues canary yellow. Lungs peppered with characteristic hæmorrhagic foci. Stomach contained degenerated blood; four hæmorrhagic areas on dorsal wall. Vessels of intestines injected; some small pin-point hæmorrhages in mucosa. Liver much enlarged, friable, reddish brown in colour. Spleen normal (perhaps slightly enlarged). Kidneys much enlarged, degenerated, and icteric. Adrenals enlarged and congested. Bladder empty. Leptospiras found in fairly large numbers in heart blood and suspensions of liver and kidneys. Cultures of heart blood yielded a growth of the organisms. The typical infection in this animal was complicated by a mild paratyphoid infection.

The strain of *L. icteroides* was carried through thirteen passages in guinea-pigs, cultures being obtained again at the seventh generation. In later passages bleeding at the nose and anus became very common. At the completion of the experiments in Vera Cruz the cultures were turned over to the Rockefeller Institute for Medical Research, New York, where the organism was identified by immunological tests as belonging to the group of *L. icteroides* and distinct from *L. icterohæmorrhagiæ*. It has been maintained up to the present time and is still virulent for guinea-pigs.

Of the other cases studied (Cases 3, 4, 5, 8, 9), Case 3 was in the fifth day when discovered and Case 9 was indefinite and probably not yellow fever. Cases 5 and 8 were in the third day and Case 4 in the second day of the disease. The first two represent unfavourable cases for transmission purposes, while the last three mentioned may be considered as favourable. Transmission was attempted with all cases. With Case 9 there was no evidence of reaction. In the other cases, some of the animals innoculated showed the hæmorrhagic spots in the lungs, so characteristic of the leptospira infection, although no symptoms of infection had been detected during life. Control guinea-pigs, injected with normal human blood or with normal guinea-pig blood, fail to show these lesions.

That the transmission of yellow fever to animals and the isolation of *L. icteroides* is by no means easy is evident from the experiments which have been described. Only one animal of each of the first three generations acquired an infection which could be passed to other animals. The slight degree of pathogenicity of the human strain of *L. icteroides*, and the great variation in the susceptibility of individual guinea-pigs to infection with the organism, make it necessary to use a number of suitable (young) animals for inoculation with a given material. Moreover, the leptospira is by no means constantly demonstrable in the blood and organs, even in severe infection, either by dark field examination or culture, and it will not grow in the presence of bacteria or molds. Much difficulty was encountered in the present study, owing to the heat and humidity of the climate, in keeping the culture medium free from molds, and the most elaborate precautions had to be taken to avoid contamination from this source. Secondary bacterial infection (paratyphoid) in the guinea-pigs also proved troublesome, though as the strain became more virulent the incidence of secondary infections decreased.

II.—Serum Treatment of Yellow Fever.

During the course of the isolation experiments, I had the opportunity to observe a number of cases of yellow fever which were treated with the anti-*icteroides* immune serum prepared at the Rockefeller Institute for Medical Research, by Dr. Noguchi [5], and through the co-operation of Dr. Mauro Loyo, of the Beneficencia Español, I have been able to obtain the clinical notes.

With one exception (Case 1), in which the use of the serum was delayed until late in the third day of the disease, all the patients treated recovered. The charts and histories of the cases fail to convey an adequate idea of the action of the serum, because the improvement in the patient's morale or mental condition cannot be expressed in terms of temperature, pulse, or albumin. Unless the patient is actually seen, the status of the case may be misunderstood. In Case 2 this is well illustrated. At the time of the black vomit, and when albumin was present in such amounts that it had to be shaken out of the tube, the chart and laboratory findings made this appear a hopeless case. Nevertheless, as I have noted in the history, the patient's subjective condition was excellent.

In Case 2 it will be noted that there is almost a mathematical drop in the temperature with each dose of serum, and in practically every case the pulse began its downward trend with the beginning of treatment. Every time a patient was treated with serum, he was watched closely, and the pulse and temperature taken every half hour. With the exception of some uneasiness, and in one instance a rash, there was no unusual symptom following the treatment. The pulse and temperature dropped along the same lines and with the same degree during these half-hour intervals. It might be said that the use

of serum removes the discrepancy between temperature and pulse (Faget's sign). At all events, there is parallelism of temperature and pulse when serum was used, and a wide divergence otherwise, as shown before serum was given in Cases 4 and 6.

Seven cases in all are recorded. Cases 1 and 2 of the serum series are the same as Cases 1 and 2 of the transmission series, and the histories have already been given in the first part of this paper. Cases 3 and 4 of the serum series are the same as Cases 4 and 5 of the transmission series, and Case 7 of the serum series corresponds to Case 8 of the transmission series.

The total number of cases reported during the Vera Cruz epidemic was 204. One death occurred among the seven treated cases, and eighty-five deaths among the 197 untreated, that is, the mortality among treated cases was 14 per cent., as compared with 43 per cent. among untreated.

Since this difference is of prime importance in deciding on the efficacy of the treatment, it was believed profitable to examine it from a statistical standpoint so as to obtain a quantitative measure of its reliability. Accordingly the mean number of expected deaths based on the experience among untreated cases, and the standard deviation of the sample, were computed. The formulæ used were as follows [7]:

$$\text{Mean} = m\,\bar{p} + \frac{m}{n+2}\,(\bar{q} - \bar{p})$$

$$\text{Standard deviation} = \left\{ m \left(\bar{p} + \frac{\bar{q} - p}{n+2} \right) \left(\bar{q} - \frac{\bar{q} - \bar{p}}{n+2} \right) \left(1 + \frac{m-1}{n+3} \right) \right\}^{\frac{1}{2}}$$

Where in this case $n = 197$
$p = 85$
$q = 112$
$\bar{p} = 0.43$
$\bar{q} = 0{\cdot}57$
$m = 7$

Solving the equation for the mean, the mean number of expected deaths, had no treatment been used, is found to be 3·015. The actual number of deaths in the treated group was 1·0. The difference between the expected and the actual number is found to be 2·015.

Solving for the standard deviation it is found to be 1·33. Now the difference divided by the standard deviation ($\frac{2{\cdot}015}{1{\cdot}33}$) is 1·515. From a table of the area of the normal curve it is found that the area from the middle of the curve out to 1·515 is 0·435. Therefore the probability of a difference as great or greater than the one observed is (0·5 − 0·435) or 0·065. From this it is seen that if, out of 197 untreated cases, eighty-five die; then samples of seven drawn from untreated cases would have one or fewer deaths in each sixty-five samples out of a total of 1,000. Thus there is small chance that the treatment had no effect and that the seven treated cases were merely a random sample from untreated cases. Quantitatively, there are 935 chances out of 1,000 that the treatment was effective.

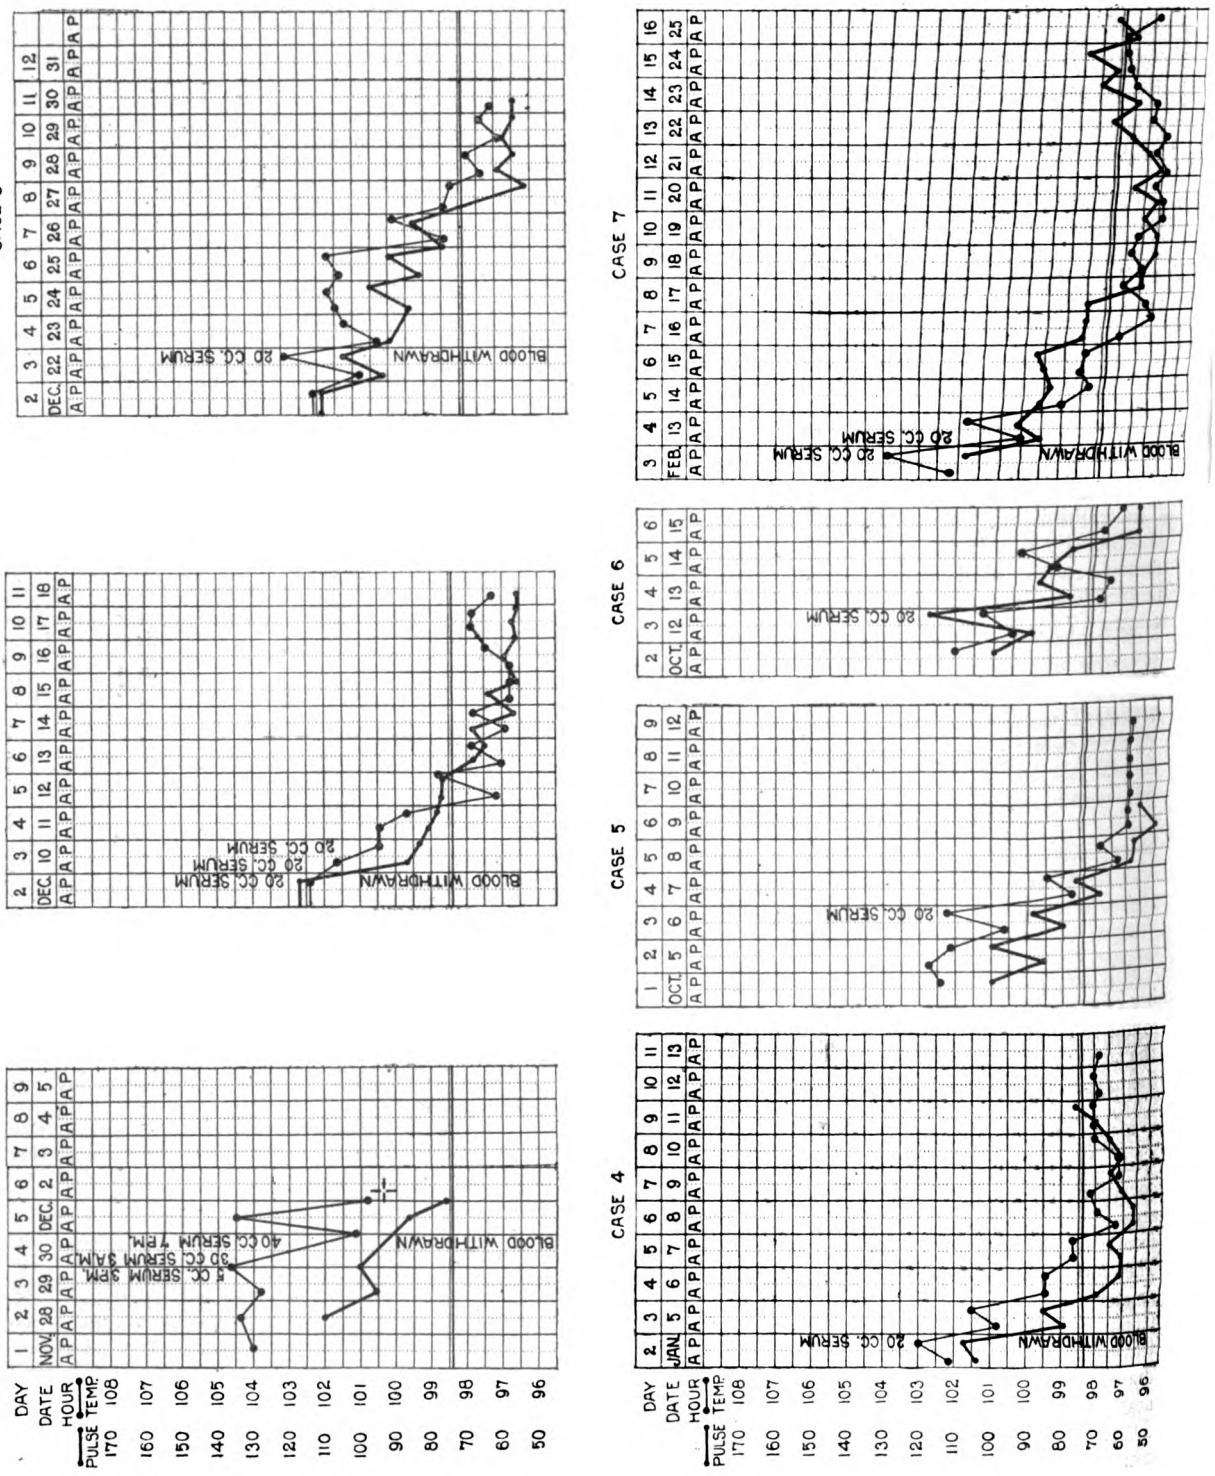
Case 3 (Chart III).—M. G., age 19, resident of Vera Cruz for three years. Taken sick shortly after dinner on December 20, 1920; headache and pain in the back and limbs. Admitted to the hospital on December 21 at 2 p.m. Face flushed, conjunctivæ slightly injected. Temperature 102·6° F. December 22 the temperature had fallen somewhat, and the patient's condition was apparently improved. In the afternoon, however, the temperature rose suddenly to 103·5° F., and tenderness developed in the epigastrium. Serum was given immediately (20 c.c.). The effect on the pulse, temperature, and general condition was evident within three hours. By the morning of the 23rd the patient's condition had improved to such an extent that it was decided no more serum was necessary. The tenderness of the epigastrium was considerably relieved, the patient was quiet, cheerful, and alert. His condition steadily improved, and he was discharged January 10, 1921.

Upon admission to the hospital the nitric acid test had shown no evidence of albumin in the urine; albuminuria appeared the following day, however, and increased to a considerable amount on the fifth day. At no time was the amount of urine less than 400 c.c. for twenty-four hours. There was no vomiting or bleeding from the gums or nose at any time.

The delay in the use of the serum was an attempt at control, to determine whether the case was a sufficiently mild one to improve without serum treatment. The developments of the 22nd suggested that the case was becoming a grave one, an opinion held by three physicians who had watched it from the beginning.

Case 4 (Chart III).—C. G., age 19, had resided in Vera Cruz for seven months. Onset evening of January 2, 1921, with headache and pain in the back and limbs. Admitted to the hospital on the afternoon of January 4. Face flushed, puffed, eyes bloodshot; patient restless but alert. 20 c.c. of serum was given immediately. Marked improvement was evident in pulse, temperature, and general condition. The following morning the patient's condition was such that it was decided no more serum was necessary. He improved rapidly, and was discharged January 13.

Albuminuria appeared on the third day in the hospital and persisted in traces until the seventh. There was no tenderness in the epigastrium, vomiting, nor bleeding from gums or nose at any time.



Case 5 (Chart III).—T. R. T., age 17 years. Duration of residence in Vera Cruz unknown. Onset in the morning, October 4, 1920; admitted to hospital afternoon of same day. Even at this early period the diagnosis was undoubted. October 5, condition the same. October 6, pains severe, patient restless and excited, temperature 102·3° F., conjunctivæ injected. The administration of 20 c.c. of serum was followed by a favourable effect on pulse and temperature. Improvement continued steadily after this time, and the patient was discharged on October 15.

A trace of albumin appeared in the urine on the fifth day in the hospital, but had disappeared by the next day. There was no vomiting at any time.

Case 6 (Chart III.)—A. L. Z., age 25 years, had resided in Vera Cruz for twelve years. Onset, October 10, 1920,

CHART III.

CASES TREATED WITH ANTI-ICTEROIDES SERUM

with chill, followed by fever. Admitted to hospital October 11 at noon, complaining of severe pains in head and back. On October 12 the diagnosis was clear, and the patient was given an injection of 20 c.c. of serum. There followed what is described as a violent reaction. The patient tossed about on the bed, and a reddish violet rash developed on the neck, especially near the back The attending physician administered a dose of caffeine and ordered a cold bath. Notwithstanding this heroic treatment, the temperature and pulse showed marked improvement, and from this time on the patient recovered rapidly. He was discharged on October 19.

The urine showed a trace of albumin on the fourth day in the hospital, but it had disappeared on the next day. There was no vomiting.

Case 7 (Chart III).—G. M. M., age 16 years, had resided in Vera Cruz one and a half years. Onset, February 10, 1921, with chill, followed by fever and pains in back and head. Admitted to hospital on the morning of February 12, in the third day of disease. Face flushed, conjunctivæ injected, urine showed a small amount of albumin. In the afternoon the patient was worse and had periods of faintness. The pulse condition was so poor that the attending physician thought best not to give serum immediately. By 4 p.m. the patient had rallied somewhat, and an injection of 20 c.c. serum was given. Temperature and pulse showed marked improvement. Another dose of 20 c.c. was given the following morning. The temperature rose that afternoon, but the next day it fell to normal, the general condition was much improved, and the patient made an uneventful recovery. He was discharged in thirteen days. The amount of albumin had reached an appreciable amount on the third day in the hospital, but it had disappeared completely by the ninth day. The quantity of urine reached the low mark of 100 c.c. for twenty-four hours on the third day; two days later it was 700 c.c. There was much soreness in the epigastrium, but no black vomit.

In addition to these cases observed in detail, it may be of interest to record the experience of the port quarantine officer at Gutiérrez Zamora. Because water transportation was possible, anti-icteroides serum was available at the port. Eighteen cases were treated with the serum during the first four-day period of the disease and from this group one death resulted and this was a patient treated at the end of the fourth day. In contrast to this there were three cases found in early stages of the disease (first three days) that did not receive the serum. Two received no treatment and the third was given 45 centigrammes of neosalvarsan (French) with no effect. All of these three cases terminated fatally.

III.—Vaccination against Yellow Fever.

The epidemic in Vera Cruz began on June 8, 1920' in the central part of the town. The second case occurred in the next house, the third across the street, and succeeding cases in the same block, the epidemic radiating from this block as a centre until the whole town was involved. The measures adopted were immediate screening of the patients by means of a metallic screen booth, fumigation of the infected houses with cyanide, and anti-mosquito work, including inspection, covering of tanks, and emptying or oiling of containers.

As one of the protective measures, vaccination [5] [6] of all non-immunes who desired it was begun at once. In all, 748 persons applied for vaccination, of whom 514 reported for the second injection. No reason can be given for the fact that 234 persons failed to appear for the second injection. None of the persons vaccinated had any history of having had yellow fever or having been present during an epidemic anywhere.

The total number of cases occurring during the epidemic was 204, of whom 86 died. Among the 748 persons vaccinated, three contracted yellow fever from one to four days after vaccination. Since this period is too short for the development of any appreciable immunity, these three cases may be regarded as controls, that is, they show that the vaccinated were exposed to yellow fever. Two other vaccinated persons contracted a disease which may or may not have been yellow fever. Both were extremely mild, recovery being complete in four days, and no examination seems to have been made for malaria. If we accept these two cases, which developed one month after vaccination, as yellow fever, then the incidence of yellow fever among the vaccinated was two, while among the unvaccinated there were 199 cases.

As to what percentage of unvaccinated non-immunes these 199 cases represent, it is difficult to say. The total foreign population of V era Cruz could not have been large, and it is not unl kely that the 748 vaccinated represented the larger portion of them. The population of Vera Cruz (which is estimated at about 65,000) is fairly permanent. Most of the non-immunes are Spaniards, who have taken work in Vera Cruz until they definitely decide where to settle. There is never any large importation of non-immune labour such as occurs in a sugar or a banana state. The largest group of non-immunes ever arriving is the military force, but in this case those known to be non-immune (i.e., coming from mountainous districts) are never intentionally sent to Vera Cruz ; usually transfers of troops are made from one coast town to another.

On the other hand, a certain number of young natives must have been non-immune, since there had been no cases of yellow fever in Vera Cruz since 1909 and no considerable epidemic since 1904. The belief was common that anyone who is born in Vera Cruz, or has lived there any considerable time, is immune, and it was not until the last part of the epidemic, after two native Veracruzanas and two young children had died of yellow fever, that the natives of the city began to apply for vaccination.

Although there is no way to estimate the unvaccinated non-immune population, it cannot have been more than a few thousand at most. Hence an incidence of less than three per 1,000 among vaccinated (two among 748), as compared with twenty to forty per 1,000 (assuming that there were 5,748 to 10,748 non-immunes) among unvaccinated, is an indication that most vaccinated persons escape infection.

We may record here an incident which was of considerable interest, though perhaps of little scientific importance. In a sectarian school, which was practically a non-immune community, since most of the teachers were Americans, and the pupils came from more or less distant mountain regions, four cases of

yellow fever occurred. One of the four, an American teacher, died, and immediately afterwards the whole community—about 154 persons—was vaccinated. No further cases of yellow fever developed.

SUMMARY.

Seven cases of yellow fever were studied during the epidemic in Vera Cruz in the fall of 1920. Transmission of the disease to guinea-pigs was accomplished in one of the seven cases, and from the animals of the third generation a strain of *Leptospira icteroides* was isolated in pure culture.

The strain induced in guinea-pigs all the typical symptoms of experimental yellow fever in this animal: fever, intense jaundice and nephritis, hæmorrhages into the gastrointestinal tract, and degeneration and necrosis of liver and kidney.

Of seven cases of yellow fever treated with the anti-*icteroides* immune serum, all recovered except one, in which treatment was delayed until the latter part of the third day of illness; that is, the mortality among treated cases was 14 per cent. (one in seven cases) as against 43 per cent. (eighty-five in 197 cases) among untreated. The favourable effect of the treatment was evident within a few hours by the fall in temperature and pulse-rate and by the improved subjective condition of the patient.

Among 748 non-immune persons vaccinated with the killed cultures of *L. icteroides*, two cases suspicious of mild yellow fever occurred after the lapse of one month, while among unvaccinated non-immunes 199 cases of yellow fever occurred. While the number of non-immunes present in Vera Cruz is not accurately known, it could not have been large, because of the small foreign population of Vera Cruz and the comparatively recent occurrence of epidemic yellow fever, hence it is believed that the vaccination considerably reduced the incidence of the disease.

Intradermal Salt Solution Test in Scarlet Fever and Diphtheria Patients (W. J. Baker, *Jour. Amer. Med. Assoc.*, Nov. 15, 1924).—From the study of seventy patients with scarlet fever and thirty patients with diphtheria, two-thirds of whom were children, it appears that in these diseases the disappearance time of intradermally injected salt solution is reduced. The reduction parallels the severity of the intoxication. This test aids in indicating how the patient is getting along and in predicting the outlook for the near future.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these,** with remittance, **is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

A WHITE AUSTRALIA: IS IT A POSSIBILITY?

By SYDNEY J. SKERTCHLEY, J.P.

(*Continued from page* 168.)

CHAPTER XII.

Urban Australia.

The cry of "back to the land" has been ringing in English ears for years. It is felt by many, sus-

pected by most, and known by experts that not only does city life tend to impair physique, but it so affects the vital powers that sterility, not comparative, but absolute, is the penalty exacted by nature for the indulgences the town offers. France has been compelled to echo the same cry. M. A. de Quatrefages, the eminent anthropologist already quoted more than once, wrote as follows, so long ago as 1886:

"The very progress of civilization sometimes results in the vitiation of certain conditions of life. Such is the almost inevitable result of the crowding together of human beings in a relatively limited space. This is one of the points most clearly demonstrated in the statistical researches of M. Boudin upon the comparative mortality of the country and of barracks for example. A comparison of our large towns and rural districts leads to the same result, and points to a special action upon the organs of reproduction. M. Boudin could not find a pure-blooded Parisian whose genealogy could be traced for more than three generations. At Besançon, town families become extinct in less than a century, and are replaced by others from the country. London, I have been assured, presents a similar phenomenon."

Let us see what London proves. In 1885, my friend Dr. J. Cantlie, above cited, delivered before the Parkes Museum of Hygiene a lecture on "Degeneration among Londoners," which roused much attention. He says, "Some four years ago, when my attention was first drawn to this subject, I started with the premises that a Londoner was one whose grandparents and not the parents only, came under the category; but I had to stop, as I could find no such specimens." The nearest approach he could get were of generations whose grandfather or grandmother came from the country. This interesting brochure gives much detail, which, though important, we must pass over in silence. Among other matters, he shows that London is not governed by Londoners: "Of the last thirty Lord Mayors mentioned (in Orridge's account of the Lord Mayors of London) twenty-seven were born in the country, and the remaining three of country parents." I will take it, then, that no one who has paid attention to the subject doubts the appalling effect of town life. Let us now see how this new land of ours, this splendid country that has only 1·46 European inhabitants to the square mile, distributes its population.

Mr. Knibbs writes: "A feature of the distribution of population in Australia is the tendency to accumulate in the capital cities. To such an extent is this metropolitan aggregation carried, that in every State the population of the capital far outnumbers that of any other town therein, and ranges between nineteen and forty-six per cent. of the entire population of the State." The actual percentages on the total of the State are: Melbourne, 43·11; Brisbane, 25·04; Adelaide, 45·41; Perth, 19·26; Hobart, 21·92; Commonwealth (six cities), 36·21. This is over five times the proportion obtaining in Prussia, and between twice and three times that of England. Now this is a very important, and for us an unfortunate fact, and we must give a few more details, to bring home the magnitude of the misfortune.

The total population of the Commonwealth in 1907 is given officially as 4,197,037. There are sixteen towns having populations of over 20,000, if we include Rockhampton, which fell just below that figure. They are:

Sydney	577,180
Melbourne	538,000
Adelaide	178,000
Brisbane	135,655
Newcastle	63,250
Perth	50,380
Ballarat	48,607
Bendigo	44,458
Hobart	40,326
Broken Hill	31,000
Kalgoorlie and Boulder	29,242
Geelong	28,021
Launceston	24,536
Fremantle	21,000
Charters Towers	20,976
Rockhampton	19,691
Total ...	1,850,622

This, in round numbers, means that nearly one-half of our population is concentrated in sixteen centres.

This is a very serious condition of things. I have not at hand particulars enabling me to compare European countries in this connection, but I have little hesitation in saying that it is unparalleled. Other countries, again, have many populous centres, whereas each of our States has but one, and this the capital. How different this is from the home land is illustrated by the fact, seldom realized, that a radius of twenty miles round Manchester embraces a larger population than a similar circle struck from London's centre. It means more even than mere numbers indicate. It shows that the mass of our immigrants linger about the capitals at which they disembark, and, moreover, that even our natives tend to flock to the towns, not only not making good the deficit due to impaired vitality but swelling the already too rapid growth of the cities as compared with the settlement of the soil. City life in Australia is no exception to city life elsewhere; it means rapid decay of reproductive power; it spells not merely arrest, but retrogression. Our urban population is disastrously disproportionate to our area.

As I pointed out in my first chapter, this inquiry does not deal with causes, but with effects. The causes which lead to decrease of population are many, and vary from time to time; and from place to place; and to discuss them would be to darken counsel with words. What we have in hand is a review of the facts, a simple statement of the nature and results of immigration. Climate, disease, changed habits due to new conditions reacting upon the organism, and many other direct or in-

direct causes, we have seen, have invariably brought about the same result—the lessening of the fertility and ultimate extinction of the newcomer. Nevertheless, we may here pause to ask whether, in view of the vital importance of the question to ourselves, we can trace any determining cause for the steady decline of the birth-rate of Australia.

I am inclined to attribute a large share of this melancholy condition to the abnormal aggregation of our population in cities. It is difficult to prove this, and will be until special means are adopted by our statisticians to determine the relative rates of natural increase in the urban and country areas. These gentlemen now work on a common basis, so that their results are comparable, and their onerous duties are carried out so efficiently as to claim the admiration of all who have to consult them technically. I trust that, now that the importance of this matter is demonstrated, this distinction may be made an object of their research. How great the difference between the two conditions may be roughly gathered from the following table, by Sir J. A. Baines, in the *Journal of the Royal Statistical Society*, 1903. I take it from Dr. Gregory's new work on Australasia, before quoted, and may remark that the learned writer is a strong advocate

	Densely peopled			Sparsely peopled		
	Percentage on total		Density	Percentage on total		Density
	Area	Population		Area	Population	
Victoria	20·43	73·51	48·94	34·16	3·51	1·39
S. Australia	1·34	79·71	23·79	2·51	1·67	0·27
Queensland	1·49	44·26	22·28	53·94	4·85	0·07
New Zealand	31·60	46·31	10·92	68·40	53·69	5·85

of the White Australia aspiration, and so is a hostile witness.

The constrast is a remarkable one, and worthy of serious study.

Yet there are some few details that tend to show, what I have no doubt is the fact, that the urban birth-rate is lower than the country birth-rate. For example, Mr. Thornhill Weedon, in his last official Queensland report (1908 for 1907), says: " The ratio of birth increase was 3·73 for the whole State, but was twice as great outside as within the metropolitan area. Great variations were apparent between the two years (1906-7) in the number of registrations in the different district groups. Thus, in the Moreton district, where there were 2,008 births in 1906, there was a decrease of thirteen in the following year; whilst on the Downs, with approximately a similar number in the previous year, there was in 1907 an increase of 253 numerical, or thirteen per cent. proportional." The first statement directly confirms my suggestion: and the second, though not quite so strong, supports it, for Moreton district is the metropolitan area, and includes Brisbane, and the Downs is rural; but as it includes Toowoomba, the largest inland city in the State, with a population of 14,087, it is not as typical as could be desired.

Here let one pause to point out a grave error, often committed even by scientific writers. They fail to see that though the healthiness of a district lowers the death-rate, it has no necessary effect upon the birth-rate. Australia, as we have seen, has a low birth-rate combined with a low death-rate. This combination increases the natural rate of increase. Yet, in spite of this, the net rate of increase, as we have shown, has steadily fallen. Australia is healthy enough; its people live longer than the average, but, in spite of this, the birth-rate has decreased. Yet writers confuse these factors.

For example, Dr. Gregory, in his "Australia," vigorously maintains the permanent habitability of the tropics by Europeans. He quotes with approval from a paper by Mr. Sambon in the *British Medical Journal* (1897) the opinion: " First, that European emigrants can live and perpetuate their kind in tropical regions; secondly, that the difficulties in the way of colonization are not due to climate, but to parasitism; thirdly, that acclimatization is, to a great exent, a mere question of hygiene." Having accepted this fiction as if it were fact, Dr. Gregory proceeds to clinch his argument with real facts, pointing out case after case of tropic or hot unhealthy lands—India, the West Indies, Algeria, &c.—which have been rendered more salubrious by modern scientific skill. Algeria delights him, and in triumph he quotes old General Duvivier's saying that (I translate) " cemeteries are the only colonies always flourishing in Algeria," only to point to the moral that " Algeria is now one of the best and most popular of sanatoria for European invalids." So it is: but Europeans only get well there, they do not get born there, which is the matter at issue.

So far from such facts as the above proving the case they are cited in support of they tell quite the other way. There is no doubt whatever that improved hygiene, including sanitation, the treatment and sometimes the abolition of diseases, the more rational way of living, &c., have in the last half century added a cubit to the span of life. Yellow fever in Cuba, malarial fever in Panama, are no longer the terrors they used to be; they are under even stricter control than small-pox in England. But the net result of this splendid work has been to reduce the death-rate, not to increase the birth-rate.

Annotations.

Observations on North China Intestinal Parasites of Man, Ernest Carroll Faust, *Amer. Jour. Trop. Med.*, July, 1924).—An intensive study of third-class patients on the medical service of the Peking Union Medical College Hospital was undertaken to determine the importance of parasitic infection in clinical diagnosis in North China. Sixty cases were studied. Each case was under a careful scrutiny for a period of ten days or more, during which time every stool passed by the patient was examined. In all 1,409 stools were studied, or an average of 23·48 per patient. Controlled methods of preparation of the stool for examination indicated that concentration methods were valuable only where a single specimen of stool was available for study. In cases where large numbers of stools of the same patient were examined concentration methods added only ten per cent. to the findings. Forty per cent. of the infections were diagnosed after the first day, thirty-five per cent. of which were diagnosed first from unconcentrated preparations. Eighty per cent. of the cases studied harboured intestinal entozoa. While this infective incidence is comparable to that of a sick population in Central China, it is less intensive than the latter. The respective indices for the two areas are as follows: Central China (Wuchang survey), protozoa, 228·7; helminths, 234·3; North China (present study), protozoa, 101·6; helminths, 88·03. The clinical significance of the study is demonstrated by the fact that 53·3 per cent. of the series harboured clinically important parasite infections. Twenty per cent. of the cases had a major diagnosis due to parasites; 46·6 per cent. had a minor diagnosis of parasites; 13·3 per cent. of the cases had both major and minor diagnoses occasioned by infections of the digestive tract due to parasites. No proof can be advanced from the present study regarding flagellate entozoa in amœbic dysentery that there is a necessary relationship between the two infections. In the cases studied at least 89 per cent. of the patients secured their infections in the North China nosogeographic area. They belong to the lower middle-class and the poor class, which groups, on account of undernourishment, are likely to be more troubled with clinically important infections than are the upper classes. The Chinese, as a people, are not less susceptible to parasitic infection than other peoples, although light infections among Chinese are less likely to be clinically significant than in Occidentals living in China. Improper disposal of night-soil is responsible for all the helminthic infections in the intestinal tract of man in North China as determined by this study.

Herpetomonad Flagellates in the Latex of Milkweed in Maryland (F. O. Holmes, *Phytopathology*, Vol. XIV, No. 3, March 1924).—A flagellate infection of milkweed (probably *Asclepias syriaca* L.) was discovered during the autumn of 1923 near Baltimore, Maryland. The flagellates correspond fairly closely to those properly known as *Herpetomonas elmassiani* (Migone), described in 1916 by Migone in Paraguay. So far as is known this is the first report of such organisms in the United States. A red and black hemipterous insect, *Oncopeltus fasciatus* (Dall) is suspected of carrying the flagellates from plant to plant.

Case Resembling Endemic Typhus Fever (Brill's Disease) (*Med. and Scientific Arch. Adelaide Hospital*, No. 3, *Annual Report*, 1923).—G. C. female, 20, waitress, living at Hindmarsh, was admitted to hospital September 25, 1923, complaining of severe headache, abdominal pain and vomiting. Illness had begun September 22, with sudden pain in the lower part of the left chest, which had been increased by deep breathing, but had not been accompanied by cough. She had been drowsy since the onset of her illness, and had had diarrhœa during the first two days. She had had no epistaxis. Spleen slightly enlarged. Tender on palpation on the right hypochondrium. No rash was present. On September 26, agglutination reactions against the *B. typhosus* and *B. paratyphosus* A and B were negative. On September 29 a rash consisting of pink coloured macules and papules appeared on her arms, hands, thighs, feet and trunk. These disappeared on pressure, and varied in size from a pin's head to a third of an inch in diameter. She had also complained of severe aching pain all over her body. Rash had quite faded by October 4. Temperature, which had been 104°F. on admission, fell slightly but persistently until October 7, when it was normal, and continued so, coincident with her relief from symptoms. She was discharged well on October 17. On October 16 the Weil-Felix reaction was positive up to a dilution of 1 in 2,560.

A Microscopic Study of Mercury Absorption from the Skin (K. G. Zwick, *Jour. Amer. Med. Assoc.*, December 6, 1924).—Microscopic examination of intact animal skin, to which mercury in the form of mercurial ointment had been applied by unction, established: (1) The presence of globules of mercury (*a*) in the infundibula of the pilosebaceous follicles; (*b*) in the orifices and excretory ducts of the sebaceous glands. (2) The absence of globules of mercury (*a*) in the intact epidermal layers that are not constituents of the integumentary appendages; (*b*) in the cutis vera. Microscopic findings lead one to conclude that percutaneous absorption of mercury following inunction of animals with mercurial ointment takes place preponderatingly from the material deposited in the pores, consisting of the orifices of the hair follicles and of the excretory ducts of the sebaceous glands. Percutaneous absorption of mercury is not materially influenced by removing from the intact skin the excess of mercurial ointment deposited on it during inunction, because mercury does not penetrate into or through the intact epidermis.

The Effect of Carbon-Tetrachloride on the Egg-Laying Powers of the Female Hookworm (W.C. Sweet, *Amer. Jour. Hygiene*, November, 1924).—In most instances carbon-tetrachloride in doses up to 2 c.c. had very little inhibiting action on the egg-laying power of the female ankylostome. All inhibition had disappeared by the seventh day. Re-examinations in either field or laboratory work could be made one week after treatment. In this series of egg counts the number of eggs per gramme of fæces from the same persons was found to vary with the character of the stool. The ratio established was very close to that found by Stoll working on necators in Porto Rico. The theoretical number of worms responsible for the eggs counted was found to be high and, on theoretical grounds, it was predicted that female ankylostomes would be found to have about five times the egg-laying powers of female necators.

Treatment of Hookworm Disease with a Combination of Carbon-Tetrachloride and Oil of Chenopodium. Comparison of Results of Simultaneous and Delayed Administration of Magnesium Sulphate (F. L. Soper, *Amer. Jour. Hygiene*, November, 1924).—Hookworm infestation in Paraguay is very heavy. Fortunately, the infestation is over ninety per cent. of the less resistant and probably less harmful necator. The combination of carbon-tetrachloride, three parts, with oil of chenopodium, one part, in adult dose of 2·4 c.c. (1·8 c.c. of the former and 6 c.c. of the latter) is very effective in an area of low ankylostome infestation. No toxic symptoms were reported. Like other anthelmintics, this combination gives a higher percentage of total worms removed in heavily infected cases than in those with few worms. This is probably due to a larger percentage of immature forms in heavily infested cases. The simultaneous administration of magnesium sulphate tends to delay the expulsion of many worms until the second day. There appears to be, however, no diminution or delay of anthelmintic action. A simultaneous reduction of toxicity and cost per person treated may be expected from the introduction of this method of administration in field work against hookworm disease.

Abstract.

THE ABSENCE OF ENDEMIC GOITRE IN HONOLULU.[1]

By J. Christopher O'Day, M.D., F.A.C.S.

THE goitre problem of the Pacific Coast, particularly of its north-west portion, is still unsolved. Towards such a solution there has been no little endeavour, yet up to the present time no reward has been claimed. As a result of my own investigation the conclusion was reached that endemic or retentive goitre had to do with the character of the drinking water. The conclusion, however, was based entirely on personal and the general observation of others. The problem in no way is able to lend itself to actual scientific research, and this in face of the fact of our work being carried on in a district where endemic goitre enjoys an incidence of close on to 50 per cent., namely, Portland, Oregon. With the co-operation and guidance of no less able clinicians than Lawrence W. Snelling and Franklin C. Maclean, interest in the ætiology of retentive goitre gave way to that of those hypersecretive types that were accompanied by a diabetic syndrome. When further work and observation showed that this diabetic syndrome would entirely clear after lobectomy, we set about to discover, if possible, just what it was in these odd cases of Graves's disease that was directly responsible for the loss of the carbohydrate tolerance.

First, was there a lesion of the sympathetic system which caused the hypersecretion of the thyroid? If so, was the same lesion capable of disturbing the secretion of the islands of Langerhans and thereby precipitating the diabetic syndrome? Again, could the hyperthyroidism produce the extreme thirst, polyuria and the ravenous appetite and the glycosuria be but a mere metabolite? But when it was continuously and invariably observed that the metabolic rate was always in proportion to the degree of hyperthyroidism, and that the basal metabolism was in no way related to the carbohydrate overthrow, our questions were forced to go unanswered.

In a subsequent article, Snelling emphasized the point by showing that the degree of hyperthyroidism bore no relation whatever to the precipitation of the diabetic syndrome.

It was during this time that Maclean was carrying on the research work, the result of which has been published.

The sugar content of the blood in diabetes of thyroid origin is as variant as that of the pancreatic lesion, and resolves itself into that last conjecture of a hypothetical sugar threshold. But the hyperglycæmia and increase of the metabolic rate, which are constant findings with hyperthyroidism, cannot be regarded as a step towards the development of the occasional cases wherein the sugar mobility assumes the rôle of the pancreatic lesion.

While this reference to hyperthyroid goitre is foreign to that which the title of this article more reasonably suggests, it is mentioned since it is now known that Lugol's solution is quite capable of restoring both the carbohydrate tolerance and a marked return toward the normal metabolic rate. But the improvement is not permanent and a second administration of the drug is disappointing.

Up to a certain point only is the iodine able to stay the storm—at that point help is needed. Whatever the help may be remains to be discovered. That the kidney function might be the factor has nothing beyond the notion to sustain it. The

[1] Abstracted from the *Medical Journal and Record*, February 4, 1923.

results of our observation and investigations have been published.

Endemic or retentive goitre has not been observed in Honolulu. It was this fact which led to our comparing the water supply of the island city with that of the goitre districts of the coast. Before making such comparison it may be of interest to mention, in brief, the presence of toxic goitre among the Oriental races of the islands.

It should be recalled that the percentage of toxic or hyperthyroid goitre is no greater within the endemic districts than it is, generally speaking, throughout the United States and Canada. This type of goitre is encountered in Honolulu, but just what incidence to population has not been learned. While it is among the Japanese that it seems to be the most prevalent, once comparison is drawn between the Japanese population, the predominant of the Orientals, it is immediately made to appear that toxic goitre here occurs in about the same proportion as that noted throughout the mainland and Canada.

In this reckoning the native Hawaiian cannot be included, for the type of individual that is prone to this affliction is but too seldom met among the phlegmatic people. It was Dr. Wayne Babcock, of Philadelphia, who first drew my attention to this, the consideration of types.

The first change necessary to start the development of endemic or retentive goitre is that which takes place in the character of the thyroid's secretion. Its consistency becomes viscid to a degree wherein it is no longer able to enter the stomata of the lymph radicles. Accumulation within the follicles results, and the gland is made to bulge proportionate to the degree of accumulation. We conjectured that some definite arrangement existed between the secreting follicles and lymph radicles, and which, if understood, would eliminate the speculative conclusions, of which there were two, namely, was the thickening of the thyroid secretion due to a faulty functioning of the follicles or was it the result of a scanty lymph supply into the follicles for the physiological thinning of their secretion? In other words, just how did the mineral free water exert its deleterious influence on the interdependence of thyroid and lymph commingling?

With this in mind, a number of normal thyroids were injected, several methods of injecting being used, but no one of the subsequent sections threw the least light on the mechanics of the interrelated function of blood supply to that of lymph and the gland's secretion. With a preponderance of evidence to support the belief that endemic goitre is caused by the character of the drinking water, it is interesting, at least, to find further proof on comparing the character of the drinking water of Honolulu with that of the districts where this disease is prevalent.

The artesian water with which the city of Honolulu is supplied is one of the finest drinking waters in the world. It is unique in its low content of sodium iodide, and which seems to be bound in a rather unstable way with an equally low content of the chloride of soda and potash. Calcium carbonate represents the highest per cent. of mineral content, yet insufficient to cause the water to be hard. Its bacterial count is nil. The artesian wells providing this water vary in depth from 500 to nearly 1,000 ft. An average of 20 ft. deducted from the depths of each well will replace the number of remaining feet below sea level.

The discrepancy in the depths of the wells is due to the elevations and depressions in the roof of the artesian basin and not to the surface location of the well. The almost continuous rainfall of the mountain tops has to percolate through thousands of feet of volcanic ash, rock, lava, and in many places substrata of ectopic coral before reaching the artesian basin. From this it may be readily understood how such altitudes would place the plus pressure on the side of the artesian basin and prevent the waters of the ocean from finding their way into the basin.

February, 1925.

Typhus-Like Fever, Probably Tick-Typhus, in Central India (J. W. D. Megaw, F. B. Shettle and D. N. Roy).—These cases are of interest as furnishing fresh evidence of the occurrence in India of a typhus-like fever which is identical with or closely related to the spotted fever of the Rocky Mountains. All the cases occurred among a body of more than two thousand men who were engaged in manœuvres in two camps, each situated about ten miles from Saugor, in Central India, and about twenty miles from each other. The disease is liable to attack persons leading an open-air life, and in this respect resembles Rocky Mountain fever and the typhus-like fever of the Kumaon Hills. The clinical characters also show a close resemblance. Lice are completely excluded as cause of the disease, and ticks are doubted for more than one reason, although it appears to be probable that the cases belong to the tick-typhus group.

Indian Tick-Typhus (J. W. D. Megaw).—The author asserts with some confidence that a tick-borne fever of the typhus group occurs in India, and the use of the term "tick-typhus of India" or "tick-typhus" will be most appropriate as a provisional designation for the disease. The term "spotted fever of India" has been suggested with a view to indicating the relationship to the known disease which it most closely resembles, but the word "spotted" has been used for so many diseases that it does not convey any precise idea, whereas the term "tick-typhus" will be applicable to the disease in any part of the world.

Notes on Carbon Tetrachloride as an Anthelmintic (A. C. Chandler and A. K. Mukerji).—An anthelmintic should be judged on the basis of (*i*) safety for the patient; (*ii*) effectiveness in expelling worms; (*iii*) simplicity of administration on a large scale; (*iv*) lack of unpleasantness in taking

or in after-effects; and (*v*) cheapness. No one anthelmintic can be expected to be effective for all kinds of worms. As regards safety to the patient, CCl_4 in a dose of from 3 to 5 c.c. can be regarded as being as safe as any effective anthelmintic, and distinctly safer than oil of chenopodium, providing certain precautions be taken. It can be given with confidence to kala-azar and malaria patients during remissions of fever, is well tolerated by young children, and is safe for pregnant women. It is distinctly superior to chenopodium in eliminating necators, whereas it is approximately on a par or a little inferior in removing ankylostomes. It is also much cheaper than chenopodium. CCl_4 has a distinct ascaricidal action, especially when combined with chenopodium. Alone it is a little less effective than either chenopodium or santonin. Given orally it seems to have a more decided action on oxyuris than any other anthelmintic tried. The drug has little or no action against trichuris, strongyloides or tapeworms.

Gaucher's Type of Splenomegaly in a Mahratta Village, with a Case Treated by Splenectomy (W. C. Spackman and F. P. Mackie).—It is stated by the inhabitants of Dhagur that a disease exists there which is always fatal after a number of years, beginning at an early age and attacking only Mahrattas. A considerable number of young males are carried off by it. The disease is known as *potedhagur* (big stomach). There is a low type of fever and progressive weakness. There is no kala-azar in the district.

Variations in the Potency of Digitalis Preparations in the Tropics (R. N. Chopra and S. C. Bose).—Clinical observations as well as biological and chemical assays of tincture of digitalis show that it undergoes deterioration rapidly in a tropical climate such as that of India. This deterioration cannot be accurately determined by any single method in the laboratory, such as Hatcher's "cat method"; the "frog method"; or Kundson and Dresbach's chemical method. Clinical tests give the most reliable information. The average dose of 15 c.c. of the tincture per 100 pounds of body weight required to get the patient under digitalis effect in 36 to 48 hours is considerably increased after the tincture has been in the tropics even for a short time. Deterioration is due to some change in the digitalis glucosides, the nature of which has not yet been determined. The tinctures on dilution become darkish in colour, unlike good tinctures, which are light green and uniformly opalescent. Such tinctures are more toxic to cats when given intravenously, but a considerable weakening in the therapeutic efficacy is evident. The dosage of tincture of digitalis generally employed by medical practitioners in India (i.e., 5 to 10 minims three times a day) is far too small to get the patient under the digitalis effect within a reasonable period (three to four days). With tinctures of standard strength doses of at least 20 to 30 minims three times a day should be given. If rapid effects are desired in urgent cases these may be increased from 45 to 60 minims until the amount calculated by Eggleston's method is given.

An Investigation into the Origin of Cholera Epidemics in the Jheria Coal-Fields (G. C. Maitra).—A cholera-like disease with indefinite etiology exists in the coal-fields. Further investigation will be made of this important condition when opportunity offers. This disease appears to be of low infectivity and was never seen to assume epidemic proportions nor to give rise to multiple cases in the same family. Cholera epidemics due to Koch's vibrio were imported last year into the coal-fields from the pilgrim centres of Puri and Baidyanath. Elaborate and costly disinfection measures are only justifiable when the outbreak is due to the genuine cholera vibrio, and as this can only be ascertained by careful bacteriological examination, a competent bacteriologist and epidemiologist with a mobile laboratory is a necessity for the coal-fields. In the absence of a competent bacteriologist all cases which have the clinical features of cholera must, of course, be dealt with as if they were true cholera. The value of specific immunization against cholera, both subcutaneously and by the mouth, cannot yet be assessed without further extensive trial side by side with other methods of preventive medication. The scientific method of prevention is not necessarily the best; the prejudices of the affected population and the local conditions must be taken into account.

The Treatment of Asthma (H. W. Acton and R. N. Chopra).—For treatment of asthma during the stage of attack, ether, chloroform, chloral hydrate and morphia are all useful, but they act without removing the cause, and are merely used as a *placebo* to relieve symptoms. In *sympathetic predominance* adrenalin fulfils all requirements. In *vagal predominance*, on the other hand, adrenalin, when injected intramuscularly, has only a slight and evanescent effect in overcoming the bronchial construction. The drugs preferred during acute attacks are the phenacetin group. The nitrites give great relief in the failing renal heart and in cardiac failure. The value of atropine and cocaine, when given as a fine spray, is very great, for both paralyse the vagus and lessen bronchial secretion.

The Migration of Hookworm Larvæ in Soil (A. C. Chandler).—These experiments confirm the conclusions reached by Augustine, Cort and Payne concerning (1) the practical non-existence of lateral migration of hookworm larvæ; (2) the easy scattering of larvæ by surface water; (3) the tendency to upward migration through coarse soil; and (4) the very restricted migration on the sides of a soil wall. The author's observations, however, point to a definite negative geotropism as the principal factor in guiding larvæ upward, rather than an upward flow of surface water, as suggested by Payne.

YELLOW FEVER RESEARCH, 1918-1924: A SUMMARY.

By HIDEYO NOGUCHI, M.D., M.S., Ph.D., Sc.D.

Member of the Rockefeller Institute for Medical Research, New York.

ISOLATION OF LEPTOSPIRA ICTEROIDES.

Leptospira icteroides was first isolated in Guayaquil, Ecuador, in 1918 [1], from six of twenty-seven selected cases of yellow fever diagnosed by Pareja and Elliott [2]. The same organism was isolated by Kligler and myself [3] in Mérida, Mexico, in 1919-1920, from blood taken from a yellow fever patient on two successive days, the second and third of his illness. Pérez Grovas [4] obtained a strain of *L. icteroides* in Vera Cruz in 1920 from one of two cases of yellow fever studied, and in the same year Kligler and I [5] isolated the organism from four of thirteen cases in northern Peru. Le Blanc [6] succeeded in isolating a strain from one of two early cases in Vera Cruz in 1921. The latest positive results (1923-24) have been obtained in Palmeiras, Bahia, Brazil, by Vianna and Bião, of the American-Brazilian Yellow Fever Commission, who isolated two strains from two of nine cases [7]. Negative results were obtained by Lebredo [8] in Mérida, Mexico, in the summer of 1919, and by Borges Vieira [9] in the suburbs of Bahia in 1920.

One of the Guayaquil patients died four days after the onset of illness, and the liver, which was removed a few hours post mortem, was found to contain a small number of leptospiras; guinea-pigs were inoculated with the suspension of the liver, and a strain of *L. icteroides* was obtained from the passage animals.

Of the sixteen positive blood specimens,[1] twelve were withdrawn between one and three days, two between three days and four days, and two a little later than four days after onset; hence the indications are that the organism is present in the peripheral circulation more frequently (88 per cent of cases) during the first three days of the disease.

The total number of strains of *L. icteroides* isolated is therefore fifteen.

The ætiological relation of *L. icteroides* to yellow fever can be shown also by Pfeiffer tests, with cultures of the organism, of the serum of cases already in the convalescent period. Perez Grovas [10] found the Pfeiffer reaction with *L. icteroides* constantly present in seventeen convalescents from yellow fever. The American-Brazilian Yellow Fever Commission [7] made Pfeiffer tests of the serum of fourteen cases of yellow fever in Brazil against *L. icteroides* from sources in Ecuador, Mexico, Peru, and Brazil, and obtained positive reactions in all. Parallel reactions with *L. icterohæmorrhagiæ* were negative, as were also Pfeiffer tests of normal sera. Pothier and Pareja [11], in Colombia, in 1923,

[1] One of the fifteen patients yielded positive results in the case of specimens drawn on two successive days.

obtained positive Pfeiffer reactions with *L. icteroides* and negative with *L. icterohæmorrhagiæ* in four persons recovering from a disease suspected of having been yellow fever, the clinical diagnosis being thus confirmed.[1]

Adaptation of Leptospira icteroides to Experimental Animals.

Young guinea-pigs, which are the only animals so far found to be useful in the transmission of yellow fever directly from human cases, are, however, rather refractory at best, while fully-grown guinea-pigs are so resistant that even adapted guinea-pig passage strains fail to infect them. Even in young guinea-pigs a clear-cut, typical infection, with hæmorrhages, jaundice, and nephritis after three to six days incubation, is not always induced by inoculation of blood from yellow fever patients, but a suggestive febrile reaction and capillary injection of the conjunctivæ, after a relatively long interval,[2] may be the only symptoms noticed. The period of incubation in the first generation in guinea-pigs has occasionally been as long as eight, nine, or even ten days, and only a few animals among many receiving the same blood may react to the inoculation. If the mild infection at first induced is allowed to run its course, the animals completely recover, but if the blood, or a suspension of liver and kidney, taken at the height of fever, is inoculated into several young guinea-pigs, the febrile reaction may occur sooner and the other symptoms of yellow fever become more distinct in some of the animals. A fatal infection is sometimes induced in the second generation, but it may be necessary to make further passages before the strain acquires sufficient virulence for the guinea-pig to induce typical fatal infection. Autopsy shows the characteristic petechial spots in the lungs, hæmorrhages into the gastro-intestinal tract, acute nephritis, and yellowish-brown liver.

In the early experiments in Guayaquil, the necessity of timely transfer from mildly infected to new animals was not realized, and the opportunity of obtaining a larger number of strains of the organisms was thus lost. Of the twenty-seven cases studied, there were five which furnished strains of moderate initial virulence, one which required three passages in the guinea-pig to induce a fatal infection, and nine others which induced an initial disease so mild that the opportunity for transfer was lost before the nature of the infection was realized. That these animals (sixteen in all), which showed only a slight febrile reaction and a trace of jaundice, actually passed through a mild infection with *L. icteroides* was subsequently proven by their immunity to massive doses of adapted strains of the organism or by the characteristic hæmorrhagic spots in the lungs revealed by examination after recovery. Injection of blood from patients suffering from diseases other than yellow fever does not confer immunity against *L. icteroides*, nor produce the petechial lung hæmorrhages, in guinea-pigs.

L. icteroides is essentially a human pathogen, but when fully adapted to the guinea-pig its virulence for this animal may reach such a titre that 0·00001 c.c. of a suspension of liver or kidney of an infected animal, or of culture, will induce a fatal infection, with characteristic hæmorrhages, jaundice and nephritis. The incubation period becomes fixed to three to six days, as in human yellow fever.[1]

Guinea-pig passage strains of *L. icteroides* are virulent also for young puppies, marmosets, and "prego" monkeys(*Cebus macrocephalus*), and when used in massive quantities, representing several thousand minimum lethal guinea-pig doses, induce symptoms and lesions more strikingly like those of human yellow fever: intense jaundice, anuria, albuminuria, and "black vomit." Guinea-pigs also invariably show effused dark-coloured blood in the stomach, and hæmorrhages into the intestines are common. Autopsy reveals fatty liver, congested kidneys, and normal spleen. The histopathological changes in experimental yellow fever have been studied in detail by Perrin [12] and Muller [13]. The reader is referred also to the recent work of W. H. Hoffmann in Havana [14]. All these investigators have concluded that the pathological changes induced in experimental animals by *L. icteroides* are identical with those of human yellow fever.

Muller [13] has studied also the hæmatological findings in experimental yellow fever and confirmed the earlier observations [15]. There is moderate leucopænia, comparatively slight reduction in hæmoglobin and red blood cells or none at all, as in human yellow fever [2], [16], [30].

One of the proverbial symptoms of yellow fever is the so-called Faget's sign, or relatively slow pulse with high temperature. Cohn and I [17] studied the effect of *L. icteroides* infection on guinea-pigs and marmosets by means of electrocardiographic records and found that the same phenomenon appeared in experimental animals. Relative brachycardia is observed also in human infectious jaundice, and in experimental infection with *L. icterohæmorrhagiæ*.

The Filterability of Leptospira icteroides.

Reed and Carroll [18], Rosenau, Parker, Francis, and Beyer [19], Marchoux, Salimbeni, and Simond [20], showed that the virus of yellow fever passes through the pores of Berkefeld filters. In the early experiments in Guayaquil [21], it was found possible to infect guinea-pigs with the filtrate obtained by passing dilute infective liver and kidney suspension

[1] Recently Muller and Blaisdell have obtained positive Pfeiffer reactions with the sera of persons who had yellow fever during the Salvador epidemic of 1924.

[2] It may be mentioned here that in Rocky Mountain spotted fever, the incubation period in guinea pigs is between three and six days, but in the case of a weakened guinea-pig passage virus it may be as long as sixteen days. Such a virus regains its usual virulence on subsequent transfers to guinea-pigs.

[1] That the incubation period in human yellow fever may be longer than six days was observed by the French Commission to Brazil (*Ann. de l'Inst. Pasteur*, 1903, xvii, 665), who described two instances of experimental, and three of natural infection, in which the incubation period was estimated at twelve to thirteen days.

through Berkefeld filters, and subsequent experiments (Nichols [22], Dieterich [23], the American-Brazilian Yellow Fever Commission [7]) have shown that *L. icteroides*, whether in infected organ suspensions or in culture, is capable of passing through Berkefeld filters of the V and N grades. It is of special interest that Nichols used in his filtration experiments the original filters employed by Walter Reed and his associates in their historic experiments in Havana.

The filterability of *L. icteroides* conforms with one of the most important characteristics of the yellow fever virus, and in this respect *L. icteroides* differs from all organisms previously thought to be the cause of yellow fever.

Cultural Properties of Leptospira icteroides.

An interesting point in connection with the cultivation of *L. icteroides* is the adjustment of reaction of the culture medium. In an earlier publication [21] it was stated that growth of the organisms occurs in the "leptospira medium" [1] when the hydrogen-ion concentration is between pH 6 and pH 7·4. The question has recently been restudied with the collaboration of Dr. Telémaco Battistini [24], not only with *L. icteroides*, but also with *L. icterohæmorrhagiæ* and *L. hebdomadis*, and it has been found that all three species of leptospiras grow well between pH 5·45 and pH 7·21, but not at all at pH 4·65 or pH 8·19. The *icteroides* undergoes degenerative changes much sooner at pH 7·21 than at 5·45 to 6·26, while *L. icterohæmorrhagiæ* and *L. hebdomadis* are as active at pH 7·21 as at pH 5·45. It is evident, therefore, that *L. icteroides* prefers slight acidity and scarcely tolerates an alkalinity beyond pH 7·21. In view of the alkalinity which may be introduced into carefully adjusted media by the use of ordinary soft glass test-tubes, particularly when they have been used for some time, it is well to adjust the culture medium to a point near pH 6 instead of pH 7·4, as formerly recommended. Many of the irregular results previously obtained in the cultivation of *L. icteroides* are undoubtedly explained on the basis of unsuitable reaction of the culture medium employed.

In the light of the exact determination of the hydrogen-ion concentration for the growth of *L. icteroides*, and of the recent work of Rous [25] on the pH of various animal tissues, it becomes evident why the organism does not multiply in the blood or body fluids of which the pH ranges from 7·6 to 8·2, as in the case of man and some animals. Rous found that the pH of the liver and the kidney in a mammalian (mouse), on the other hand, varies from 5·4 to 6·6, hence they offer an optimum reaction for the multiplication of *L. icteroides*. The particular attack of yellow fever on these two organs may perhaps be partly explained by this factor. *L. icterohæmorrhagiæ* shows similar, though less pronounced, predilections. All the organs or tissues spared by yellow fever have a pH either too acid or too alkaline for the survival and multiplication of *L. icteroides*. The pH range of *L. icteroides*, in comparison with that of most pathogenic bacteria, is rather narrow.

The disappearance of *L. icteroides* from the liver and kidney of experimental animals (young guinea-pigs, puppies, and certain monkeys) is proportional to the degree of histological (hence functional) changes induced by the invading organisms. The more profound the changes, the fewer the surviving organisms, until none at all can be found when the injuries reach a certain limit. The cessation of physiological function of the involved organs and consequent lack of nutrient substances leads to the total disappearance of the *icteroides* towards the later stage of a fatal infection. The phenomenon is perhaps somewhat more constant and rapid in human yellow fever than in experimental animals, but it is marked in the monkey, *C. macrocephalus*, in which *L. icteroides* induces an infection comparable in every respect to human yellow fever [7], [13]. The disappearance of *L. icteroides* from the entire system in the case of a non-fatal infection is obviously due to the appearance of specific immune substances resulting from the infection.

Differentiation of Leptospira icteroides from L. icterohæmorrhagiæ and L. hebdomadis.

While a few clinicians [26], [27] regard that yellow fever and infectious jaundice are quite dissimilar in clinical manifestations, the majority of those who have had experience with both diseases agree that the essential features are similar [2], [28], [29]. Both are characterized by sudden onset, capillary suffusion of the face and conjunctivæ at the beginning of fever, severe headache, backache, and muscular pains in the limbs, nausea, early epistaxis, &c., the preliminary symptoms leading in both diseases to jaundice, acute nephritis, and hæmorrhages. The so-called Faget's sign, or relatively slow pulse with high temperature, is present in both diseases. Herpes labialis,[1] considered by some as almost pathognomonic for infectious jaundice, is also observed in yellow fever patients [21].

Some have laid stress upon the paler character of the jaundice in yellow fever, but all grades and all shades of colour, from pale lemon to deep orange, have been met with in both diseases. The clinical difference between yellow fever and infectious jaundice appears to be the somewhat slower course and usually less fatal character of the latter infection. In yellow fever death may occur in five to seven days, while in infectious jaundice the greatest mortality is between the ninth and eleventh days. In some cases of in-

[1] The formula for this medium is as follows:—

0·9 per cent. NaCl	800 parts.
Fresh rabbit serum	100 ,,
2 per cent. nutrient agar (pH 6·5—7·0) ...	100 ,,
Rabbit hæmoglobin (made by laking one part of the defibrinated blood with three parts of distilled water)	10-20 ,,

[1] Herpes labialis has now been shown to be an independent infection caused by a filterable virus. It may occur in association with a number of diseases, hence it has no significance for diagnosis.

fectious jaundice there may be a second rise of temperature towards the end of the second week, but many patients recover without relapse [31]. Relapses have also been known to occur in yellow fever, and are regarded as of unfavourable prognosis [32].

Seven-day fever [33] is also characterized by jaundice, hæmorrhages, and nephritis, but all of a far milder degree than in yellow fever or infectious jaundice.

Morphological Differentiation.

The most reliable means of morphological differentiation is the study of cultures under the dark-field microscope. It is understood that for the purpose of comparison the culture media must be identical in composition and hydrogen-ion concentration, and the cultures must be of the same age and grown under the same conditions of temperature. With the co-operation of Dr. Battistini [24] comparative studies of this kind have been made.

L. icteroides is decidedly shorter (4 to 14 μ) and somewhat thinner (0·2 μ) than *L. icterohæmorrhagiæ*. The elementary spirals are less closely set. The shorter forms assume a semi-oval circle, the longer specimens show greater flexibility, doubling up at any angle. All rotate swiftly, with some lateral vibratory movements.

L. icterohæmorrhagiæ is considerably longer than *L. icteroides* (8 to 24 μ), usually more uniform in length and heavier in aspect. The elementary spirals are more closely set, although in a very long specimen the spirals are somewhat looser. They have the well-known hooked ends and straight bodies, and rotate swiftly and gracefully without lateral vibration.

L. hebdomadis averages slightly longer (10 to 30 μ) than *L. icterohæmorrhagiæ*, and the elementary spirals are almost geometrically equidistant and distinct. The organisms rotate swiftly and evenly without relaxation of the elementary spirals and without bending the ends into a hook, the body being almost a straight line in living forms. Killed specimens have the characteristic hooked ends of a leptospira. Occasionally one observes living organisms showing a small hook at one end, but they soon stretch out with change of movement. There is no difficulty in distinguishing this species from the other two.

Stained preparations may also be used for differential purposes. Leptospiras do not stain readily, especially in culture on the semisolid leptospira medium which gives the richest growth. The best results are obtained by fixing the culture organisms in buffered formalin [34] and staining the dried, thin films with a saturated alcoholic solution of basic fuchsin or gentian violet for a few seconds, or with Giemsa's solution (1 in 20 in distilled water) for two hours. Osmic acid fixation of the wet film, followed by staining with Giemsa solution, also gives good results. In well-stained preparations the elementary spirals can be easily recognized. The thin, delicate, rather short hooked forms of *L. icteroides* can be distinguished from the somewhat heavier and longer *L. icterohæmorrhagiæ* with terminal hooks and the rather straight and coarser *L. hebdomadis*. It is essential for the purpose of comparison to use cultures grown under identical conditions and stained in the same dye solution.

I have had opportunity recently to show cultures of the three leptospiras to Professors Inada, Brumpt, Calkins, Iturbe, and others, all of whom recognized the morphological differences between the species.

Immunological Differentiation.

In the earlier experiments [35] it was shown that *L. icteroides* and *L. icterohæmorrhagiæ* can be distinguished by means of monovalent immune sera. Recently Dr. Battistini [24] has undertaken anew a determination of the immunological relations between *L. icteroides*, *L. icterohæmorrhagiæ* and *L. hebdomadis*, growing the organisms on culture media containing 10 and 1 per cent. of monovalent immune rabbit sera. It has been found that the different strains of *L. icteroides* (from Guayaquil, Mexico, Peru, and Brazil) undergo agglutination and disintegration when inoculated into media containing anti-*icteroides* immune sera, but grow well on media containing anti-*icterohæmorrhagiæ* or anti-*hebdomadis* immune sera. Conversely, the strains of *L. icterohæmorrhagiæ* (obtained from sources in the United States [36], Ecuador [37], and Sumatra [38]),[1] undergo similar changes in media containing anti-*icterohæmorrhagiæ* sera, but grow luxuriantly in media containing anti-*icteroides* or anti-*hebdomadis* immune sera. In the same way, anti-*hebdomadis* sera affect only *L. hebdomadis*.[2]

The experimental infection with *L. icteroides*, like human yellow fever, confers a lasting immunity. As has already been mentioned, the serum of persons recently recovered from yellow fever contains certain immune principles which produce the Pfeiffer phenomenon with *L. icteroides*. Parallel reactions with *L. icterohæmorrhagiæ* have been uniformly negative, and normal sera invariably give negative reactions with both organisms. The duration of the Pfeiffer phenomenon has not been determined but is variable in different individuals. Positive reactions were obtained with the sera of five convalescents in Peru [5], and in the case of two persons who had had yellow fever as long previously as ten and eleven months, while in two other persons who had had the disease ten months previously the reaction was incomplete or doubtful. In Guayaquil [40] fifteen of eighteen convalescents or recovered persons gave a positive reaction; in Colombia and Brazil the reaction was positive in all cases studied. Pérez Grovas [10] found that the reaction was not present as early as the eighth day (one case), but was constantly present after the twelfth day (seventeen cases). There are two instances on record of long duration of the Pfeiffer phenomenon. One is that of Dr. Henry Hanson, a sanitarian [41] who had had severe yellow fever four years previously and had remained in an infected area for two years afterwards; a strong positive reaction was obtained with his serum. Dr. Kligler, who had a sharp attack of yellow fever in Morropón in 1920,

[1] I am indebted for several strains of *L. icterohæmorrhagiæ* to Professor G. Baermann, of Petoemboekan Hospital, Sumatra.

[2] Two strains of *L. hebdomadis* have been obtained through the kindness of Professor R. Inada, Tokyo Imperial University.

and recovered promptly following the administration of anti-*icteroides* serum by Dr. Caballero within forty-eight hours of onset, recently found that his serum still gave a mild positive reaction (four and a half years).

Pérez Grovas [10], employing the strain of *L. icteroides* isolated by him in Vera Cruz [4], studied 183 cases of yellow fever for the purpose of determining whether specific agglutinins for *L. icteroides* could be demonstrated, and found that agglutination tests were more sensitive than Pfeiffer reactions, and that the agglutinating properties of the serum in yellow fever are constantly demonstrable, and as early as the beginning of the second week, that is, earlier than the Pfeiffer phenomenon. Sera from twenty-three normal individuals, and from seventeen persons suffering from diseases other than yellow fever, and sera from persons who had had yellow fever years previously, gave negative agglutination reactions. Positive reactions were obtained in seven of eleven vaccinated persons who had received the second injection of vaccine eleven to fifteen days previously.

The various immunological experiments described clearly establish the immunological entity of *L. icteroides*.

The Non-contagiousness of Infection with Leptospira icteroides.

Like most insect-borne infectious diseases, yellow fever is not transmitted from person to person by direct contact. The excreta and vomitus are not infectious, and only in a few instances out of hundreds of autopsies has it been suspected that a physician performing post-mortem examination has acquired the infection by this means. Generally speaking, the performance of autopsies on yellow fever cadavers is without danger, owing undoubtedly to the disappearance of the virus before death occurs.

L. icteroides behaves much the same with respect to contact as does the virus of yellow fever. Among hundreds of susceptible young guinea-pigs which have been kept in the same pens or cages with fatally infected animals, not a single instance of contact infection has been observed, notwithstanding the animals shared the same food, and the well lived amidst the excreta of the sick. When a fatal *icteroides* infection has been allowed to run its natural course, and the liver and kidneys reveal profound fatty degeneration and necrosis, blood or organs taken at autopsy are seldom infectious, and *L. icteroides* is recovered from such animals only in a small percentage of instances. In the Brazilian monkey, *C. macrocephalus*, in which typical yellow fever was allowed to run its course, no leptospiras could be demonstrated in the material obtained at autopsy.

Ædes ægypti, Yellow Fever, and Leptospira icteroides.

The theory of Finlay that *Ædes ægypti*, formerly called *Stegomyia calopus*, transmits yellow fever from man to man, was first experimentally demonstrated in Havana in 1900-1901 by the Yellow Fever Board of the United States Army under Major Walter Reed. Non-fatal yellow fever was induced in eighteen non-immune volunteers by subjecting them to the bites of mosquitoes twelve days or longer after the insects had bitten patients who were in the early stages of yellow fever (one to three days after onset). A single experiment was made with a mosquito which had sucked the blood of a patient four days after onset of yellow fever, and a negative result obtained, but inasmuch as some mosquitoes which had ingested blood during the first three days of illness failed to infect under the same conditions, the Board did not conclude that the virus is not present in the blood later than three days [42]. The French Commission to Brazil obtained negative results in three instances in which blood taken on the fourth day of illness was inoculated into normal persons [20], hence they considered that the virus probably disappears from the blood circulation about this time.

With regard to the incubation period of the virus of yellow fever in the mosquito, that is, the period between the infecting meal and the time when the mosquito actually becomes infective, the report of the Army Board states that the exact length of the period could not be determined, inasmuch as no experiments were performed with contaminated mosquitoes between the eighth day after the infecting meal, when the result was negative, and the twelfth day, when the mosquitoes were found to have become capable of conveying infection. Carter [50], before the experimental demonstration of mosquito transmission of yellow fever, had determined, by painstaking study of an epidemic in Orwood, Miss., that there was a definite interval between the occurrence of yellow fever in a given house and the time when the house became a source of infection. When all other sources of infection could be excluded, he found that the interval between the first (primary) case of yellow fever and the secondary cases in a given house varied between eleven and a half and twenty-three days. Hence, when we subtract the period between exposure and onset, about three days at the shortest, the minimum period of incubation of the virus in the mosquito becomes about eight and a half days. Reed [43], in comparing the Board's experimental results with the empiric observations of Carter, expressed the opinion that the minimum period of mosquito incubation might be about ten days. Notwithstanding these definite indications that the period is as short as eight and a half to ten days, however, it is usually referred to in the literature as twelve days.

When *L. icteroides* was first isolated in Guayaquil, the question of mosquito transmission of the organism immediately suggested itself, and experiments were undertaken to determine whether the experimental, as well as the human, infection could be transmitted by *A. ægypti* [44]. Six experiments were carried out with mosquitoes infected from human beings, and in one of the six (in which eight insects were used) typical experimental yellow fever was induced in guinea-pigs by the bite of mosquitoes fed twenty-three days previously on a yellow fever patient. In a parallel series of experiments in which the insects

were fed on experimentally infected animals, two guinea-pigs developed the typical infection, one of which had been bitten by nineteen mosquitoes infected eight and twelve days previously, and the other by eighty-three mosquitoes fed eight days previously. Twenty-five mosquitoes of the latter lot were emulsified in Ringer solution two days later and the entire suspension, in which a small number of leptospiras was demonstrated by dark field examination, inoculated into a young guinea-pig. The animal developed typical infection and died eight days later. *L. icteroides* was demonstrated in all of the animals infected by mosquitoes. Another group of the infected mosquitoes was placed in 10 per cent. formalin and brought back to the Rockefeller Institute, but impregnation of the mosquito tissues with silver nitrate made them so powdery that they were useless, hence the study of the distribution of the leptospira in the mosquito body had to be postponed until opportunity for further study should present itself.

The successful transmission of experimental yellow fever from guinea-pig to guinea-pig by means of mosquitoes which, in one instance, had had their infective feeding only eight days previously, cannot be regarded as conflicting with the data obtained in man, for reasons already stated.

Iglesias [45], head of the Vera Cruz yellow fever laboratories of the Mexican Department of Health, was successful in infecting mosquitoes by feeding them on an infected guinea-pig and in transmitting the infection subsequently from the mosquitoes to normal guinea-pigs. Two animals, exposed to the bites of the infected mosquitoes twenty-three and thirty-one days, respectively, after their infecting meal, showed suggestive symptoms of mild experimental yellow fever, and in the transfer from one of them the leptospira was demonstrated in the blood.

The experiments so far made are sufficient to establish the fact that the virus of yellow fever and *L. icteroides* are alike transmissible by *A. ægypti*.

Application of Immunity Phenomena to Prophylaxis and Serum Treatment of Yellow Fever.

As is well known, there are a few instances in which killed cultures of pathogenic micro-organisms are capable of inducing immunity to subsequent infection with virulent strains. An attack of yellow fever confers lasting immunity, and the question at once arose whether the injection of killed cultures of *L. icteroides* would induce appreciable protection against the living organism.

Experiments on guinea-pigs were undertaken by Pareja and myself [46] immediately after the isolation of *L. icteroides* in Guayaquil, and it was found that animals which had received killed cultures resisted subsequent infection. In view of this result, we were asked to inoculate a large number of non-immune soldiers who were to be transferred from non-infected regions to Guayaquil. Of 149 soldiers vaccinated in Quito, 29 received 2 c.c. of killed cultures, the remainder 1 c.c. Among the latter group three later contracted yellow fever. Among another group of 176 soldiers and their families, vaccinated after arrival in Guayaquil with a vaccine preparation about one-fifth the strength of that used in Quito, two cases of yellow fever developed. One may be regarded as a control, in that it developed shortly after vaccination, before immunity could have developed.

The relatively small incidence of yellow fever among the vaccinated group, as compared with that among the other non-immune population of Guayaquil, indicated that it was desirable to continue trial of the vaccine, and subsequent preparations have been of a strength such that one cubic centimetre contains 2,000,000,000 leptospiras, as compared with 2,000,000 in the earlier preparation. Two injections of 2 c.c. of the vaccine are administered whenever possible. This material has been used extensively in Mexico, Peru, Salvador, Guatemala, British Honduras, Brazil, and the West Coast of Africa, more than 20,000 individuals having been vaccinated. Although in many instances the vaccinated were not subsequently exposed to yellow fever, owing to the decline of the epidemic or to their having left the epidemic area, there were nevertheless a large number whose immunity was subjected to test. Table II shows the relative case incidence of yellow fever among vaccinated and unvaccinated in various epidemics during the course of the past six years. There are two groups, those who contracted yellow fever before sufficient time had elapsed after vaccination for immunity to develop (a period of ten to fifteen days being required), and those taken ill later than this period. Although many cases have occurred during the pre-immunity period, only rarely has a vaccinated person contracted yellow fever later, notwithstanding the high case-incidence among unvaccinated during the same period. The pre-immunity cases may be regarded as controls, and the occurrence of yellow fever among them as showing that vaccinated persons were exposed to yellow fever equally with non-vaccinated, while the abrupt drop in incidence among vaccinated after the fifteen-day period, notwithstanding continued occurrence of cases among unvaccinated, indicates that the vaccination confers protection against infection. The protection induced by vaccination lasts about five to six months.

The presence of immune substances in the serum of persons who have recovered from yellow fever, as shown by the Pfeiffer reaction, is not so permanent as the immunity of the body as a whole. Persons who have had yellow fever years ago remain immune, though their serum may not give a positive Pfeiffer reaction, hence the immunity induced by natural infection must be due to at least two factors, one humoral, more transient, the other histogenous and lasting. Only the former is transferable to non-immune persons, and the serum of yellow fever convalescents is useful for treatment in proportion to the amount of immune substance present [20], [39].

It is possible, however, to produce immune substances artificially in enormous quantity in the serum of certain naturally less susceptible animals by

* These figures include only persons vaccinated while in an endemic or epidemic area, or about to enter such an area, that is, persons who were subject to exposure to yellow fever after vaccination.

† The cases recorded in this column were in persons who were already in the epidemic area when vaccinated, and who contracted yellow fever before there had been sufficient time (ten to fifteen days) for the development of immunity.

‡ The vaccine employed during these preliminary experiments in Ecuador contained about 2,000,000 organisms per c.c., while that used on all subsequent occasions was a thousandfold stronger (2,000,000,000 organisms per c.c.).

§ The vaccinations were carried out in Quito on September 24, 1918, and the vaccinated troops arrived in the epidemic area (Guayaquil) on October 7.

‖ Received 1 c.c. only.

¶ The supply of vaccine being almost exhausted, the remainder was diluted. In this instance only 1 c.c. of the diluted vaccine was injected.

** Incomplete vaccination (1 injection only). In two of these cases the diagnosis was doubtful.

†† This is the only case recorded in which yellow fever occurred notwithstanding two injections of vaccine and a lapse of time ample for development of immunity. The patient received anti-*icteroides* serum on the second and third days of illness and recovered.

‡‡ Incomplete vaccination (1 injection only).

repeated injections at regular intervals of living cultures of *L. icteroides*. During the past several years we have been able to prepare[1] in horses an immune serum such that a quantity as small as 0·0001 c.c. is capable of protecting a guinea-pig against 1,000 minimum killing doses of *L. icteroides*, when given simultaneously. Such potency is never found in the serum of yellow fever convalescents. Somewhat larger quantities of the serum save guinea-pigs already infected, when administered during the early period (the first three days) of illness. There was sufficient justification, therefore, for employing this immune serum in the treatment of yellow fever in man.

The first use of the anti-*icteroides* serum in human yellow fever was by Lyster, Pareja and Bailey in 1919, and favourable results were reported [47]. Treatment was continued by Lyster and his associates in the Central American countries and in Mexico, in British Honduras by Cran [48], and later in various localities. The results are summarized in Table III.

The statistics clearly indicate the efficacy of the serum when administered during the first three days

[1] This work has been conducted under my direction by Mr. Julius Klosterman.

* Received total of 20 c.c. in two days—"too small an amount to have any material effect" (Dr. Bailey).
† Patient subjected to forced journey during first two days of illness; disease extremely severe; patient exhausted, with severe nephritis, when admitted to hospital.
‡ Day of disease on which serum was given not recorded.

of illness, the mortality being 16 per cent. as against 50 to 100 per cent. during the same epidemic period among cases treated after three days or not treated with serum at all.

It is understood, of course, that serum treatment must be accompanied by reasonable symptomatic treatment. It is well known that undue physical exertion may bring about a fatal termination even in mild yellow fever, and that rest, proper nursing, and suitable diet (Carter recommends no food but plenty of water) are essential [49]. The effect of the serum is indicated, according to those who have used it, not only by the reduction in mortality but in the prompt alleviation of symptoms [6].

RELATION OF VACCINATION AND SERUM TREATMENT TO SANITARY REGULATIONS.

When specific prophylaxis and serum treatment for yellow fever were suggested, special emphasis was placed upon the fact that they were supplementary means of fighting the disease and would not supplant the method of elimination by mosquito control [51]. They were intended, the one to give non-immune persons temporary protection until the mosquito index is sufficiently reduced for safety, the other to give the patient the benefit of a curative serum without neglect of the usual symptomatic care [52].

Protection induced by the use of killed micro-organisms is, in general, not so durable or complete as that brought about by spontaneous infection or by modified live virus such as is used for small-pox vaccination. Moreover, the proof of effective cow-pox vaccination can always be seen in the local manifestations, and the presence or absence of protection against small-pox in a vaccinated person is readily determined by the outcome of subsequent vaccination. Hence a certificate of small-pox vaccination can very well be accepted in lieu of quarantine. In yellow fever[1] we have no parallel procedure to which we may resort in order to prove that all vaccinated individuals are protected. But since susceptible animals become resistant to the *icteroides* infection after inoculation of killed cultures, and since the blood serum of vaccinated persons acquires protective property against *L. icteroides*, as shown by tests in guinea-pigs, it is assumed that vaccinated persons are protected, and this assumption seems to be well borne out by the actual results obtained with yellow fever vaccine in several thousand human beings, as already described. Results analogous to those obtained in yellow fever, and also decidedly favourable, have been reported by Inada on the use of vaccine and serum against infectious jaundice in Japan [54].

The efficacy of vaccination against yellow fever has therefore been substantiated, as was that of antityphoid vaccination, and its use in combination with other prophylactic measures has been generally adopted. It may be said, as was said by Russell [53] in connection with antityphoid vaccination, "there is no occasion for conflict between the advocates of general and individual prophylaxis; one is as necessary as the other, and no one interested in the suppression of this disease can afford to ignore either."

SUMMARY.

The properties of *L. icteroides* are the same as those already demonstrated for the virus of yellow fever: it passes through bacterial filters; it is killed by a temperature of 50° C. maintained for five

[1] The basis for yellow fever vaccination is analogous to that for vaccination against typhoid fever, and the same general laws apply to both.

minutes; it is transmissible from man to animal and from animal to animal by means of infected female *A. ægypti* mosquitoes. *L. icteroides* is invisible under the ordinary microscope but visible by dark-ground illumination.

L. icteroides induces a symptom complex and pathological changes in suitable experimental animals (young guinea-pigs, puppies, and certain monkeys) which are identical with those of human yellow fever.

Yellow fever and infectious jaundice are distinct, independent infections. They are very similar in character.

L. icteroides is distinct, both morphologically and serologically, from *L. icterohæmorrhagiæ* of infectious jaundice and *L. hebdomadis* of seven-day fever.

The prophylactic value of the vaccine prepared with killed cultures of *L. icteroides* and the efficacy of the anti-*icteroides* immune serum prepared in horses were demonstrated in animal experiments and have been substantiated by the results of vaccination and serum treatment in human beings.

The evidences just summarized appear to warrant the conclusion that *L. icteroides* is the cause of yellow fever.

There is no reason for modification of any of the established measures of general prophylaxis or sanitary regulations now in force against yellow fever; specific prophylactic measures and serum treatment should be employed simultaneously with the anti-mosquito campaign and the proper symptomatic treatment of yellow fever.

BRITISH INDIANS AND BILHARZIA DISEASE.

By F. G. Cawston, M.D.Cantab.

In the *Indian Journal of Medical Research*, vol. vii, No. 1, July, 1919, Mr. Stanley Kemp and Dr. F. H. Gravely published a carefully written paper "On the Possible Spread of Schistosomiasis in India." The danger was accentuated by the return of troops harbouring *Schistosomum mansoni* and *S. hæmatobium*,

which infection they had acquired whilst on active service in Egypt. At that time little was known of the extent to which the problem of *S. japonicum* had reached in southern China, nor was this condition recognized as a possible menace to health on the north-eastern frontier of India; however, the various schistosomes, which Mr. R. E. Montgomery had described in his "Observations on Bilharziosis among Animals in India," in the *Journal of Tropical Veterinary Science*, 1916, vol. i, indicated that other than the common bilharzia parasites of man might possibly be found in India, and this danger was confirmed by Mr. B. B. Seymour Sewell's description of "Cercariæ Indicæ" in the *Indian Journal of Medical Research* for June, 1922. In the July number of this journal for 1921, Dr. M. B. Soparkar had published some "Notes on some Furcocercous Cercariæ from Bombay," but there was little or no evidence to prove that any of these cercariæ represented the larval stage of human parasitic worms.

In the course of a paper which appeared in the *Indian Journal of Medical Research* for 1920, entitled "Is Human Bilharziosis likely to spread to India?" Dr. M. B. Soparkar makes the interesting statement that "On the occasion of a recent visit to our laboratory, Major Christophers informed us that his patient had been to Africa, though this is not stated in his published account." This patient's urine contained spindle-shaped ova in addition to the usual terminal-spined ova of patients infested with *S. hæmatobium*, as reported by Dr. S. R. Christophers and Dr. J. W. W. Stephens in the *British Medical Journal* for 1905, vol. v, page 1289. Indians in Natal are very susceptible to invasion by the bilharzia parasites, and some of those who acquire the infection here make occasional visits to various parts of India, more particularly to Madras.

Undoubtedly *S. hæmatobium* is the commonest schistosome in these patients, and I have found it present in all cases that are suffering from bilharzia infection, even though they may also be harbouring *S. mansoni* or passing in their urine the spindle-shaped ova, which usually measure 0.24 mm. in length and have been regarded as the ova of *S. bovis*, which has been shown to occur in the pools from which the majority of these cases have acquired the infection.

Dr. Andrew Balfour has directed my attention to the report of Giulio Bertolini on "*Bilharzia crassa* and the lesions caused by it," which appeared in *La Clinica Veterinaria*, Part 1, 1908. The eggs of this parasite would appear to differ from those found by Sonsino in Egyptian cattle, and the lesions caused by this parasite are less severe than is common amongst cattle in Egypt. It occurs in 9 per cent. of Sardinian cattle.

The identity of the parasite which attacks human beings in Natal remains uncertain until an example of the adult worm is available; in fact, from the ova some of these cases have been suspected as being *S. spindalis* (Montgomery). The symptoms would appear to be slightly more severe than is common with *S. hæmatobium* infection alone, for these patients have submitted themselves for treatment during the first month or two after the hæmaturia was noted, which is relatively uncommon with other patients, many of whom suffer for years before deciding to undergo treatment. At the same time one Indian patient came to me for treatment with ten years' history of *S. hæmatobium* infection, and a schoolboy with infection due to *S. hæmatobium* AND *S. ? bovis* gave only about ten weeks' history of hæmaturia. Unlike the cattle condition, it is difficult or impossible to find the ova in the fæces or in rectal wash, even by the floatation method; though I have obtained the ovum from the rectum in one small native boy. Although the ova are less numerous than those of *S. hæmatobium*, they are readily detected in the centrifugalized urine, and are easily told from the common variety because of their length and narrower appearance. Some experiments which I made to secure the cercariæ from miracidia obtained from these spindle-shaped ova, using examples of *Physopsis africanus* (Krauss), proved negative.

Whilst on active service in 1916 I drew the attention of the military authorities in South Africa to the danger of *S. mansoni* infestation becoming endemic in South Africa, a danger which was aggravated by the fact that troops were returning from Egypt and many were remaining at Durban, where the intermediate hosts for both *S. hæmatobium* and *S. mansoni* were breeding in enormous numbers without any serious efforts being made to clean up the infected areas. In fact, I actually treated some troopers who claimed to have acquired bilharzia infection through bathing in the Umbilo river whilst encamped at Congella. At that time *S. mansoni* infestation was unknown in South Africa, except in native labourers who had been imported from Portuguese East Africa for work on the Johannesburg mines. The presence of this parasite, along with *S. hæmatobium* in some schoolboys that I was treating at Durban during the next few years, was not considered sufficient evidence of a recent introduction of the parasite to Natal, as it was felt that the parasite might have existed in Natal previously, or might occur sporadically in any infested district; but the fact that others besides myself have found the lateral-spined ovum in the urine of bilharzia patients only during the last year or so, and the fact that two such cases have occurred in a fortnight at Durban, indicates that there is a real danger of this parasite becoming a menace to the health of Natal, especially as these two cases were suffering from dysenteric symptoms which had not been noted in the other patients who harboured both varieties of the bilharzia worm. Meanwhile, the pools which I have shown to be infested with *S. hæmatobium*, *S. bovis*, *S. mansoni*, and enormous numbers of fresh-water snails infested with *Fasciola gigantica*—the very same pools from which I assisted Dr. Annie Porter to obtain the examples of *Limnæa natalensis* (Krauss), from which we both obtained the carcariæ which grew into the adult *F. gigantica* in 1919—remain a constant source of danger to Durban, because of the numbers of European children, Indians and natives who bathe and fish in them. Parasitic diseases of this kind are less easy to control amongst Indians

than amongst Europeans, and it might be useful for the Indian Government to make representations to the Union Government in order that suitable efforts may be made to safeguard the large number of Indian school children in Natal from the possible invasion of bilharzia parasites.

Studies of fusiform Bacilli and Spirochætes (Further Observations on the Distribution about the Genitalia of Normal Women and Their Significance in Certain Genital Infections and Tumors) (I. Pilot and A. E. Kanter, *Arch. Dermatology and Syphilology*, vol. 10, No. 5, November, 1924).—Fusiform bacilli as well as spirochætes are frequently present in the smegma secretion of a normal woman. They are usually absent in the cervix and vaginal tract. They play no rôle in the production of leukorrhœa, they are important infecting agents of the vulva, erosive and gangrenous, vulvitis, condylomatous, acuminate, necrotic fibroids and carcinoma of the uterus and vagina. Infection with these organisms is characterized by necrosis and foul odour. The presence of these organisms normally would indicate that many ulcerative processes about the genitalia are due to autogenous infection and are not necessarily the result of bacteria from other sources.

Precipitation and Complement-fixation Reactions with Residue Antigens in the Non-Hæmolytic Streptococcus Group (Charles H. Hitchcock, M.D., *Journal of Experimental Medicine*, November 1, 1924).—The applicability to the non-hæmolytic streptococci of the technique used for the extraction of a soluble precipitating substance from the hæmolytic streptococci is demonstrated. With this substance as antigen, it is demonstrated by means of precipitation and complement-fixation that the non-hæmolytic streptococci form an antigenically distinct, but entirely heterogeneous group. Such cross reactions as do occur within this group are not useful in the systematic classification of these organisms.

The Effect of Heat on Flagellar and Somatic Agglutination (Marion L. Orcutt, *Journal of Experimental Medicine*, November 1, 1924).—Heat at 70° C. destroys the form of the flagella and their ability to combine with flagellar agglutinins, but it does not destroy their antigenic nature, since they can still generate flagellar agglutinins in the animal body. Heat at 70° C. and even at 120° in the autoclave does not destroy the forms of bacilli themselves nor their ability to become agglutinated and to absorb agglutinins. Somatic agglutinins are destroyed to a considerable extent by heat at 70° C., and completely destroyed by heat at 75° C. Heat at 70° C. causes little or no destruction of flagellar agglutinins, but a temperature of 75° changes the agglutinins so that they react more slowly and produce a slightly lower reaction with a zone of inhibition in the stronger dilutions.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—**All literary communications** should be addressed **to the Editors.**

4.—**All business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings** per annum, may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these,** with remittance, **is given when MS. is sent in.** The price of reprints is as follows:—

		£	s.	d.
50	copies of four pages	0	16	6
100	,, ,, ...	1	3	3
200	,, ,, ...	1	6	6
50	copies beyond four up to eight pages	1	13	0
100	,, ,, ,,	2	6	0
200	,, ,, ,,	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

A WHITE AUSTRALIA: IS IT A POSSIBILITY?

By SYDNEY J. SKERTCHLEY, J.P.

(*Continued from page* 180.)

CHAPTER XIII.

Birth-rate in Australia.

IT may, and doubtless will be academically argued that to lower the death-rate, that is to make a land

healthier, must react upon the birth-rate by improving the physique. It seems so logical an inference that it appears to have been accepted as axiomatic. Yet it is not true. If it were we should invariably find that as the death-rate fell the birth-rate rose. But it does not. If it did, then in the United States and Australia the birth-rate should have steadily risen as scientific methods prevailed, but we have seen it has steadily fallen as life has been lengthened.

It may be painful to (some) scientific minds to have to admit total ignorance. But it must be done sometimes, and the laws which regulate reproduction are among the mysteries yet unsolved. At least, they are for me. I do not know why the pretty moth *Ciaaria sagittata*, only lives in a very limited area near Chatteris, Cambs., though its food-plant abounds everywhere in the surrounding Fens. I do not know why the swallow-tail butterfly in England cannot live except in certain limited areas of those same Fens and Broads, while on the Continent it roams over the gardens and feeds on carrot-tops; especially I do not know why in captivity it relishes and thrives on the said carrot-tops which it will not touch when at large in England while it thrives on them in France. I do not know why the Ammonites gave up the ghost at the close of Cretaceous times, while the *Nautilus* lives on. I do not know why *Lantana* and the Sensitive Plant have over-run Southern Asia, and while both swarm in Hong-Kong, only *Lantana* has made itself a pest in Australia. I cannot see why the *Ichthyosaurus* should have died out and the *Ceratodus* survived in Queensland. Forty years of thought and reading have left the question of distribution of species quite unanswered, in spite of much literature. And distribution depends on reproduction; no species can permanently colonize unless its natural increase overmasters the death-rate; neither can man.

So with this question of human natural increase; we can only say that neither climate, habit, nor hygiene, has more than a modifying influence. Something, one knows not what, lies deep at the root of the matter. It is this that kept the Roman Empire within ethnographic limits; it was this that prevented the Fair Whites holding all Europe when it was in their grasp; it is this that has brought about in the United States, and is bringing about in Australia, not merely individual decadence, but the decadence of the race as a whole. It is because no one, to my knowledge, has hitherto clearly grasped this, the greatest lesson of history, that folk are prone to argue about a Monroe doctrine, and a White Australia, not from the point of view of its possibility, but as a certainty whose details alone need expounding. Instead of asking How, they should begin with If.

I cannot sufficiently emphasize the healthiness of Australia. It shows itself in our diminishing death-rate. And it, above all, demonstrates it in the rate of infant mortality under one year. The details are shown in the table below showing the deaths per thousand.

These statistics prove that our rate of infant mortality has decreased from 103·61 per thousand to 81·06 since 1901, which is as low as that of Norway, and lower than any other European country. The rate for England and Wales is 132, for the German Empire 205. Well may Mr. Knibbs call this "a very enviable position." An Australian child has a better chance of getting over his critical first year than any other child on earth, and having done so has a greater chance of seeing old age. In 1907 no fewer than twenty-seven persons of 100 and upwards died in the Commonwealth; the doyen being a patriarch of 119 who had spent eighty-seven years in this country. Our land is healthy, our marriage-rate is the same as that of England, and yet our rate of natural increase has declined rapidly. This is the crude fact: if we but knew the cause we might suggest a remedy.

One of the causes of our poor natural increase I have shown to be the abnormal aggregation of our population in cities. I take it, but cannot yet prove it as true, that the birth-rate, or more strictly, the rate of natural increase, is greater in rural than urban districts. But unless this higher rate is of such magnitude as to more than counterbalance the urban deficit, the net result is merely to slow down the speed of decline; not to arrest it; still less to turn it into an advance. I am sorry to say that the material at my disposal compels me, very reluctantly, to think that our rural natural increase is a decreasing quantity.

State	1901	1902	1903	1904	1905	1906	1907
N. S. Wales	103·74	109·74	110·35	82·42	80·55	74·53	88·46
Victoria	102·94	108·60	106·40	77·92	83 30	92·92	72·60
Queensland	101·94	100·17	119·88	76·13	75·52	74·68	75·65
S. Australia	99·99	94·00	97·09	70·51	72·96	75·90	66·57
W. Australia	128·89	142·01	141·22	103·02	104·19	110·00	97·51
Tasmania	89·05	79·06	110·83	90·70	80·65	90·19	82·97
Commonwealth	103·61	107·15	111·36	81·77	81·76	83·26	81·06

I am driven to attempt to account for this sad fact in a manner which must give pain to many loyal Australians, and to suggest a remedy that will be repugnant to a large section of the community.

I am inclined to believe that some, perhaps, a considerable percentage of the comparative sterility, is due to the conditions in which the women, and to a lesser degree the young children, are placed in our rural districts, and especially in what we call the "back blocks." I have seen much of this life, and have been able to compare it with similar life in America, and I have no hesitation in saying the conditions are far harder here than there. This is true not only for the wives of the small farmer, the station hands, and general rouse-abouts, but for the middle class also, for the storekeeper's wife, and the wife of the professional man. It is sufficient to refer to what Australians think about Australian life "out back." Whether the writer's outlook be ultra-

democratic as in "The Children of the Bush," or aristocratic (if the author will pardon the adjective) as in "We of the Never-never," the same strain runs through them. It is no idyll, this woman's life at the back of beyond. It is strenuous, often grimly so; the woman works as hard as the man, often on a farm, at the self-same tasks, and this in addition to household and maternal duties. And she has no domestic help. Pride may not let us openly avow it, but this throwing of the heavy duties upon educated ladies makes the middle-class wife, and the labouring man's wife too, age prematurely; they have practically no leisure. It tells most upon the gently nurtured; the skilful fingers stiffen, the hands get spoilt, accomplishments are dropped one by one, and the care-worn soul drifts into indifference to the arts that make life truly civilized. This want of domestic help is a very real one. It is driving the American matron into the hotel and lodging house, and destroying the home life; it is doing as great an evil to the Australian without offering even such poor refuges as her American cousins flee to. Who that has lived where the black fellow remains, say, in North Queensland, has not seen the stolen picaninny "rescued" from its dusky parents, to be brought up to the blessings of civilization and "service"?

As I am writing in Australia, for Australians, I need not enlarge upon this rather painful subject. Indeed, I should barely have alluded to it, only I have found by experience that the life of the back blocks is unknown to many urban Australians, who are apt to treat the pathetically true stories of our authors as but tales to while away the time while the billy boils. I have many a time while among these winners of the wilderness, let my fancy roam back to the Shetlands, and the Hebrides (not of our south), where also the women work too hard—and compared them with those around me, and felt the lots of the latter were indeed hard, even though, knowing nought else, they never thought of repining or realized they were in very truth heroines. Life on the land is life indeed to the man—to the woman, the life giver, it is—what I have shown it to be.

Make the woman's lot easier; make it more womanly, and the birth-rate will be favourably influenced. There is but one way to do this, abhorrent as the means is to the Australian democratic idealist. Australia's future depends upon the possession of abundant and inexpensive labour. Her practice already stultifies her theory, for the small settler gets his labour without any wage at all; he depends upon his unpaid wife and little ones.

But, if I am asked whether even this will put Australia into a desirable condition of natural increase, I fear the answer cannot be given with that assurance which the more pronounced advocates of a White Australia take for granted. There is not the vaguest evidence that Australia possesses a single peculiarity that exempts it from the operation of the great though unexplained law which has so invariably pronounced the fiat, thus far shalt thou go and no further. From the earliest prehistoric times of which we have sufficient knowledge—many thousands of years—races have, by conquest and by immigration, striven to enlarge their borders. For awhile, for a few centuries, they succeed; they even, at first, increase and multiply at an abnormal rate, but sooner or later the law of the soil takes effect, partial and then total sterility ensue, and finally the autochthones come to their own again. Races do not fuse in the sense we once imagined they did. There are no permanent half-castes; and since the researches of Mendel we know the reason why.

Nor is it altogether the advantage in competition which the man of the soil has over the new-comer which determines the issue. Extermination of the native does not give the immigrant enhanced powers of increase. The redskin is rarer in the New England States of America than the blackskin is in the New England of the State of New South Wales. Yet, alas that it should be so, the blood of the Pilgrim Father and the Covenanter is as scarce in the land of his adoption as is the blood of the dusky brave whom he swept out of existence.

Annotations.

The Determination of Phenolsulphonephthalein in the Urine in Jaundice (H. A. Abramson, *Arch. Internal Medicine*, Nov., 1924).—The indiscriminate use of alcoholic zinc acetate or saturated barium hydroxid to remove bile pigments from urine containing phenolsulphonephthalein in jaundice may give erroneous readings, because of absorption of the dye. A relatively more accurate method using saturated barium hydroxid as precipitant is described, in which the loss of dye by absorption may be estimated.

Tryparsamide in the Treatment of Neurosyphilis (U. J. Wile and L. M. Wieder, *Jour. Amer. Med. Assoc.*, December 6, 1924).—Tryparsamide has shown itself, during a brief period of observation, of great service in causing a profound change for clinical betterment in a certain group of cerebrospinal syphilis cases, notably in some cases of general paralysis. The type of case found most favourably influenced has, singularly, been the type in which a considerable degree of deterioration had apparently occurred. The most striking clinical changes noted have been increase in weight, colour, and general appearance. In nine cases a marked improvement of the mental state of the patient has been found coincident with the improvement in the general appearance. In five cases, the treatment by tryparsamide was followed by clinical improvement when other forms of therapy, including intraspinal treatment, had failed. This clinical betterment is not paralleled in these cases by striking corresponding changes for the better in the spinal fluid. For this reason, it is possible that the improvement characterized by gain in weight and general appearance may be due partly to the effect of

the drug on syphilitic foci outside the nervous system, as well as to the tonic effect of the arsenic content of the drug. Gastric crises and the lightning pains of tabes dorsalis have, as yet, not yielded to tryparsamide treatment in this series.

Results Secured by Standard Methods of Treatment in Neurosyphilis. Review of 405 Cases (J. H. Stokes and L. W. Shaffer, *Jour. Amer. Med. Assoc.*, December 6, 1924).—In certain types of neurosyphilis the patient's prospect for clinical and serological recovery persisting for a period of years, with restoration to physical well-being and social efficiency, is good. Such results can be secured by the energetic and persistent application of methods of treatment and serologic control already familiar and available to well-equipped general practitioners as well as experts. The intravenous use of arsphenamin (not neoarsphenamin), the simultaneous administration of a soluble mercurial salt intramuscularly, and sodium iodide intravenously, with the use during rest periods of inunctions and, in resistant cases, of intraspinal Swift-Ellis treatment (Ogilvie modification) have been the mainstay of the various methods by which those results have been obtained.

Reinfection in Syphilis. Report of Thirteen Cases (J. Russell Driver, *Jour. Amer. Med. Assoc.*, November 29, 1924).—The thirteen cases of syphilitic reinfection reported satisfy quite closely the requirements laid down to constitute a true infection. A diagnosis was made in twelve of these cases, and treatment started at extremes of from three to twelve weeks, with a median of six and one-half weeks after exposure. Only one old syphilitic patient was treated. In his case, treatment was instituted seven years after infection. These patients, on an average, received from six to twenty-four injections, and from fifteen to fifty mercuric salicylate injections, with a median of twenty-five injections, in order to render them bacteriologically free from spirochætes and in a position to get a new syphilitic infection. No hard and fast rule is laid down as to the amount of treatment necessary to cure a case of syphilis. Each case is one unto itself, but in this series of early-diagnosed syphilitic cases, the foregoing treatment was apparently sufficient. The period of time that intervened between the first and second infection varied from one month to 120 months, with a median of fifteen months. It is believed that this indicates that the first syphilitic infection confers no immunity on its host for any period afterwards. As soon as he is free from the first infection he is open to another one if exposed. From reports of others and this series, it is evident that the curability of syphilis is definitely possible, provided: (*a*) an early diagnosis can be made by the dark-field, and (*b*) early, vigorous treatment can be instituted with arsphenamin and mercury injections. With modern therapy, syphilitic reinfection is probably more frequent than is suspected, and if more patients with syphilis could be closely followed over a period of years, such would be found to be the case.

Report of an Epidemic of Paratyphoid Fever in Patrons of a Cafeteria (E. M. Wade and Orianna McDaniel, *Jour. Amer. Med. Assoc.*, November 1, 1924).—Of 106 cases of paratyphoid fever occurring largely among university students (University of Minnesota) 103 were patrons and employees of a cafeteria. The three remaining cases were in university students who stated that they had not eaten at the cafeteria and had not come in contact with known cases. Four cafeteria employees, of whom two had no symptoms and two were but mildly ill, were found to be carrying paratyphoid bacilli. Evidence was presented indicating probable infection of still other cafeteria patrons and employees. Evidence pointed to pasteurized milk, sold in bulk, as the vehicle of infection, the probability being that the milk was infected after delivery to the cafeteria. The impossibility of fixing on any one individual among the food handlers as "the carrier" responsible for infecting the milk was brought out. Evidence was presented indicating a probable increased prevalence of paratyphoid fever in Minneapolis, synchronous with this outbreak but not directly related to it. Bacteriologic investigation of a small number of rodents and rodent viruses failed to indicate that rodent viruses are a factor in the occurrence of paratyphoid fever.

Incidence of Spirochæta Pallida *in Cerebrospinal Fluid During Early Stage of Syphilis* (A. M. Chesney and J. E. Kemp, *Jour. Amer. Med. Assoc.*, November 29, 1924).—Virulent strains of *S. pallida* have been recovered by rabbit inoculation from the spinal fluids of patients with early syphilis in approximately 15 per cent. of cases when the fluids themselves were normal according to the routine laboratory tests. This is in substantial agreement with the results of other workers who have used the same method.

Syphilitic Aortic Insufficiency (R. W. Scott, *Arch. Internal Medicine*, November, 1924).—A series of twenty-five patients with syphilitic aortic insufficiency was observed clinically, and the diagnosis confirmed by post-mortem examination in every instance. The anatomic changes found in all cases were: (1) syphilitic mesaortitis with extension of the process to the aortic area causing insufficiency at the orifice, and (2) hypertrophy and some degree of dilatation of the heart, chiefly of the left ventricle. One case in four had some grains of coronary occlusion. It was suggested that the progressive widening of the aortic orifice, either from leaflet involvement or ring dilatation, and occlusion of the coronary arteries are the chief factors responsible for the relatively short duration and uninterrupted progression of the heart failure observed in these

patients. The histologic changes in the heart muscle were similar to those frequently seen in hypertrophied hearts from other causes. To attribute these changes to latent myocardial syphilis seems unwarranted by the evidence afforded by this series of cases.

Relations Between Gastric Achylia and Simple and Pernicious Anæmia (K. Faber and H. C. Gram, *Arch. Internal Medicine*, November, 1924).—Gastric achylia is usually found in pernicious anæmia. It is sometimes missing and four such cases are described. In four cases, the histories and examination of which are given, gastric achylia and normal hæmoglobin were demonstrated as long as twelve years before the onset of pernicious anæmia. The results of hæmatologic examination in ninety cases of gastric achylia are described. It is shown that hæmoglobin below normal is present in 41 per cent. of these cases, or in 36·5 per cent. of the sixty-three uncomplicated achylia cases. This anæmia is of the type of simple anæmia and may resemble a chlorosis. It differs from chlorosis by its presence in both sexes and all ages and by its tendency to recur.

Diabetes Mellitus. A Contribution to its Epidemiology Based Chiefly on Mortality Statistics (H. Emerson and Louise D. Larimore, *Arch. Internal Medicine*, November, 1924).—The increase in the incidence and death-rate from diabetes in the United States, and in New York City in particular, has been more rapid than that of any other disease for which we have records in the last fifty years. This increase, while it has affected all ages to some degree, has been most marked among women at all ages and among both men and women over 35 years of age in particular. There are wide variations in the susceptibility to diabetes, or at least to their ability to survive when it develops in them, among persons of different races, those of Semitic stock showing consistently the highest death-rates and those of the Negro race in the United States the lowest. It is not at all clear that these marked differences in the death-rates from diabetes in the people of various races are of fundamental biologic significance, since many elements of occupation, economic status, dietetic habits, &c., may be found sufficient to explain the range of experience with what may fairly be considered a disease of a fatigued function in the great majority of cases. The changes in food habits in the United States have probably contributed to the increase of diabetes, the higher carbohydrate element and greater abundance of superalimentation being believed to be a cause of overfatiguing the function of sugar tolerance.

Two Cases of Melioidosis (A. T. Stanton, W. Fletcher and K. Kanagareyer, *Journal of Hygiene*, December, 1924).—Two cases of fatal melioidosis are described. The first a robust Indian labourer; the second a well-nourished, muscular European. In the first case there were no signs of the disease at first, except enlarged spleen; later, there were signs of consolidation at the bases of both lungs. Constipated at first; diarrhœa came on towards the end, and the patient collapsed and died at the end of the third week. In the second case the illness commenced gradually with pain after food, occasional vomiting and looseness of the bowels. The temperature became high and of the swinging type, accompanied by rigors and sweats. The liver was enlarged. The patient died on the twenty-fifth day. Inoculations were carried out on various animals.

Experimental Production of Pneumococcus Pneumonia in Mice by the Inhalation Method (E. G. Stillman and A. Branch, *Jour. Exper. Med.*, December 1, 1924).—Non-immune mice which are alcoholized and die of septicæmia following exposure to a spray of virulent pneumococci rarely show any localization of infection in the lung. Mice which have been partially immunized by previous inhalations of living or killed pneumococci, and which while alcoholized are exposed to an atmosphere of virulent pneumococci often develop a pneumococcus lobar pneumonia. Mice which have been rendered relatively immune to one type of pneumococcus may frequently develop lobar pneumonia after the inhalation of pneumococci of another type.

The Occurrence of Gastric Lesions in Rats. Their Relation to Dietary Deficiency and Hair Ingestion (A. M. Pappenheimer and L. D. Larimore, *Jour. Exper. Med.*, December 1, 1924).—Ulcerative lesions of the rumen with papillary epithelial hyperplasia occur in a large proportion of rats maintained on a deficient diet, and are rarely, if ever, present when the diet is complete. It has not been possible to ascribe the lesions to lack of any of the known dietary components. The facts that rats on improper diets tend to eat hair, that hair fragments have been found in a number of instances embedded in the ulcers, and surrounded by a definite inflammatory reaction, and finally, that the ulcers have been experimentally produced in rats on a *complete* diet, when chopped hair was added to the food, lead the authors to believe that the ingested hair is an important factor in the causation of the lesions. Whether the hair splinters act merely as mechanical irritants, or as the carriers of an infective agent, has not been determined. It is probable, moreover, that the deficient diets in some way, as yet not understood, intensify the injury caused by the hair. However produced, the lesions are so frequently found that they should be taken into account in experimental work on rats, especially in judging of the effects of dietary influences by the weight curves. That the presence of severe ulcerative lesions in the prostomach must unfavourably affect the general nutrition of an experimental animal, seems beyond question.

Tissue Resistance and the Cause of Permanent Acquired Immunity (S. Nukada and T. Matsuzaki, *Jour. Exper. Med.*, Nov 1, 1924).—The resistance against toxic products of typhoid bacilli of the heart tissues of typhoid-immune animals is greater than that of non-immunized animals. The acquired increase of resisting power is specific. The increased resistance is not caused by antitoxin, but by a specific biological alteration of tissue-cells. It is maintained that permanent acquired immunity, at least in typhoid, instead of being due principally to antibodies, is caused by a lasting specific increase of resisting power acquired by the tissue-cells against the toxic products of bacteria. This theory seems to hold good with other infectious diseases in which one attack conveys permanent immunity.

The Reaction of Pathogenic Fungi to Ultra-Violet Light and the Rôle played by Pigment in this Reaction (A. Pena Chavarria and J. H. Clark, *Amer. Jour. Hygiene*, November, 1924).—X-rays, up to ten skin doses, have a slightly stimulating action on pathogenic fungi of the skin. Visible and near ultra-violet light together are stimulating in moderate doses, but have a slight inhibitory effect in heavy doses on non-pigmented fungi. Non-pigmented fungi may be sensitized by eosin, and probably by other well-known sensitizing dyes, so that they are readily killed by visible light. This reaction takes place *in vivo* as well as *in vitro*, so that it may be of clinical importance. For ultra-violet light has a strong lethal action on non-pigmented fungi. When a fungus, such as *Montoyela*, develops pigment under ultra-violet light a very long exposure is necessary to produce lethal action. Sun-lethal doses in this, and presumably in all species, result in stimulation, provided the doses are short enough. Therefore it is suggested that the function of pigment in fungi, and in the human skin as well, is to regulate the energy absorbed by the underlying cells so that they receive only a sublethal stimulating dose. Pigmentation is therefore a defensive mechanism which favours stimulation and prevents lethal action.

On the Occurrence of Cell-Inclusions in the Rabbit Cornea After Inoculation with the Vesicular Contents and Naso-Pharyngeal Secretion of Varicella Cases (C. E. Simon and J. M. Scott, *Amer. Jour. Hygiene*, November, 1924).—Inasmuch as Bertarelli bodies and Swellengrebel bodies may be encountered in the normal, non-inoculated and non-scarified rabbit cornea, neither can be regarded as specific of varicella, and neither can hence be utilized as a criterion of infection with the hypothetical virus of that disease. The bodies in question are evidently not inclusions of the first order in the sense of the chlamydozoal doctrine. The absence in the varicellated cornea of cell inclusions, corresponding to the zoster bodies of Lipschutz, might on first consideration be viewed as arguing against a supposed causative connection between herpes zoster and varicella, were it not for the fact that Lipschutz could only exceptionally obtain a reaction on the part of the rabbit cornea to inoculation with vesicular fluid from zoster cases. The authors are of the opinion that so far as the development of inclusion bodies is concerned, the rabbit cornea is not a suitable test object in searching for the causative agent of varicella.

The Chemotherapy of Sulpharsphenamin. Toxicity and Trypanocidal Efficiency (G. W. Raiziss, M. Severac and J. Moetsch, *Jour. Amer. Assoc.*, November 29, 1924).—Whether the drugs studied in this paper are evaluated on the basis of the absolute weight of their respective minimum effective dose or on that of their arsenic content, it is found that much more sulpharsphenamin (or the corresponding French product, sulfarsenol) is required to sterilize animals infected with *Trypanosoma equiperdum*, than arsphenamin or neoarsphenamin. In the same series of experiments, it required about 18 mg. of sulpharsphenamin per kilogram to produce the results obtained with, approximately, 4 mg. of arsphenamin or 6 mg. of neo-arsphenamin. Taking the chemotherapeutic $\frac{\text{Maximum tolerated dose}}{\text{Minimum effective dose}}$ index, as the criterion of therapeutic efficiency, sulpharsphenamin based on trypanocidal tests is considerably inferior to arsphenamin, and at most one half as efficient as neo-arsphenamin. The trypanocidal efficiency of sulpharsphenamin is practically the same, whether administered intramuscularly or intravenously.

Studies Based on a Malignant Tumour of the Rabbit. VI. Variations in Growth and Malignancy of Transplanted Tumours. Part I. Results of Transplantation for the First Twenty Generations (H. Wade Brown, Louis Pearce, and Chester M. Van Allen, *Journal of Experimental Medicine*, November 1, 1924).—The results of transplantation, as recorded in the first section of the paper, are analysed from the standpoint of the influence of the factors of serial passage, the material used for inoculation, the age and breed of the animals, and the time or season at which the experiments were carried out. The material used for the inoculation of different groups of animals appeared to have comparatively little effect on the ultimate results. The character of the animals used was found to be a factor of more importance in that the tumour displayed definite peculiarities of growth and malignancy referable to age and to breed or colour markings. Still it seemed unlikely that any of these factors would account for the variations in growth and malignancy that had been observed. After considering the various possibilities presented, it appeared that the principal factors concerned in determining the results of transplantation were adaptation to passage and variations in the conditions of season and weather that prevailed during the time the experiments were being carried out, the one affecting the energy of cell growth and the other affecting animal economy.

THE IMMUNOLOGICAL RELATIONSHIPS OF THE LEPTOSPIRA GROUP OF SPIROCHÆTES.[1]

By TELÉMACO BATTISTINI, M.D.

(From the Laboratories of the Rockefeller Institute for Medical Research, New York.)

NOGUCHI, in his study of the immunological relation between *Leptospira icteroides*, of yellow fever, and *L. ictero-hæmorrhagiæ*, of infectious jaundice [1], carried out agglutination, complement-fixation, and Pfeiffer reactions with the sera of experimentally-infected animals and demonstrated that these organisms are serologically distinct. Tests of the protective properties of monovalent, as well as polyvalent, anti-*icteroides* and anti-*ictero-hæmorrhagiæ* immune sera always showed the immunological identity of each of the two species. The results of parallel Pfeiffer tests of the sera of convalescents from yellow fever against *L. icteroides* and *L. ictero-hæmorrhagiæ* have shown a specific immunological reaction of such sera to *L. icteroides* but none to *L. ictero-hæmorrhagiæ* [2] Pérez Grovas [3], in Vera Cruz and others in later epidemics [2, 4, 5] confirmed Noguchi's results.

Noguchi has recently studied the serological relationship between the different species of leishmania [6] and found that the type of growth obtained on culture media into which monovalent immune sera had been incorporated furnished a simple and precise method of differentiation of species. This procedure, which is similar to that used by Oba [7] in testing the effect of immune sera *in vitro* upon *L. ictero-hæmorrhagiæ*, has been applied to the study of the three types of *Leptospira* now recognized, *L. icteroides*, *L. ictero-hæmorrhagiæ*, and *L. hebdomadis*[2] (seven-day fever), with the results here reported.

[1] Work done under the auspices of the International Health Board of the Rockefeller Foundation.

[2] The culture of *L. hebdomadis* Strain B was obtained through the kindness of Professor Inada.

TECHNIQUE.

Monovalent sera specific for *L. icteroides*, *L. ictero-hæmorrhagiæ*, and *L. hebdomadis* were prepared in rabbits by intravenous injections at intervals of five to six days, of gradually increasing doses (0·5, 0·1, 1·5, 2·0, and 2·0 c.c.) of actively growing cultures two to three weeks old. The animals were bled by heart puncture eight days after the last injection. The sera were kept in the ice-box until the time of use, no preservatives being used.

The sera were mixed with the culture medium[1] in concentrations of 1:20 and 1:100, and the sera-containing media were distributed into small test-tubes in quantities of 2 c.c. The two dilutions of a given monovalent serum were tested against each of the three types of *Leptospira*, a capillary drop of a young, actively growing culture being inoculated in each instance. The tubes were incubated at 26°C., and examinations were made by dark-field microscope at intervals of 48, 72, 96, and 120 hours after inoculation.

\+ = Active growth, as usual.
− = Marked agglutination and degeneration followed by death of the organisms within 120 hours.

TABLE.

As the table shows, the three monovalent anti-*icteroides* sera tested against five strains of *L. icteroides* produced on the first day marked agglutination and degeneration, followed within four to five days by complete fragmentation of the organisms. On the other hand, these sera had no effect upon the three strains of *L. ictero-hæmorrhagiæ* nor upon the strains of *L. hebdomadis*, all of which grew luxuriantly in the media containing the anti-*icteroides* sera. Conversely, the anti-*ictero-hæmorrhagiæ* serum, while producing agglutination, degeneration and final destruction of all the strains of *L. ictero-hæmorrhagiæ* within three to four days, had no influence upon the growth of *L. icteroides* or *L. hebdomadis*. The anti-*hebdomadis* serum had a similar agglutinating and degenerating effect upon

[1] The formula for Noguchi's *Leptospira* medium is as follows:—

NaCl, 0·9 per cent.	800 parts
2 per cent. nutrient agar, pH 7·4	100 ,,
Rabbit serum	100 ,,
Rabbit hæmoglobin	10-20 ,,

The hæmoglobin solution is prepared by taking 1 part of rabbit blood with 3 parts of distilled water.

the *hebdomadis* strain, but none at all upon the strains of *L. icteroides* and *L. ictero-hæmorrhagiæ*.

SUMMARY.

The immunological properties of the three known species of *Leptospira* have been studied by cultivating the organisms on media containing monovalent homologous and heterologous immune sera. This method of studying the effect of immune sera permits continuous observation over as long a period as desired and thus diminishes the possibility of misinterpretation resulting from gross observations or a single microscopic examination. It also reduces the chance of possible error due to changes which may occur on standing in mixtures of culture with serum alone.

The results obtained constitute additional evidence of the serological distinctions existing among the three species of *Leptospira*, *L. icteroides*, *L. ictero-hæmorrhagiæ* and *L. hebdomadis*.

TROPICAL OTO-LARYNGOLOGY WITH SPECIAL REFERENCE TO THE PHILIPPINE ISLANDS.[1]

By ANTONIO S. FERNANDO, M.D.,
AND
FELISA NICHOLAS-FERNANDO, M.D.,
Manila.

THE influence of tropical climate on the causation of disease, the social characteristics of the people, their customs and habits, the influence of heredity, lack of sanitation and many other factors which are not yet fully understood have united together to stamp medical practice in the tropics with peculiar characteristics. The consideration of these factors has resulted in the study of the so-called tropical medicine. In surgery, although the general principles of pathology, therapeutics and operative technique are applicable everywhere, McDill, in his book, entitled "Tropical Surgery and Diseases of the Far East," very well says when referring to the practice in these islands: "The diagnosis and treatment, at their best, require not only a far greater application and correlation of laboratory findings and bedside observations than in our climes, but all of the general and physical conditions of these people must be appreciated and taken into consideration just as well." He continues: "The fish and vegetable diet, non-indulgence in alcohol and the placid existence led by the majority of the natives are to their advantage. They take anæsthetics quietly and react favourably after severe operations."

Another branch of medicine which in the tropics acquires distinct peculiarities is ophthalmology. Elliot, in his great work on "Tropical Ophthalmology," shows how the tropical climate with the almost suffocating heat of the dry season, the heated winds overladen with dust, and the glare of the tropical sun, have a direct influence in the causation of eye diseases. Thus he describes what he terms glare asthenopia and glare conjunctivitis as that group of troublesome symptoms not infrequently found in patients who have for a long period been exposed to the tropical glare. This is but one of the many instances he described in his book. Other factors he mentions as influencing the high incidence of eye diseases in the tropics are the habits and customs of the people with their unqualified practitioners and their primitive and often dangerous methods of treatment and their distrust of the Western methods, and the prevalence of such general diseases as malaria, dysentery, beriberi and others which have eye manifestations. On the whole, the value of that book on tropical ophthalmology lies in the fact that in it the author gives the vast experience (slow-won and often painful, he says) he acquired in India, in a clear, systematic and scientific way. In it he has incorporated also such useful knowledge gathered from the vast and disordered heaps of publications of tropical investigators, abstracted, classified and commented.

Just as all these factors present in the tropics influence the practice of medicine, surgery and ophthalmology, so they do influence oto-laryngology. While reading McDill's "Tropical Surgery," we came across this statement, referring to the practice in the Philippines: "Nothing unusual was noted in the diseases of the eye, ear, nose and throat." (The author was formerly the head of the Department of Surgery of the Philippine General Hospital.) Our observations, however, differ from his. In the literature we find much that has been written about certain ear, nose and throat lesions, especially in connection with such general diseases as entail an involvement of these organs. However, much of these do not go beyond a mere mention of the lesions without such detailed description of them as would be enough to satisfy the need of those that have limited their practice to this speciality. Those writers are not to be blamed for this, inasmuch as the majority are general practitioners whose chief interest is in the general manifestation of the disease. Those who, therefore, practise oto-laryngology in the tropics are the ones called on to develop

[1] Read before the joint annual meeting of the Philippine Islands Medical Association and the Manila Medical Society, December 19, 1924.

this branch of medicine to meet the need which is making itself felt. Their co-operation with the general practitioners will then be of great value, and real scientific work can be accomplished. Medical progress demands the development of this subject, but it will probably take another master mind like that of Elliot to blaze the trail for us in this new and fascinating field of medicine—tropical oto-laryngology

The science of oto-laryngology itself is of recent birth. In Europe and in America, however, it has had such rapid and tremendous progress in spite of its young age, because eminent investigators have entered the field and applied the latest methods of investigation adopted by modern medicine. Otologists, for instance, have invaded even the realm of brain surgery in the study of internal ear diseases; rhinologists, that of the base of the skull to find the easiest way of reaching tumours of the hypophysis; the laryngologists have invented delicate and wonderful instruments and apparatus for the removal of tumour and foreign body in the œsophagus and bronchus. The valuable help of the X-ray has often been resorted to in the correlation of pathological lesions with their clinical manifestations.

Conditions in the tropics, however, are in many respects different. One who has studied and practised abroad and accustomed to such highly scientific atmosphere, on coming here will encounter different problems. He will see the field almost unexplored, and will notice that other influences are at work which make the practice here different from that of his colleague in the West. Elliot very well says that " the surgeon who has become accustomed to the nature of his surroundings in a tropical country learns to accept as a matter of his every-day life things which arrest the attention of visitors from more civilized parts of the world. He is awakened to the privileges of his position by the extraordinary interest such travellers take in what to him have become the routine happenings of an exiled existence." Indeed, when one of the famous oto-laryngologists of America has visited us, his curiosity and interest in tropical ear, nose and throat diseases have made us realize the probable importance of some of our observations of the cases we meet here.

In our present work we, therefore, have attempted to present as best we could what little we have acquired and gained in the way of personal experience in the Philippine General Hospital during the brief period of six years. Most of our observations have been made in the free dispensary or out-patient service of the hospital, where a vast amount of material is available for research work, but a great deal of which, we are sorry to say, is only pitifully wasted. The patients that flock to the dispensary for treatment come from practically all parts of the islands, although the great majority are from Manila and the neighbouring provinces. The average yearly attendance in the department of eye, ear, nose and throat of the free dispensary is about 9,000; of these, about 6,000 are ear, nose and throat cases. In a survey of dispensary cases published by the senior author of this paper in the *Journal of the Philippine Islands Medical Association*, vol. ii, No. 3, 1922, and from a table of diseases of the last six years which we include in this report, we can obtain an idea of the most common diseases found here and their relative frequency, the low incidence of some and the prevalence of others. To what can we ascribe, for instance, the high incidence of acute rhinitis and tonsillitis which come with almost unfailing regularity during certain parts of the year, the so many cases of middle-ear suppuration, especially among children of the poorer class, the large number of furunculosis of the ear, the relative frequency of atrophic rhinitis in young girls and women who lead a sedentary life, and the comparatively few cases of septal deviations? To answer these and many other questions we have to turn our attention to the probable influence which our climate, the education, social condition, habits and customs of the people, and certain anatomical peculiarities may exert. We will now attempt to discuss briefly each of these conditions.

The Climate.

In the study of Philippine climate, certain geographical features must be considered, for these are mainly responsible for the variation in the temperature, and the amount and distribution of rainfall. These are the comparatively great extent of the archipelago from north to south, the numerous islands which compose it, and the fact that the mountains usually traverse the larger islands in a north to south direction. Regarding the temperature, it may be stated in a general way that the range increases with latitude and altitude, the increase being proportionately greater with regard to the latter. At Davao, the annual range is about 4° F., at Manila about 6° F., and in Batan Islands 12° F. Those places at sea level have about the same average mean temperature. In Manila, for instance, it is 80° F. The highest record in this city being 100·9° F. At Baguio, however, having an elevation of about 4,970 ft., the average mean is 64·6° F., the lowest record being 37·4° F. The usual average temperature in Manila for the month of May is 83°F., and for the month of January 77° F.

As regards rainfall, the variation in regions east and west of mountain ranges is very great, although the intervening distance is sometimes only a few kilometres. Distance from a mountain mass, together with the direction of winds also greatly influence rainfall. There are three seasons of rainfall in the Philippines.

(*a*) The typhoon season—from June through October, also known as " rainy season " on account of heavy rainfall. South-westerly winds are frequent, as also thunderstorms.

(*b*) North-east monsoon season—from November through February, the winds from north, north-east, or east, and heavily laden with moisture. Because of the mountain range, the moisture is usually deposited upon eastern shores of the Philippines.

and thus the regions facing China Sea have at this time " dry season."

(c) Thunderstorm season—comprising March, April and May. Rainfall is very irregular.

Because of the different amount of rainfall received by different localities in the Philippines during these three seasons, the archipelago may be divided into three regions of rainfall.

(1) Regions of defined wet and dry season. Rainfall occurring during the typhoon season. These regions have five rainy months and seven dry months. Manila is included in this region.

(2) Regions of long rainy and short dry season.

(3) Regions of continuous rainfall, i.e., with fairly even distribution of rainfall over the entire year.

Now, in the discharge of their respiratory functions the nasal passages are constantly exposed to these ever-changing atmospheric conditions of heat and cold, dryness and moisture. The excessive heat during the months of March, April and May in Manila, and the rather abrupt changes of temperature during the transition of one season to another as caused, for instance, by increased humidity of the air after unexpected rain, producing sudden chilling of the body, have greatly been responsible for the high incidence of acute inflammation of the upper respiratory passages during those months and towards the end of October and in November. It has been found that " cold " may be induced also by prolonged exposure to sun's rays.

The table given at the end of this paper does not show as it should the many cases of acute rhinitis, simply because people do not usually seek treatment for this condition unless there is complication in throat, ear or Eustachian tubes giving pain or much discomfort. If to the dry and heated winds of the dry season is added the effects of dusts, one can easily understand how much the mucosa of the nose and throat suffers. To have an idea of how much discomfort this means he has but to motor to the provinces during the hot days and judge for himself.

However, certain chronic catarrh of the upper respiratory passages which do not respond to medicinal treatment are favourably influenced by climate. In view of this, it is necessary that oto-larvngologists should study the climate in their locality and in the different popular health resorts in these islands. All catarrhal diseases of the upper respiratory passages are favourably influenced by an atmosphere free from dust. We have seen a few cases of chronic rhinitis which could not be improved with local treatment, recovering after a couple of months stay in Baguio.

Education, Social Condition of the People, Quackery.

The Filipinos have been described by McDill in the following words: " The natives of the Philippine archipelago belong to the Malay race, and while there are very few pure Malays among the leaders, the stock has been improved by the admixture of other blood, especially that of Chinese. They are the most enlightened and vigorous branch of the Malays, have been Christians for centuries and are nearest akin to Europeans in thought and aspirations of any alien race."

The majority of the patients coming to the dispensary, and on whom the main observations here have been made, are however of those who are still influenced by quackery or primitive methods of treatment. Many of them seek treatment only after the " herbolarios " or their household remedies have failed to give relief, and when, as it usually happens, more harm than good has been done. The common practice, for example, of removing a fish bone from the throat with the fingers without giving these even a preliminary wash, or by means of the dirty methods of the " suhi," is not devoid of serious consequences at times. This kind of foreign body in the throat is of common occurrence here because fish is a staple food. (The " suhi," by the way, is a person who was born with breech presentation and is supposed by many ignorant people to possess miraculous power of removing fish bone from the throat. He does this by massaging the neck of the patient and then making him (the patient) gargle water which has been in his own mouth). A case came to us of an old woman who after traumatizing her throat with futile efforts to remove with her fingers a fish bone stuck in the pharyngeal wall, went to a "suhi" who prescribed the miraculous gargle. When she was admitted to the hospital she had severe dysphagia and also dyspnœa due to the presence of a large retropharyngeal abscess. We had a case of an abscess at the vallecula consequent to attempts at removing with dirty fingers a sugar-cane fibre which had stuck there. In another case, the epiglottis was acutely inflamed and infected due to similar procedure. Obscure painful affections in the throat are sometimes treated by the so-called " bantil."

The apparent neglect of some of their ailments and sometimes the distrust of the ignorant in modern methods of treatment are responsible for many very chronic and very advanced conditions of the disease met with. Especially is this so in cases of new growths of the larynx and pharynx, the disease is seen at a stage when any operative interference is no longer of value. We have met with huge-sized nasal polyps causing marked disfigurement, very advanced cases of atrophic rhinitis, and large mastoid abscesses.

However, there are certain household remedies employed for some of these diseases. Thus, for tonsillitis, commonly known to the laity as " sampaga," the infusion of certain leaves is used for gargle.

The heated juice of " suro-suro " instilled into the ear canal is said to give relief in cases of acute pain in the ear as in furunculosis. Ringing in the ear is usually treated by inserting a piece of garlic in the canal. A more extensive communication on this subject will probably be published later.

Influence of Certain Habits and Customs.

The habit of chewing buyo has long definitely been known to be responsible for some cases of

carcinoma of the mouth. The new growth, although starting from the cheek or gum, may involve the tonsils and pharyngeal mucosa. Certain ignorant people have the habit of going to the Chinese barber shop to have the ear cleansed of wax. Here, the Chinese, with a bundle of variedly-shaped sticks and brushes, patiently digs up and removes the wax. The most astounding feature of this procedure is that the Chinese ear cleaner has but one set of instruments for all his clients and sterilization is unknown. The trauma that may be inflicted, plus the dirt, will naturally cause disease. The origin of many cases of furunculosis, otitis externa diffusa, and papillomatous growth formation in the canal has been easily traced to this dirty procedure. Those who cannot afford to pay the Chinese use miscellaneous things—tooth-pick, hair-pin or small bamboo stick. The custom of perforating the ear lobule of female infants by the ignorant midwives for the earring is not infrequently followed by infection of the wound.

Influence of Certain Anatomical Characteristics.

The Filipinos, as a whole, have a small nose with low bridge, the vestibule, more or less, rounded and the septum low. This explains the fewer cases of fracture and deviation of the septum causing annoying symptoms. Our records of operation in the hospital show very few of submucous resection of the septum. Again, the face of the Filipinos is usually broad, the hard palate not so highly arched, and the nose not so narrow as the Caucasian. This is also probably why we see so very few cases of classical adenoid fascies.

Parasites in the Ear, Nose and Throat.

No cases of animal parasites in the ear, nose and throat have been seen, but several cases of otomycosis have been observed. This is usually manifested by itchy sensation in the ear, slight deafness and presence of whitish macerated masses in the canal. This condition, when secondarily infected, gives rise to more severe symptoms. So far, we have failed to observe parasitic disease of the maxillary antrum or tonsil.

Ascariasis is prevalent here and it is not uncommon to see the worm coming out through the nose in children.

Rhino-sporidiosis and rhino-scleroma have not been observed. About four years ago, one of us, in collaboration with Professor Haughwout, then of the Department of Protozoology, College of Medicine, University of the Philippines, examined specimens of nasal polypi removed from patients in the hospital, but no parasites were found.

The Ear, Nose and Throat Involvement in Certain General Diseases.

Another factor which, in the tropics, is responsible for the many ear, nose and throat diseases is the prevalence of those general diseases like leprosy, beriberi, yaws and others which have certain manifestations in these organs.

Leprosy.

Our observations are based on some 400 cases examined at Culion Leper Colony, one of the biggest leprosarium in the world. The pinna is almost always involved in the nodular or mixed type of leprosy, the involvement usually consists of diffuse or nodular infiltration starting in the lobule and helix, causing enlargement of the auricle. The nodule may ulcerate. Later, the condition may be followed by atrophy of the skin, and the pinna then appears very thin and small. Middle and internal ear involvement has not been observed. However, Mercado, in his work entitled "Leprosy in Filipinos and its Treatment" (*Revista Med. y Farm.*, 1914, vol. v, No. 8, August) very clearly states that leprosy causes deafness by extension of infection from the nasal mucosa. In the examination of cases in Culion the above findings of Mercado we did not observe.

Involvement of the Nose.

Externally, one sees the tip of the nose and the ala nasi with nodular or diffuse infiltration in the nodular type. Sometimes this is so extensive in advanced leprosy that the weakened anterior septum gives way to this weight and the result is that breathing may be partially obstructed. Frequent nasal catarrh and later on occasional epistaxis seem to be early complaints of the patients. The complaint of obstruction in nasal breathing is more often due to the engorgement of the turbinal mucosa, and in those advanced cases with atrophic condition in the nose, this may be due to presence of crusts in the cavity. Infiltration or ulceration at the anterior portion of the septum at Kiesselbach's area—is an early and very common sign. A small nodule may even be found at this region. Ulceration leads eventually to perforation of the septum at its anterior part. When small it may produce a whistling sound during expiration. In advanced cases there is produced subsequently a sinking down of the bridge of the nose. Among the 400 consecutive cases examined, 80 cases, or 20 per cent., had perforation. With the changes in the septum there are also changes of atrophy in the turbinals, the cavity becomes cavernous, and thick, hard, dry crusts adhered to the nasal wall. This atrophic rhinitis is striking in that it does not have the very offensive smell and the abundant foul discharge of the ordinary and the syphilitic form of atrophic rhinitis. In speaking about the lesion in the nose Mercado, in his article cited above, states that in all their patients treated in the clinic of San Lazaro Hospital, he observed loss of smell "from the time a pathological sign or lesion makes its appearance in the nose." This observation has not been confirmed by us in our examinations made in Culion. Among the lepers pulmonary tuberculosis is very common. Might not this atrophic condition of the nose with its protective powers destroyed share with other factors in the high incidence of tuberculosis among these patients?

Throat Involvement.

In the throat there were seen seven out of the 400 cases with infiltration and ulceration of the uvula and posterior pillars. In advanced cases we noticed atrophic pharyngitis. In these there was marked diminution of irritability, and patients seldom complained of pain, not excepting those with ulcers in the throat. Our observation is that the throat is affected only in advanced leprosy and usually where there is extensive destruction of the interior of the nose. From ordinary inspection, we have obtained the following findings: from a ward where the cases were advanced, 62 per cent. of the patients had throat and mouth involvement; another ward with moderately advanced cases, 53 per cent.; and in a dispensary clinic where patients were strong, 10 per cent. Hoarseness is not uncommon in advanced cases, but the lesion in the larynx should be carefully differentiated from the tubercular, as many of these patients have also pulmonary tuberculosis. Tracheotomy is once in a while resorted to for the relief of choking due to closure of glottis by leprotic growth.

Yaws.

The tertiary manifestations of this disease in the nose, pharynx and palate have been observed here. They are in the form of ulcerations and infiltrations more or less extensive, with bony destruction at times and much deformity giving rise to what has been termed rhino-pharyngitis mutilans. A preliminary study of this condition has been published by one of us (see Nicholas, "Tertiary Manifestation of Yaws in Nose and Throat," *Journal Philippine Islands Medical Association*, 1924, vol. iv, No. 4).

The pinna may be involved. A case presented to a staff meeting of this hospital by Drs. Guerrero and Sison had one auricle entirely eaten up. The case had been admitted three years before and was mistaken for a new growth; was subjected to radium therapy but did not improve. Later, the patient came back with periostitis of the extremities and diagnosis of yaws was then made and confirmed by X-ray and Wassermann test.

Beriberi.

That beriberi gives rise to laryngeal symptoms in the form of paralysis of the recurrent laryngeal has already been observed. (Please refer to Fernando, "Laryngeal Symptoms in Beriberi," *Philippine Journal of Science*, 1924, vol. xxiv, No. 1.) In this report paralysis of only the left vocal cord was found in all three cases, but recently we had a case admitted to the medical ward with complaint of numbness and marked weakness of the legs. Two weeks after onset of the disease the patient developed hoarseness to the extreme of reducing the voice to a whisper. Upon examination there was found paralysis of the left vocal cord and paresis of the right. We consider this as a clinical proof that the paralysis of the nerve is not due to pressure on the nerve but rather to a neuritis. As beriberi is prevalent here notice should be taken of this symptom so that it may be correctly diagnosed.

Small-pox.

This disease may leave extensive scar formation in or around the nasal orifice producing partial or complete atresia. Plastic operation may be necessary to establish normal respiration.

Hay Fever.

Before concluding, a short remark may be necessary regarding this disease. Do we have hay fever in the Philippines? So far, we have not observed a typical case. There is a form of spasmodic rhinitis, resembling hay fever and characterized by frequent and violent sneezing early in the morning, followed by a clear watery flow. Late in the night the patient begins to complain of nasal obstruction, usually more on the side lain on, like the intumescent rhinitis, but during the day he feels perfectly well.

Conclusion.

The foregoing observations represent our experience over a period of six years' work in the Free Dispensary of the Philippine General Hospital, where the majority of the patients attending are of the poor and ignorant class.

The authors of this paper, more than anybody else, are aware of the incompleteness of this work, the omissions in it, and its shortcomings. No pretence is made to cover exhaustively the subject, for we know that it is beyond our reach. We welcome all criticisms as well as every help, for should we have the chance we intend to carry out further this preliminary study, including at the same time an account of the little experience we have gained regarding certain special treatment to suit tropical conditions, and thus we may perhaps be able to present a work worthy of your consideration.

Table of Diseases of the Ear, Nose and Throat

showing roughly the average number of cases per year as compiled from the records of the Eye, Ear, Nose and Throat Dispensary of the Philippine General Hospital from 1918 to 1923 inclusive. These do not include all the cases treated.

Diseases of the Ear.

Diseases	Average per year from 1918-1923 inclusive
Abscess, mastoid	11
Cerumen, impacted	24
Catarrh of Eustachian tube	23
Foreign body	18
Furunculosis	189
Hæmatoma, pinna	16
Mastoiditis	11
Myringitis	64
Otitis externa	75
Otitis media suppurativa	417
Otitis media catarrhalis	80
Oto-sclerosis and dry otitis media	32
Polyp, aural	8
Papilloma, ear	5

Diseases of the Nose.

Diseases	Average per year from 1918-1923 inclusive
Abscess, septum	7
Empyema, maxillary antrum	35
Ethmoiditis (without polyp)	7
Foreign body	30
Polyps, nasal	62
Rhinitis, acute	79
,, subacute	31
,, chronic	176
,, atrophic	131
,, chronic hypertrophic and chronic intumescent	241
,, suppurative	8
,, ulcerative	11
Perforation, septum	12
Ulcerations and submucous infiltration of septum	40
Carcinoma, nose	5
New growths, antrum, maxillary (carcinoma)	2
Furuncle, vestibule	50

Diseases of the Throat.

Abscess, peritonsillar	21
Adenoids (alone)	36
Foreign body	15
Laryngitis, acute	24
,, chronic	27
,, subacute	7
,, tuberculous	49
New growth, tonsil	3
,, larynx	2
Peritonsillitis	14
Pharyngitis, acute	190
,, subacute	78
,, granular	58
,, chronic	194
,, ulcerative	8
Tonsillitis, acute	63
,, subacute	20
,, acute follicular	63
,, chronic hypertrophic	288
,, ulcerative	8

PROPHYLAXIS IN MALARIA.

By H. A. Spencer, M.R.C.S., L.R.C.P.Lond.

THE question of effective protection against mosquitoes, and infection by them, under all conditions, has recently come into prominence once more in connection with sundry articles on malaria published in your journal about a year ago, inquiries for recommendations there anent having been received from several parts of the Union of South Africa and Rhodesia, particularly regarding the dose of quinine considered to be protective, and whether this method can be accepted as effective.

The only really reliable preventive against infection is, of course, to enclose one's living quarters with mosquito gauze and to insure that it is always in thorough repair; nothing more than is already known regarding fly-doors and mosquito-blinds can be said of this method, but it may interest readers to know that my own house was thus protected fourteen years ago, and that the ordinary dark green (iron) gauze, kept by every general store, then erected is still in thorough repair and looks like remaining effective for some years to come. Objection is sometimes taken to the interference of such blinds with the admission of light, an objection easily removed by painting the gauze white, with the precaution of diluting the white lead very freely with turpentine.

There are those, however, who must leave such protection periodically, whose duties take them into hotbeds of malaria for varying periods during which exposure to infection is inevitable unless some sort of precaution is taken; and the question arises, what reliable prevention can be recommended in such cases?

They are at once narrowed down to two in number, the mosquito net and a prophylactic dose of quinine.

(1) The mosquito net is a flimsy thing and easily torn if not handled with affection, but it may be made thoroughly effective when under canvas in the above circumstances. Under instruction and a certain amount of supervision, native servants may be trusted to handle mosquito nets, to erect and to pack them with every care, and the protection they may afford is such that they are worth taking considerable trouble over.

I am acquainted with one disciple of Sir Ronald Ross who has for some years past periodically visited many of the most malaria-infected parts of the country to study and to treat the disease in its worst and most fatal forms, remaining under canvas for weeks at a time and moving about from place to place with literally hundreds of cases around and close to his tent; this he skilfully lines with mosquito netting, goes in and out with proper attention to details and, he tells me, he has never yet had a touch of malaria, though often the only immune person for many miles around.

I am also acquainted with members of the police force who have been provided with a small, conical mosquito net, which will fold up into a sufficiently small space to be carried in the coat pocket or a saddle-bag when they go forth upon patrol into the low veld; at night this small net has been slung to the branch of a tree or to the beam of a store veranda; it has even been trigged up with sticks and slept under, where neither of these shelters were handy, and has to these members given satisfactory protection against infection. It has to be lowered sufficiently to *tuck in* all around the upper part of the body and care taken not to expose the hands.

From results known to me and observed, I have no hesitation in recommending mosquito netting (in one form or another) as the very best preventive against infection when visiting and remaining for a time in malaria-infested parts of the country. My informant, in the first instance quoted, avowed that he would go anywhere and remain as long as ever it was necessary with his mosquito-net lined tent, and maintain his immunity to infection.

(2) There remains only the prophylactic dose of quinine as a preventive against infection, and with the above experience in view I consider that it will still find a place, but chiefly amongst those who are taken rather by surprise in the matter of a forced exposure and for a short time.

The protective dose of quinine is designed to kill parasites as soon as inoculated into the body by a mosquito, by insuring that a solution of the drug shall be in the circulation during the hours when anophelines are known to seek human blood—at night; and when one remembers how very few

parasites are likely to have been wiped off into the duct of a sebaceous or sweat-gland during the insertion and withdrawal of the mosquito's proboscis—even several times during the night—and how exceedingly vulnerable they would be at that stage of their development, it suggests to one's mind that a very high dilution of the drug would be sufficient and effective for their destruction.

It was with this in view that the medium dose of *5 grains* of quinine (on retiring at night) was recommended, a good many years ago now; numbers of medical men in India and elsewhere, over a number of years, have reported thoroughly satisfactory results with this dose and it has been generally accepted as effective.

Later on a second five-grain dose taken on waking in the morning was recommended as likely to "make quite certain of a thorough clearance," in view of the fact that anophelines are prone to seek human blood particularly in the early part of the night and in the dusk of early morning. This method was much applauded and was also widely reported to give thoroughly satisfactory results.

I have followed both methods indifferently on very numerous occasions when delayed a night, or a few nights, without my net, on the low veld where malaria was prevalent, with perfect freedom from infection for many years; whilst, however, convinced that a single five-grain dose at night is sufficient to give protection, I have been accustomed to give inquirers regarding the dose necessary, the choice of the one-night dose or the two doses night and morning and to let them please themselves how many doses they take.

It happens occasionally no doubt that an individual, seeking safety in a small prophylactic dose of quinine while exposed to infection, already harbours adult parasites in his blood, in his spleen or his bone-marrow, upon which the small daily dose has but an inappreciable effect; so that although he *prevents further infection* he may not prevent an attack of malaria as time goes on, though he probably minimizes or delays it. In view, therefore, of the very numerous instances of protection due to a small prophylactic dose and the extreme rarity of an attack of malaria materializing during or immediately after such prophylaxis, I feel convinced that this is a perfectly reasonable explanation of such exceptions.

I do not think that the question as to whether an individual accustomed to taking quinine becomes inured to the drug and should take a larger dose to secure protection, need be touched upon, in view of so many accustomed to take ten-grain doses during attacks of malaria and who, on occasion, again and again secure protection with only a five-grain dose nightly.

In conclusion, I should like to emphasize once more than *in an immune individual* it is probable that an exceedingly dilute solution of quinine in the blood is all that is necessary to destroy the very early phase of the parasite, from the mosquito's salivary glands, which is wiped off the proboscis into the duct of one of our cutaneous glands when inoculation takes place.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments, either** of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and **fifteenth** of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part **resident** abroad, proofs will not be submitted to those **dwelling** outside the United Kingdom, unless specially **desired** and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written **clearly.**

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid **delay,** all those desiring to have their papers illustrated are advised to communicate direct with the Publishers **at the** earliest possible moment.

13.—Authors of original communications are **entitled to 25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies **under the** heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these,** with remittance, **is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

A WHITE AUSTRALIA: IS IT A POSSIBILITY?

By SYDNEY J. SKERTCHLEY, J.P.

(*Continued from page* 197.)

CHAPTER XIV.

Australia and Canada Compared.

In paragraphs 163-5 I gave reasons for my hope, for it is hardly strong enough to be called a

belief, that in Canada and the adjacent part of the United States, which form the wheat district and has a drainage to the north, we have an area in which the White Race may be able to perpetuate itself. We will now compare and contrast the area with Australia.

(1) Australia (with Tasmania) lies entirely north of latitude forty-three degrees south, so that its climate is essentially warm, temperate and tropical.

Canada lies less entirely north of latitude 49° N., so that its climate is entirely temperate and arctic.

(2) Owing to its latitude Australia has no long snow-bound winter, with short days and long nights. Canada has a long snow-bound winter, with short days and long nights.

(3) Australia has few rivers of any magnitude, and these, for the most part, are often mere successions of water-holes, or even dry for months at a stretch.

Canada is abundantly supplied with large and permanent rivers and lakes.

(4) Australia's climate and physical conditions generally are quite unlike those of the European home of the Fair Whites.

Canada's climate and physical conditions are almost exactly like those of the European home of the Fair Whites.

At first sight everything seems in favour of Canada. But, again, a priori reasoning is misleading. We must deal with fact, not fancy. Now, I know Canada, and I know Australia. I admit my friend the Kanuck is a very splendid specimen of manhood; a lumber-man is a sight to do a city-bred man good, and fill him with envy when he contemplates his own un-Sandowed limbs. But he is not a finer man than his cousin of the south. Once more, let me give a personal experience. I had been away from England for some eighteen years, in America and Asia, and latterly in Australia. Landing in the old country, the first thing that struck me was the smallness of the people. I am myself but 5ft. 7½in., and in Australia always felt becomingly insignificant, but in London I passed very well for an average Briton. Both the cold of Canada and the warmth of Australia give rise to the ideal man, as an animal. Walk about the streets of Sydney or Brisbane for an hour, and you will see more six-footers than in a day's tramp in London streets. A Colonial is every inch as good a man as the Kanuck.

But I must modify this statement. So far as I can judge, it is only true of the first generation of "Australian natives." Their children, and their children's children are by no means to be measured by the fathom. Grandchildren are as yet too young for one to be sure of this, and I have to rely upon observation as to the lowering of stature in the third generation, which is unsatisfactory.

I inquired of Major Sankey, who has had over thirty years' experience of Queensland Volunteers, and whose father's military career dates back to before the State was born, as to the physique of the young men offering for recruits. He unhesitatingly declares that both in stature, chest measurement and general set up, the young Queenslander falls short of his immediate predecessors. Captain L. C. Green, of the Australian Engineers, has not so lengthy an experience, yet he tells me he notices a falling off, especially in chest measurement and general build. Queenslanders are, naturally, rather touchy about this, sometimes illogically so. I remember, after making such a statement in a lecture, one of my audience rose and firmly, but courteously, asked me if I had any evidence to produce. I simply put the question, "How tall is your father?" My friend subsided laughing; he had not recollected that his scalp-lock only reached as high as his father's epaulettes.

However this may be, the main fact stands clearly out that in the first, and, perhaps, the second generation, the native-born Australian shows a decided advance in physique over the average Englishman. This at once does away with the suspicion that the climate of Australia is more detrimental to the Fair White than that of Canada.

The effect of the long, dark winter nights of Canada has, I fully believe, a great influence. But it is upon character, not upon physique, and so is not germane to our inquiry. Still, it must be alluded to in passing. Australia has no such winter of short days and long nights. Our southern coasts are not nearer the Pole than forty degrees latitude, or, say, the equivalent of Southern Italy in Europe or San Francisco in America. The Australian winter is, as a whole, a glorious season, and virtually all the extra tropic lands have frosty nights, and much of them frosty days, too. It is an exhilarating season which lures our youth into the open-air. It is *par excellence* the season of sports. Australian winters, as compared with Canadian, are like the seasons of Hong-kong versus Shanghai. We played cricket in winter in Hong-kong, and in summer in Shanghai, and Shanghai nearly always beat us of Hong-kong: the "model Settlement" usually crowded over the "Fragrant Waters."

The Canadian winter is likewise a time of enjoyment, as I cheerfully and thankfully remember. Whose veins tingle not at the memory of sleigh rides, of ice-boats, of goose-fleshy tobogganing, and wild ski races? But Canada lies all north of forty-nine degrees N.; her winter days are short, her nights are longer; and these long, dark nights, when the hush of snow silences the night-sounds; when curtains are drawn, and the wood-fed stove beams warmth and cosiness—then is the time for study. Australia has no parallel to this, nor compensation. Her bright skies and sparkling air (how it sets one a-tingle after absence) lure our youth into the open air—a good thing, almost the best of

things—but not to be indulged in to the detriment of the intellect. This splendid open-air existence tends to harden the young Australian muscle, but not to strengthen his brain; and I see the salutary effects of the long Canadian winter nights fructifying in enlightened policy, in far-seeing public works. Canada is far ahead of Australia in her political standard. We must, to hold our own, have sound brains as well as sound bodies. I should say from my own observation, but cannot prove my case, that among the middle classes—that is those not tied to manual labour—the average Australian woman, if not better educated than the man, keeps up her education better, and is becoming the man's superior as a thinker. Anyhow, I personally would rather trust some great issues to a plebiscite of Australian women than to the men. Our women do not prove their fitness for legislators by breaking the laws, as do some of the misguided sisterhood at home, who would look down upon an Australian as a mere "Colonial!"

All this is beside the mark, yet it may be forgiven to an Englishman who is Australian by adoption, and is jealous of Australian well-being.

One fundamental difference between Canada and Australia is the splendour of the water system of the one as contrasted with the other. Water-carriage must always outbid land-carriage, and Australia has nothing like the great St. Lawrence route from the Atlantic, by Winnipeg to the head waters of the Saskatchewan, a distance of 4,500 miles. The Murray, it is true, is one of the largest rivers in the world—on the map. It is 3,800 miles long, but, alas, over most of its course it loses more water than it receives, and sometimes does not succeed in reaching the sea. In average seasons it is navigable to Albury, a distance of 1,468 miles from the mouth, but only in small vessels. There are (1908) ninety registered steamers on the river, and about the same number of barges, the largest being about 300 tons. After all, we can only look upon the Murray as a canal of no large dimensions, so far as navigation is concerned.

This is undoubtedly to the detriment of Australia; but not so great as might be supposed. Canada was ironically described by envious Yankees as a few acres of snow round the North Pole. There is a little sting of truth in the tail of this witty exaggeration. The same chill hand that lays the plough idle seals up the Canadian waterways for months and then the land of the maple like the land of the wattle, has to depend upon horse and bullock and steam. The northern Canadian rivers are impracticable from rapids and falls, and even now, along the Nelson River from Winnipeg to Hudson's Bay, an iron road is being laid to carry goods along the shortest route from Manitoba to Manchester.

Summing up, then, we find the balance is pretty evenly held between the two countries. It may lean a little towards Canada in its great waterway, but the difference is not enough for us to decide that Australia is not as fit a home for us as Canada.

The last point we have to settle in this comparison is the effect of climate and physical condition. In these Canada is undoubtedly more home-like than Australia. We have nothing in substitute for the bracing north winds, and it is the north wind that has made us north men what we are. We do not seem capable of enduring too much luxury of climate. Out of the bleak Baltic lands our Gothic forebears swept to the balmy south, and our steel sinews won it all for ourselves; but we could not hold it. Homer's heroes had our own blue eyes and blonde complexion and fair hair. Greece knows them no more, save as visitors. It is the Dark White of Mycenæ that to-day the Fair White King George rules over, but he is not of Dorian but of Danish birth.

Australia is as healthy as any part of the world; it can produce the finest type of white man, and keep him vigorous into ripe old age. But, as all this long inquiry has shown, there is not a particle of proof that on Australian soil a new and virile strain of white men is being reared, who, by natural increase, can hold the land.

I do not say we shall die out. But I emphatically declare we must die out—for we are dying out—unless we can check the fatal decline of our natural increase. We are improving our death-rate; but not our birth-rate, yet it is on this our fate depends.

If, then, I am asked for a categorical reply to the question, "Is a White Australia possible?" I answer, "Not under present conditions." But if we can overcome the tendency to aggregate in towns; if we can improve the conditions of woman's life in the bush; then and then only can a true White Australia arise.

How this latter may be accomplished I have hinted at. I will only point out that it will not be in the direction of small holdings, of one-man farms, that seem the ideal of some of our politicians. France has achieved that end, and France is paying the penalty in a declining birth-rate.

Our Fair White race was born in the rugged north. There is evidence to confirm us in the belief that it is a new race; that it is the child of the glacial period. If so, then as a new race can be born, there is hope that another race may arise in this health-giving, bright southern land. But we must produce it ourselves, out of ourselves. We cannot do this by theoretical legislation, or by restrictive edict. We must first grasp, and then grapple with the deep question of our birth-rate. This is the noblest task an Australian can undertake; it is a difficult one, but our race glories in overcoming difficulties. Some of the ways in which we may set about putting our house in order I have pointed out; if these, and others to be discovered, are put into force, we may yet more than hold our own. We shall be a new race, a new White Race, perhaps not altogether Fair White, but we shall be a strong race born of sunshine and not of the north wind, and we shall be true Britishers.

Annotations.

Treatment of Debab Trypanosomiasis of the Dromedary (E. Sergent, A. Donatien, E. Plantureux and A. Deguillaume, *Arch. de l'Institut Pasteur d'Algerie*, June, 1924).—Several medicaments have been tried in the treatment of this disease of which emetic by intravenous injections has given the best results. Administered intramuscularly in an oil solution the effects are not quite so good. Emetic-atoxyl has also proved efficacious. Atoxyl alone was active, but in doses too near the toxic dose. Novarsenobenzol acts the same as atoxyl but is less toxic. 189, trepol, oxycyanure of mercury, biodide of mercury, salicylate of soda, and quinine were efficacious.

On the Subject of Formol-Gelification in Dromedaries and Bovine Animals (E. Plantereux, *Arch. Institut Pasteur Algerie*, June, 1924).—These experiments were carried out in Algerian dromedaries with debab. Only two out of fourteen apparently healthy animals gave positive reactions. Out of thirteen serums of infected animals eight were gelified. No appreciable difference was observed in the different piroplasmoses. The anaplasmoses gave a more rapid reaction. The number of drops of formol for healthy subjects was two and for those infected one. These results are not sufficient for formol-gelification to be used in the diagnosis of bovine piroplasmosis, but it is valuable in the diagnosis of trypanosomiasis of dromedaries.

The Existence of Equine Infection due to Trypanosoma marocanum on the Borders of Algero-Morocco (E. Sergent and A. Donatien, *Arch. Institut Pasteur Algerie*, June, 1924).—The authors have tried the method of crossed reinoculation of Laveran and Mesnil and have obtained the following results. The identity is shown of trypanosomes of horses of West Morocco and those of horses of East Morocco. It is wise in using this method to assure by successive reinoculations the immunity acquired by a subject against the first virus before inoculating a second virus. According to these inoculations, sheep and goats present successively a period of infection, a period of "premunition" commencing between the sixth and eighteenth month, and a period of true immunity commencing after the second year, the duration of which is as yet unknown.

Mosquito Breeding in Specific Places (W. Rudolfs, *Journal of Parasitology*, December, 1924).—Water samples from three distinct regions (cedar swamp and acid clay pits) were studied for chemical constituents, acidity and alkalinity, and for kind and abundance of microscopic plant and animal life. Breeding occurred in the cedar swamp waters whenever the acid water was stagnant. Acidity as such does not seem to affect mosquito breeding. The chemical composition of these waters does not prevent breeding of certain species, but might determine kind of breeding. Food supply for larvæ, which might be dependent on the chemical composition of the water, seems to be the main cause for breeding. High amounts of toxic aluminium and iron sulphates of the waters from clay pits prevent mosquito breeding. *Culex pipiens* larvæ of all ages lived, pupated and hatched in all waters until the food supply was exhausted, except when relatively large amounts of Al and Fe sulphates were present.

Saponification of Bodies in the United Provinces of Agra and Oudh (R. B. J. P. Modi and D. N. Chatterji, *Indian Journal of Medicine*, September, 1924).—Of twelve cases of saponification which came under the personal observation of J. P. Modi, six cases are described in this paper. Time required for saponification in these cases varied from seven to thirty-five days. It is pointed out that saponification is more common in Lucknow than in Agra, probably due to some climatic variations. The saponified tissues in the last two cases of the series did not show any definite structure under the microscope, except masses of acicular crystals and round bodies consisting, in all probability, of natural fat and soap. Chemically, these substances consisted of a minute quantity of lime soap, free fatty acids, viz.: palmitic and stearic acids, unsaponifiable matter, and the ash containing lime, soda and potash compounds.

Investigations on Pulmonary Plague (Dr. M. Tsurumi, *Office International d'Hygiene Publique*, November, 1924).—Results on observations on the recent epidemic (1920-21) in Manchuria are given in detail. There were over 7,700 victims. Investigations show that the tarbagan is a very probable transmitter of pulmonary plague. The plague of tarbagans precedes human plague. The disease is transmitted direct from one person to another. The plague under observation began in bubonic form (thirty-seven cases); septicæmic form (thirty nine cases) then followed, and the remaining cases were all pulmonary. Pulmonary plague is generally prevalent in winter, but in this epidemic, at Karbin, where the plague was most violent, the majority of cases occurred in April. Experiments on animals also showed that contamination takes place through the sputum, through the intermediary of the air.

Laboratory Findings in an Epidemic of Glandular Fever (Ruth Gilbert and Marion B. Coleman, *Amer. Jour. of Hygiene*, vol. 5, No. 1, January, 1924).—In an epidemic of over 100 cases of glandular fever, a report on sixty-three cases was made with regard to family groups, sex, age, date of onset, symptoms and duration of illness. Thirty-nine of forty-three children in these families, or

90·6 per cent., and fifteen of thirty-two adults, or 46·8 per cent., developed the disease. Blood serum from two convalescents failed to agglutinate *B. melitensis* and *B. tularense*. Cultural examinations were made on throat cultures and one specimen of pus from an axillary gland. *Streptococcus hæmolyticus* was isolated from the pus and from four of the seven throat cultures. *Streptococci* producing methemoglobin were present in all except one of the seven throat cultures. One case of acute myelogenous leukæmia, which occurred in the same county as the epidemic of glandular fever, is reported for purpose of comparison. Blood examinations were made in thirty of the cases. Seven, or 23·3 per cent., showed polynucleosis. An increase in the number of eosinophils was noted in 66 per cent. Twenty-two, or 73·3 per cent., showed an increase in lymphocytes. Thus, a lymphocytosis may be expected in some stage of glandular fever. These observations are on the whole similar to those of earlier workers; they are, however, too meagre to form the basis of any significant conclusions.

The Early Diagnosis of True Hernia of the Diaphragm (D. P. Abbott, *Jour. Amer. Med Assoc.*, December 13, 1924).—Small hernias of the diaphragm, especially periœsophageal, are much more common than is usually supposed. A careful study of the symptomatology should suggest their presence. Routine examination of the patient with the fluoroscope, as described, will reveal small periœsophageal diaphragmatic hernias, which will otherwise be missed. Needless to say, the repair of a small hernia is less difficult than the repair of a large one, and the dangers of complications are less in the former.

Congenital Ectodermal Defect (G. M. MacKee and G. C. Andrews, *Arch. Dermat. and Syph.*, December, 1924).—Eight *bona fide* patients are recorded who presented a fairly universal congenital ectodermal aplasia. They all exhibit the same clinical characteristics, and they comprise a distinct group of congenital ectodermal defect. As there are but ten recorded cases belonging to this group, only eight of which have been described, the affection may be regarded as rare, at least until a larger number of patients are recorded. The principal clinical characteristics of this group are: congenital absence of sweat-glands; absence of pilosebaceous apparatus over most of the body; marked dental aplasia; depressed nasal bridge; atrophic rhinitis; prominent supra-orbital ridges; thick, protrusive lips; thin, glossy, smooth, dry skin; papular lesions on the face; heat intolerance. The detailed description of a new patient is presented, who, in addition to possessing all the clinical characteristics, exhibits: a mongolian facies; deformed ears; fine wrinkles of the eyelids and environs; radiating linear defects at the oral commissures and near the nostrils; aplasia of the nails; narrow lower half of face; unusually large number of papules on th face; absence of atrophic rhinitis. The affectio is familial. All but one patient are males. Mo of the patients and their ancestors appear to h free from syphilis and tuberculosis. Th cause of the developmental defect is unknow Arrest of development occurs very early i intra-uterine life. The absence of sweat glan offers an unusual opportunity to study th physiology of perspiration. Experiments an observations thus far made show that insen sible perspiration is probably independent o the sudoriparous glands; that the principal functio of perspiration is to regulate the body heat; tha the sweat glands constitute an emergency apparat for this purpose; that patients without swea glands are handicapped through inability to radiat sufficient heat under certain environmental con ditions, but they are healthy and active, an longevity is apparently unaffected.

Experimental Acne Varioliformis (M. M. Strumia *Arch. Dermat. and Syph.*, December, 1924).—Tw cases of acute acne varioliformis which were distinc tive by reason of deeply necrotic and hæmorrhagi centres and surrounding woody œdema yielde both staphylococci and streptococci in culture They were also present in the nose and throat i one case. Lesions identical in morphology wit those of acne varioliformis were reproduced in th patient by the intradermic injections of these tw organisms (both autogenous and stock), and com parable ones were repeatedly produced in guinea pigs. It follows from the foregoing that th organisms are not of a strain specific for this di ease, and that a tuberculous factor can be definitel excluded from some cases of acne varioliformis This combination of organism, in yielding so charac teristic a lesion, might be useful in other exper ments having other bearings, such as the genera subject of distribution of lesions. It is possibl that the dusky, necrotic, indolent characters o tuberculosis have been referred to the somewha similar ones of a streptococcus, and that this i responsible for some of the present ideas of th tuberculous nature of acne varioliformis. In the fu unculoid state which is known as acne varioliformis different organisms may be operative. The caus of one type is a staphylococcus and streptococcus neither of which of itself can produce the typica lesion. The deep position of the organism explain the varioliform type of scar. The hæmorrhage necrosis, woody œdema and the slow healing reflec known traits of streptococcus.

Iodine in Exophthalmic Goitre (F. R. Fraser *Brit. Med. Jour.*, January 3, 1925).—The effect o iodine administration has been studied in twenty four cases of exophthalmic goitre. Iodine ca bring about a lowering of basal metabolic rate and of heart rate, and an increase of body weight with a striking improvement in the general con dition of the patient. The improvement obtaine

with iodine does not as a rule persist. The optimum dose at the commencement of the treatment appears to be about 15 minims of a ten per cent. solution in alcohol, but this dosage cannot as a rule be maintained more than a few days or weeks. If the administration is stopped the condition immediately relapses. For prolonged treatment the dosage should be lowered as soon as the initial improvement has taken place, and the administration continued with doses of 3 to 6 minims daily. The dosages must be carefully regulated according to the condition of the patient. Increasing hardness of the thyroid gland is an indication for a smaller dosage. The condition of the patient may be made worse, instead of better, if too large a dosage is employed.

The Action of Buried Glass Capillaries of Radium Emanation on Plant and Animal Tissues. An Experimental and Clinical Study (I. Levin and M. Levine, *Jour. Amer. Med. Assoc.*, November 22, 1924).—The intratumoral insertion of bare capillary glass tubes of radium emanation presents to-day the best single method of radiotherapy in various types of carcinoma and sarcoma, for the following reasons. It allows an even distribution of small quantities of radiations throughout the tumour. On account of the intimate contact of the radio-active substance with the tumour cells, the total amounts are small, and local results are obtained without any general effect on the organism. Use is made of the beta rays, which do not act as a simple caustic agent but destroy the nearest cancer cells and at the same time create secondary gamma or Rontgen rays in the tissues, and by the aid of these influences the cancer cells situated at a greater distance in a manner analogous to the action of the gamma rays of radium and the Rontgen rays. Thus, while it is true that to date the best results in cancer therapy are obtained by proper co-ordination between surgery and all methods of radiotherapy, it is imperative that more experimental work be done on the biologic action of the beta rays of radium.

Clinical Studies on the Kahn Reaction for Syphilis (H. L. Kleim and R. L. Kahn, *Arch. Dermat. Syph.*, December, 1924).—The diagnostic value of the Kahn precipitation test for syphilis was studied in 2,600 cases in comparison with two Wassermann tests—one highly sensitive and one more conservative in character—with the following results: In primary syphilis (twenty-five cases) the Kahn test was found slightly more sensitive than either of the two Wassermann tests. In secondary syphilis (sixty-four cases) there is agreement in the three methods. In tertiary syphilis, excluding cerebrospinal (eighty-seven cases), the Kahn test was found slightly more sensitive than both Wassermann tests, except that in visceral syphilis it compared with the more sensitive Wassermann test. In cerebrospinal syphilis (192 cases), the reactions with the Kahn test fall about mid-way between the highly sensitive and conservative Wassermann tests. In latent syphilis (218 cases), the reactions with the Kahn test compare favourably with the reactions with the long ice-box fixation Wassermann test. In congenital syphilis (thirty-nine cases), the Kahn test is slightly more sensitive than either of the two Wassermann tests. In non-syphilitic controls (1,975 cases), the Kahn test gave two one-plus reactions and two two-plus reactions in dermatologic conditions apparently non-syphilitic.

Studies on Microsporidia Parasitic in Mosquitoes (R. Kudo, *Jour. of Parasitology*, December, 1924).—The development of *Thelohania opacita*, parasitic in *Culex testaceous*, *C. territans*, and *C. sp.* is given. The schizont multiplies by a binary fission. At the end of schizogony, binucleated forms are formed. After the fusion of the nuclei, the sporont is produced. Both octosporous and tetrasporous sporonts occur, which develop into normal and smaller spores and larger and abnormal spores respectively. The small and large spores are similar in structure. The spore membrane is composed of two valves. The microsporidian infection is fatal to the hosts in the cases observed.

Giardia and Chilomastix from Monkeys, Giardia from the Wild Cat, and Balantidium from the Sheep (R. W. Hegner, *Jour. of Parasitology*, December, 1924).—Cysts of giardia are reported for the first time from a monkey; they are more slender than those of *Giardia lamblia* from man and probably represent a new species. Cysts of giardia are also reported for the first time from the wild cat; they are similar in size to those of the monkey. Cysts of a chilomastix are reported for the first time from a monkey; they are significantly larger than those of *Chilomastix mesnili* from man. A balantidium is reported for the first time from sheep.

Alcoholic Injections into the Gasserian Ganglion (G. M. Dorrance, *Jour. Amer. Med. Assoc.*, November, 22, 1924).—Injections of the gasserian ganglion are usually permanent, if enough alcohol is injected. At times one is able to inject the lower one-third or half of the ganglion and not involve the entire ganglion, but no one can promise this. Paralysis of the ocular muscles occurs at times. It always clears up. The absolute indication for injecting the ganglion is in carcinoma of the upper or lower jaw, or on one side of the tongue. In outside injection as well as ganglionic injection, the prognosis can be made at the end of the month, i.e., if anæsthesia is present at the end of the month, it is apt to remain so. The results depend on just how much alcohol is distributed in the ganglion or posterior root, and, in the case of an outside injection, into the nerve fibres. Eye complications occur in about the same proportion as in division of the root by any other method.

Familial Blood Dyscrasias (L. M. Morris and E. H. Falconer, *Arch. Internal Medicine*, December 15, 1924).—The conclusions of this paper are: Before cases are grouped as familial splenomegalies, it is necessary to eliminate certain common sources of infection, syphilis, malaria, and certain of the tropical diseases being most common factors for error. Before cases are grouped as familial anæmias, it is necessary to eliminate certain common toxic and infectious factors, lead, arsenic, syphilis and malaria being common sources of error. Family diseases of the spleen are probably related in many instances to a congenital predisposition of the hæmolytopoietic system. A disposition toward inferiority of the hæmopoietic system probably exists. Detailed family histories are essential to prove this point.

A Case of Sickle Cell Anæmia with Necropsy (G. S. Graham, *Arch. Internal Medicine*, December 15, 1924).—Sickle cell anæmia has been held to constitute a definite disease entity. The present clinical and pathologic study of a well defined case is believed to confirm that view. Characteristic signs and symptoms are readily demonstrable by clinical and laboratory methods, while post-mortem examination reveals interesting lesions, particularly affecting the hæmatopoietic system. The number of cases thus far studied at necropsy is too limited to allow the formulation of any far-reaching conclusions as to the exact nature of the disease. The condition may consist in an underlying status, determined primarily by deeply rooted racial characteristics and brought into clinical evidence in occasional persons through the immediate action of toxic, metabolic or infectious exciting agents. There is a certain amount of evidence favouring the view that this immediate causative factor is bacterial, and particular suspicion is directed toward the streptococcus.

The Pathology of Pneumonia Caused by Bacillus influenzæ during an Inter-Epidemic Period (D. Brannan and E. W. Goodpasture, *Arch. Internal Medicine*, December 15, 1924).—The influenza bacillus may be an important agent in the production of broncho-pneumonia in adults during a period in which there is no evidence of an epidemic of influenza. It usually invades the lung in association with infections by the pneumococcus or other bacteria which were probably the primary agencies of the disease in which the influenza bacilli were found. The influenza bacillus produces characteristic lesions in the lung recognizable grossly and microscopically. The lesion is essentially a bronchitis, ulcerative bronchiolitis, and broncho-pneumonia with a tendency to chronicity and to the formation of bronchiectatic abscesses. Acute infections with an influenza bacillus may not be associated at any stage with a profound toxemia, nor may there be lesions of toxic origin, as were found in the pneumonias of the influenza pandemic of 1918. The influenza bacillus is to be considered as one of the important secondary in vaders of the lung, causing a broncho-pneumoni which may terminate fatally. The hyaline men brane that occurred so characteristically in earl influenzal pneumonia in the past pandemic ha been demonstrated typically in two cases in whic an influenzal infection could have played no par This lesion is probably due to an injury to th pulmonary capillary bed, and its frequency in in fluenza is attributed to a toxic injury to the capi laries of the lung from a circulating poiso generated by the logic agent of this disease.

Experimental Study of Trypanosomiasis i Palestine (I. J. Kligler and I. Weitzman, *Annal of Trop. Med. and Parasitology*, December 3(1924).—An outbreak of trypanosome infection i mules in Northern Palestine afforded an opportunit for an experimental study of trypanosomiasis i lower animals, particularly rabbits and pigs. Th morphology of the parasite, the clinical picture o the disease, and the pathological lesions produced indicate that the strain belonged to the *T. evans* group. The therapeutic effect of "Bayer 205 and the mode of the action of this dru were investigated. The drug proved very effec tive in clearing up the infection in dogs, rab bits and guinea-pigs; a single dose of 0·0 grm. per kilo of body weight was sufficien to sterilize the blood in all instances an apparently affected permanent cure in eighty pe cent. of the rabbits and guinea-pigs so treated The mechanism of the drug is of interest. *In vitro* it has very little trypanocidal power; *in vivo* on the other hand, so small a dose as 0·05 grm per kilo suffices to sterilize the blood of a heavil infected animal in about sixteen hours. Experi mental evidence is advanced in favour of the view that a real immunity or resistance to infection i set up in the body of animals cured from infection This immunity or resistance seems to be associate with the formed elements of the blood. Repeate search failed to reveal any of the usual humora antibodies. On the other hand, profound change occur in the white blood-cell formula during th infection and after the treatment. Moreover, i is possible to break down the resistance artificiall by the injection of olive oil, a substance shown b various authors to modify the white cell ratio

---

The Question of Human and Pig Ascaris (F. K Payne, J. E. Ackert and E. Hartman, *Amer Jour. of Hygiene*, January, 1924).—The hos relationship of human and pig ascarids was teste by the administration of embryonated *Ascaris* egg to pigs and primates. Repeated feedings of infecte human *Ascaris* eggs were made to five young pigs all of which suffered respiratory disturbances an other systemic disorders. Subsequent post-morten examinations showed no ascarids in the digestiv tract of any of the pigs. Severe cases of "thumps" occurred in all of the pigs fed upon the eggs o the human *Ascaris*. This appears to be the firs

record of " thumps " caused by the administration of human *Ascaris* to pigs. Infective pig *Ascaris* eggs were taken by one monkey and by two human subjects. Fæcal examinations made throughout periods of several months after the initial administration of eggs failed to show the presence of *Ascaris* eggs. The incidence of *Ascaris* in North, Central and Southern Trinidad, British West Indies, varied from twenty to seventy per cent., for the human *Ascaris*, and from 3·5 to 10·8 per cent., for the pig *Ascaris*. In the vicinity of Arouca, one of the principal swine-raising regions, the incidence of human *Ascaris* was 64·3 per cent.. as compared with QP 1 per cent. of the pig *Ascaris*. The experimental results indicate that embryonated eggs of the human *Ascaris* will not produce mature ascarids in pigs, that infective eggs of the pig *Ascaris* will not produce mature ascarids in the adult primates—monkey and man, and that there is thus a physiological difference between the human and the pig *Ascaris*.

Serological Studies of Experimental Syphilis (Satoshi Takenaka, *Acta Dermatologica*, vol. 4, fasc. 1, September, 1924).—The so-called non-specific positive Wassermann reaction in healthy rabbits, though not absolutely absent, appears only occasionally when proper precaution is taken, and is of a degree which does not interfere with the investigation of the Wassermann reactions of the rabbit. In the author's work the non-specific positive reaction constituted about one per cent. of the entire group of rabbits. The amount of serum for testing the Wassermann reactions is 0·2 c.c. and the antigen suitable for the purpose is the alcoholic extract of the ox heart treated with ether and again with aceton according to Noguchi's method. The primary sclerosis of rabbit syphilis and the Wassermann reactions generally progress in close agreement with each other. The infection or the non-infection of the testis seems to have a great significance in inducing the positive Wassermann reaction. The appearance of the general symptoms, such as keratitis, does not give rise to positive Wassermann. The effect of reinoculation on the Wassermann reaction depends on whether the primary sclerosis is produced or not. According to the antigens used, the degree of positive reaction and the percentage of non-specific reaction differ. In the diseases producing sclerosis in rabbits resembling that of syphilis—due to *Spirochæta cuniculi* or the spirochæta of rat-bite fever —even when the testes are chiefly attacked, the Wassermann is always negative. Judging from these results the Wassermann reactions of rabbit syphilis are considered specific, but they differ greatly from human syphilis in that the Wassermann reaction becomes negative on the disappearance of the primary sclerosis in this animal, and also in that the appearance of the positive reaction depends to some extent upon whether the testis is affected or not.

Current Literature.

Revista Medica de Angola. Special Number of the First Congress of Tropical Medicine in West Africa. Vol. III, 3rd, 4th and 5th Sessions.

The Box-Stove (*La Caisse-Etuve*). *Practical Process of Disinfection by High Steam Pressure of Steam-Engines* (G. Lefrou).—This new device for disinfecting bed-linen, clothes, &c., in cases of pestilential diseases has proved of great value in the Congo, where it is difficult to obtain a proper steam-stove. It consists of a solid wooden case into which the steam is forced by a locomotive engine. The stove is placed on a wagonette with wheels and is thus easily taken from place to place. The stove can hold three mattresses or 100 single-sized bed covers. The temperature inside the stove is kept at about 150°. Fusible tubes placed between the clothes inside, show that this temperature is reached in about twenty minutes. It has been observed that steam at a temperature of 80° or 90° suffices to destroy parasites and their eggs in fifteen minutes. This stove can also be used for other purposes, such as disinfecting linen on liners, in factories, &c.

Intestinal Helminthiasis in the French Colonies. Prophylaxis and Treatment According to Recent Works Published (Ch. Joyeux).—A review of the recent works published on intestinal helminthiasis in the French colonies shows the frequence of ankylostomes, ascarides and of trichocephalus; ankylostomes being the most frequent. The statistics given are principally from the examination of the stools of soldiers, prisoners, inmates of hospitals, &c. It is rather surprising that *Hymenolepis nana* does not figure in the reports, except in Algerian statistics; the parasite is common in the Mediterranean basin and nearly all hot countries. The question as to whether the number of eggs found in the stools corresponds to the number of live worms in the intestine has not yet been satisfactorily answered; opinions on this point differ. Mass treatment is more satisfactory than microscopic examination of fæcal matter. Race has no effect on the disease. One of the most important prophylactic measures to be taken is the disinfection of soils. Three medicants have proved efficacious in the treatment of helminthiasis; thymol, chenopodium oil, and tetrachloride of carbon, but the action of the latter is not equal to that of the other two.

Experiments in the Treatment of Fuso-Spirillary Ulcers in Angola (Frederico Rebelo and Carlos d'Almeida).—The ulcers of Angola belong to two types: Leishmanial ulcers, and fuso-spirillary ulcers. Cases of myasis have also been met with, and other cases of ulcers undoubtedly exist there. The authors give their results of treatment of fuso-spirillary ulcers, some of which were long-

standing lesions. The most efficacious medicaments used were neosalvarsan in intravenous injections; trepol, applied locally; washings with a solution of dakin followed by dressings with gomenol (2 per 1,000). The keroplastic action, besides continual sterilization, has been maintained by injections of "914" and trepol; also by dressings with gomenol.

Contribution to the Therapeutic of Leishmanial Ulcers (Carlos d'Almeida and Frederico Rebelo).—In the treatment of leishmanial ulcers, tartar emetic by intravenous injections has given wonderful results, even in very old cases which would not respond to any other medicament. The emetic can also be used intramuscularly with the same success, but cicatrization is slower. Solution of Bouin used in cases of ulcer proved a good keroplastic; this action has been recently confirmed by a great number of researches.

Note on the Amœbæ observed in Fuso-Spirillary Ulcers of Angola (Froilano de Melo).—It is found that in Angola human intestinal amœbæ, both *histolytica* and *coli*, can invade the ulcerous lesions of the skin, where they find the necessary elements for their nutrition and their development. It is in the fly-excrement on the ulcers that the origin of amœbic infestation is to be found; the flies are extremely abundant in Angola, and constitute a sanitary problem worthy of attention.

Bilharziosis in French West Africa (Marcel Leger).—Vesical bilharziosis has been observed in French West Africa for the past eighteen years, and is still met with very often. Fewer cases of intestinal bilharziosis have been recorded. 159 cases of infestation by trematodes have been observed by the author, 19 intestinal and 140 vesical, in 1922 and 1923. The trematodes harboured by the blacks cause very little morbid trouble. The fæces are generally normal, and the patients do not complain of any intestinal symptoms. Both *Sch. hæmatobium* and *Sch. mansoni* have been found in the intestinal cases. Vesical infestation co-existed in only two of the nineteen cases of intestinal bilharziosis. 139 of the 140 cases of vesical bilharziosis were due to *Sch. hæmatobium*, the other one to *Sch. mansoni*.

Some Considerations on the Treatment of Bilharziosis by Emetic (Carlos Franca).—Emetic, J. B. Christopherson's method, has proved the most efficacious of all the medicants used in the treatment of bilharziosis. An interesting account is given of the ovular changes observed in the examination of the urinary sediment of each patient. In regions where there is no laboratory, the sediment can be preserved in the liquid prescribed by Langeron: formol, 5 c.c.; glycerine, 10 c.c.; distilled water, 100 c.c.

Prophylaxis of Venereal Diseases (Dr. Walravens).—Statistics show that venereal diseases have greatly increased among the population of the colonies, especially in the Belgian Congo, since 1916. A law has been passed by the Belgian Government on the same lines as the law of the Swedish Government, making it obligatory for persons affected to report and receive appropriate treatment; patients can be treated free of charge if they wish.

Syphilis Among the Blacks of Senegal. The Fight Against Syphilis at Dakar (M. Nogue).—Syphilis is widely spread not only among the Senegalese, but also among the people of Sudan, and very often is found in patients under treatment for non-syphilitic diseases. Yaws, on the other hand, is very rare in Senegal. Syphilis in natives is not so benign as generally believed, and is sometimes fatal. It is responsible for a great many cases of abortion, and the debility of a number of children. The association in natives of syphilis, malaria and ankylostomiasis has often been observed. The under-nourishment of the patient and general conditions offer good ground for the development of parasites. A very good account is given of the different stages and different types of the disease.

Considerations on the Epidemiology of Plague. Man can, like the rat, be a reservoir of Virus (Marcel M. Leger).—This paper proves that man is susceptible to become a chronic carrier or healthy carrier of the Yersin bacillus. He constitutes, in the same capacity as the rat, a reservoir of virus, but is more to be feared, as the germ seems to have a lesser tendency to decrease in man than in rat. Anti-plague prophylaxis is therefore necessary not only among animals, but human subjects.

Plague in Angola (A. Damas Mora).—Plague seems to have made its appearance in Loanda in January, 1921. Nearly all the cases were of pure bubonic type. The severity of the cases seemed to depend on the number of bacilli present. Fever was always irregular. Cough was often noted with expectoration, sometimes muco-purulent. In grave cases death generally followed the third or fifth day of illness; death rarely occurred after the fifth day. All the epidemics in Angola have been preceded by a murine epizootic. There has been no evidence of the plague being of human origin.

An Epidemic of Acute Poliomyelitis in the Belgian Congo (J. Rodhain).—The epidemic of poliomyelitis prevalent in the Belgian Congo towards the end of 1919 and beginning of 1920 clinically and experimentally resembled Heine-Medin disease. It was characterized by a mortality of 27 per cent., and by the considerable proportion of the total of adults affected, 23·9 per cent. Without excluding the possibility of an exogenetic origin, it is probable that it resulted from the extension of one of the endemic centres existing in the region of Mayumbienne, Southern Congo. Malaria is not a predisposing condition of poliomyelitis, but human trypanosomiasis, on the contrary, seems to create a special receptivity for Heine-Medin disease.

This volume contains many other very interesting papers on tropical subjects by well known authorities.

NOTES ON THREE NEW YEAST-LIKE ORGANISMS AND A NEW BACILLUS, WITH REMARKS ON THE CLINICAL CONDITIONS FROM WHICH THEY HAVE BEEN ISOLATED: — FURUNCULOSIS BLASTOMYCETICA, MACROGLOSSIA BLASTOMYCETICA, STOMATITIS CRYPTOCOCCOBACILLARIS.

By ALDO CASTELLANI, C.M.G., M.D., F.R.C.P.

Director of Tropical Medicine and Dermatology, Ross Institute, London.

(1) YEAST-LIKE ORGANISM FROM CASES OF FURUNCULOSIS BLASTOMYCETICA (FURUNCULOSIS CRYPTOCOCCICA, PSEUDO-FURUNCULOSIS BLASTOMYCETICA, FURUNCULOSIS MONILIACA, FOLLICULITIS DECALVANS CRYPTOCOCCICA).

Three years ago I described a peculiar type of blastomycosis indistinguishable clinically from ordinary furunculosis, which I called at the time "Furunculosis cryptococcica," and as the condition in the first two cases principally affected the scalp under the form of a purulent folliculitis and loss of hair I suggested also the term "Folliculitis decalvans cryptococcica" for it. To date I have seen five cases; three contracted the infection in Great Britain and two in India. The strains of fungus isolated from the English cases are all identical; the strains isolated from the Indian cases are somewhat different from the organisms grown from the English cases, and differ also, though slightly, among themselves.

Description of the Organism (English cases).—Morphologically a yeast-like organism, Gram-positive, not acid-fast. The individual cells are somewhat rounded or oval. Maximum diameter of most cells 3 to 4 microns. The fungus is seldom detected microscopically in the pus of the boil-like lesions, staphylococci being generally present in very large numbers; cultural methods are necessary; the cultures from the pus as a rule look like cultures of *Staphylococcus aureus*. It may be necessary to make a dozen or more preparations from what looks a pure staphylococcus growth to find a few yeast-like cells. By plating and replating on glucose agar media the fungus is finally isolated.

Cultural and biochemical characters. — The fungus grows abundantly on *glucose agar* and grows also well, though less abundantly, on ordinary agar. The cultures on glucose agar are at first white, but after a few days show a characteristic yellowish- or yellowish-brownish pigmentation. Gelatine and serum are not liquefied.

Lead agar is not darkened during the first two weeks; later a slight darkening may take place.

Sugar peptone-waters.—The fungus when recently isolated has very little or no fermentative action on any sugar; it may produce a slight acidity in glucose and levulose, very seldom a slight amount of gas. When the fungus has been transplanted several times its fermentative action is greatly increased and it generally produces acid and gas in glucose and levulose and occasionally slight acidity in galactose; it does not form gas in any other sugars (see table I).

Litmus Milk.—The medium is not clotted, a slight acidity may be present.

Agglutination.—The fungus is agglutinated by the patient's blood in certain cases up to 1 in 400.

Ascospores, mycelium.—I have never observed asci even in very old cultures; mycelium in small amount is not rarely present in certain media, especially fluid media.

Classification.—This fungus, consisting of rather large roundish cells, some of which are budding, comes under the general heading "Yeast-like Fungi" or *Blastomyces sensu lato*, of which two large groups may be distinguished:

(*a*) Asci present.
(*b*) Asci absent.

The fungus is yeast-like, but no ascus formations are seen even in very old cultures. It should therefore be placed in the division of yeast-like fungi with no ascospores. This division, or to be more correct, family (Cryptococcaceæ Kützing 1833), contains the genera *Cryptococcus* Kützing 1833, *Torula* Persoon 1801, *Mycoderma* Persoon 1822, *Monilia* Persoon 1797, *Pityrosporum* Sabouraud 1895, which may be differentiated as follows:

(A) MYCELIUM ABSENT:

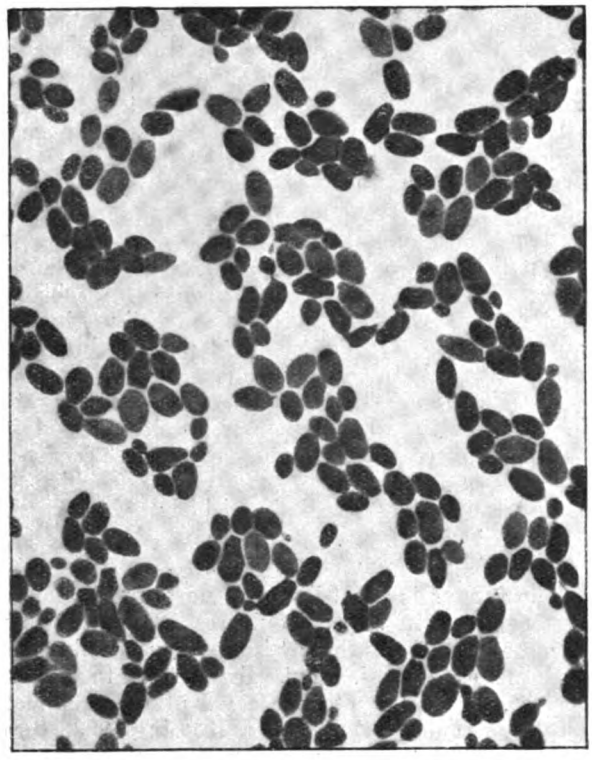
(i) Vegetative cells, elongated, in fluid media thick membrane, with bubbles of gas—*Mycoderma*.

(ii) Vegetative cells, roundish or oval.

(*a*) *Several buds at a time*, each cell contains large globule of fat, non-pathogenic, no fermentation of sugars, thick membrane with no gas bubbles, often pigment-producing—*Torula*.

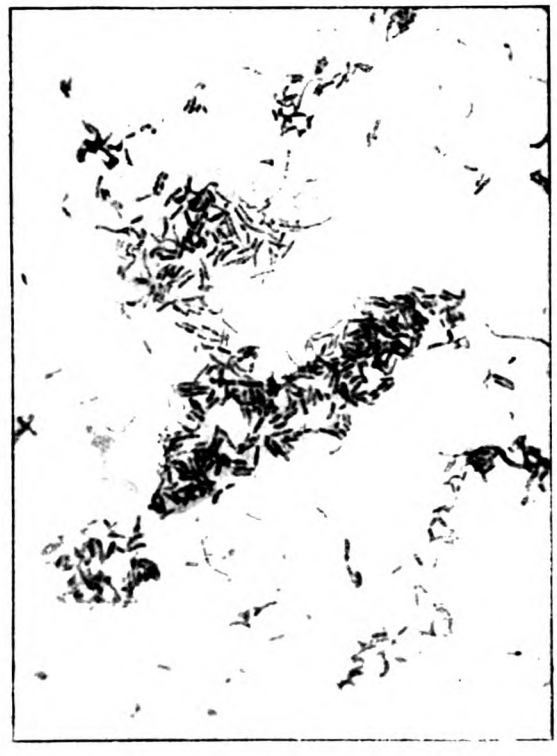
(*b*) *Monobudding*, no thick pellicle on fluid sugar media, presence or absence of fermentation—*Cryptococcus*.

(*c*) *Not cultivated*, cells never show a double contour—*Pityrosporum*.



(B) MYCELIUM PRESENT.—*Monilia*.

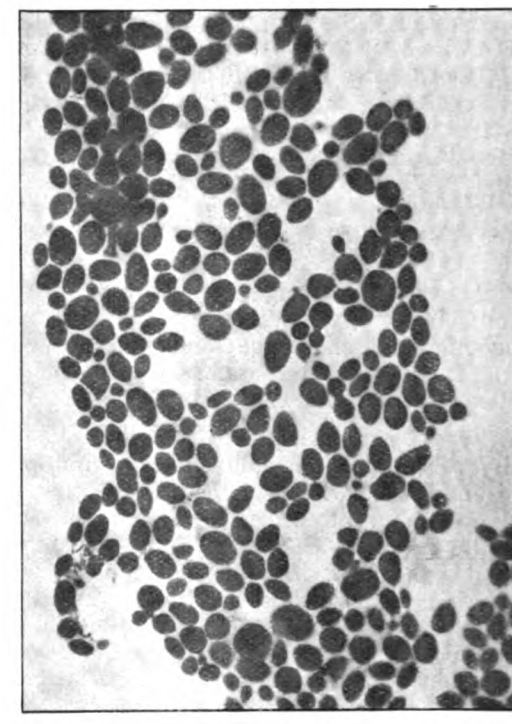
Our fungus presents, when grown on certain media, especially fluid media, a slight amount of mycelium, therefore its correct botanical position is probably in the genus *Monilia* rather than in the genus *Cryptococcus* in which I at first placed it.[1]



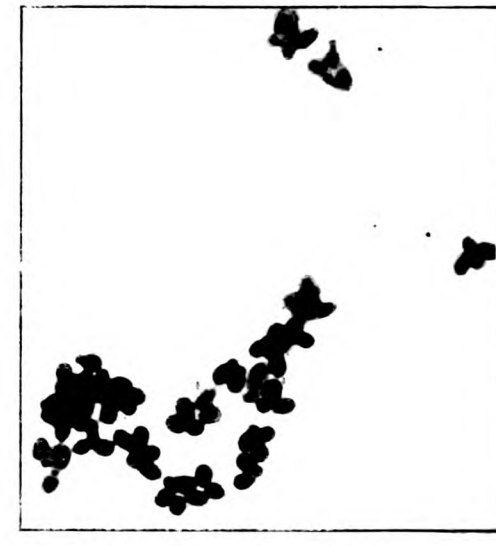
SYMPTOMATOLOGY OF FURUNCULOSIS BLASTOMYCETICA (PSEUDO-FURUNCULOSIS MYCETICA *vel* MONILIACA

[1] In practice an elaborate botanical classification of the yeast-like fungi is not necessary, and for ordinary purposes I have found the following scheme useful for the classification of these organisms:—

(*a*) Asci present	Mycelium absent—*Saccharomyces* sensu lato.
	Mycelium present—*Endomyces* sensu lato.
(*b*) Asci absent	Mycelium absent—*Cryptococcus* sensu lato.
	Mycelium present—*Monilia* sensu lato.



Cryptococcus macroglossiæ Castellani. × 1280.



Bacillus vermiculoides Castellani. × 1280.

vel CRYPTOCOCCICA, FOLLICULITIS DECALVANS CRYPTOCOCCICA).—The clinical picture of this condition is totally different from the usual types of blastomycosis cutis which are characterized by the

Yeast like fungus from pseudo-furunculosis blastomycetica × 1280.

Cryptococcus graciloides Castellani. × 1280.

presence of patches with vegetating papillary excrescences which give them a characteristic verrucose or warty appearance. Furunculosis blastomycetica is clinically indistinguishable from ordin-

ary severe furunculosis. Boils, indistinguishable from ordinary boils, may be present on the face and body, but the region, as a rule, mostly affected is the scalp. In this region numerous pustules, flattened or conical, each pierced by a hair, may be seen; in addition there may be infiltrated lesions

Yeast-like fungus isolated from a case of furunculosis blastomycetica. Glucose agar culture.

somewhat resembling flat carbuncles, which later on open and discharge through several openings. The hair in the affected areas falls off and patches of baldness, sometimes permanent, remain. The treatment I have found most useful is to give large doses of potassium iodide; vaccines prepared with the fungus seem to be useful. Staphylococcus vaccine has no action on the condition, and this shows that the fungus, and not the staphylococcus which is found in practically all the lesions together with the fungus, is the real causative agent of the condition.

(2) Yeast-like Organism from a Case of Macroglossia Blastomycetica (*Cryptococcus macroglossiæ*, *Monilia macroglossiæ*).

In Ceylon during the period 1903-1915 I observed three cases of a peculiar type of macroglossia of blastomycetic origin. Two years ago an interesting case of macroglossia of the same type was kindly sent to me by my friend Dr. Broughton Alcock,

Macroglossia blastomycetica.

and in this case, too, I isolated a yeast-like organism. A full account of the case from a clinical point of view will be given at an early date by Dr. Alcock and myself.

Description of the Organism.—Yeast-like fungus, Gram-positive, not acid-fast. The individual cells are oval, of rather large dimensions, the maximum diameter varying between 4 and 5 microns.

Cultural and Biochemical Characters.—Glucose agar.—Abundant growth, smooth surface, white colour.

Ordinary agar.— Same characters as on glucose agar, but less abundant.

Glycerine.—Not liquefied.

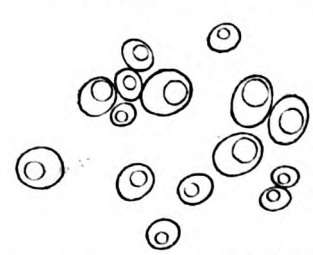
Serum.—Not liquefied.

Sugar Peptone Waters.—Does not produce gas in any sugar or other carbohydrate. Very rarely it may produce a slight amount of acidity in glucose.

Litmus Milk.—No change.

Agglutination.—Agglutinated by the patient's blood (1 in 400); not agglutinated, or only very slightly so, by the blood of patients suffering from furunculosis blastomycetica.

Presence of Asci and Mycelium. Asci have never been observed even in very old cultures; a little mycelium is not rarely visible in certain cultures, especially in fluid media. It is, therefore, probably more correct to place this fungus in the genus *Monilia* instead of the genus *Cryptococcus* as I originally did. If we place it in the genus *Monilia* it belongs to the *zeylanica* type (absence of gas in every sugar); it differs from *Monilia zeylanica* in not producing pigment, the cultures of *Monilia zeylanica* being yellow. The correct name for the organism would be *Monilia macroglossiæ* Castellani (syn. *Cryptococcus macroglossiæ* Castellani).



Remarks on macroglossia blastomycetica.—The whole tongue is very greatly enlarged, occasionally painful; the patient feels discomfort in eating, may have some difficulty in speaking; he cannot whistle. It may be very difficult to make the clinical diagnosis of blastomycetic macroglossia, as the tongue, though very greatly enlarged, may show almost complete absence of verrucoid patches so typical of blastomycosis. Deep scrapings should be made from the tongue after drying and painting with tincture of iodine, and cultures made. The finding of yeast-like organisms in superficial scrapings of the tongue has no importance as these fungi are not rarely found in that situation even in normal mouths. Potassium iodide has a very beneficial effect on the condition. Vaccines prepared with the fungus seem to be useful.

(3) Yeast-like Fungus and Bacillus living in Symbiosis, isolated from cases of Peculiar Mycotic Stomatitis.

From certain cases of stomatitis, clinically totally different from thrush, I have isolated a fungus and a bacillus which apparently live in symbiosis, both in the lesions and in cultures. In glucose agar cultures a number of minute almost streptococcus like colonies will be seen. The microscopical examination of any of these colonies will show presence of both the delicate yeast-like fungus and the bacillus. For many months I did not succeed in separating the two organisms by plating and various other devices. I noticed that a high temperature

A = acid. G = gas. O = absence of gas or coagulation. C = presence of clot. + = positive. S = slight.

(37° C.) increased the growth of the bacillus, while a low temperature was somewhat unfavourable to it. I noticed also that in McConkey lactose agar tubes, the fungus had a tendency to become more abundant, while the bacillus had a tendency to become more scanty. Making use of these two observations by repeatedly inoculating McConkey lactose agar and keeping some of them at 37° C., others at 15-22° C., I succeeded finally in separating the two organisms, of which I will give here a brief description.

(A) Yeast-like Fungus (*Cryptococcus graciloides* n. sp.).—Very delicate yeast-like organism, Gram-positive, not acid-fast. Each cell is roundish or more often oval, with frequently a flask-like shape. In preparations from the cultures the average maximum longitudinal diameter of most cells is 3 to 4·5 microns, and the maximum average transverse diameter is 2 to 3 microns.

Cultural and Biochemical Characters.—Glucose Agar.—Minute colonies somewhat streptococcus-like.

McConkey Lactose Agar.—Minute colonies, but growth often more abundant than on glucose agar.

Gelatine and Serum.—Growth exceedingly scanty; neither of the media is liquefied.

Lead Agar.—No evident darkening of the medium.

Glucose and Other Sugar Peptone Waters.—Apparently no production of acidity or gas, but the organism grows extremely scantily in these media, and sometimes no growth at all takes place.

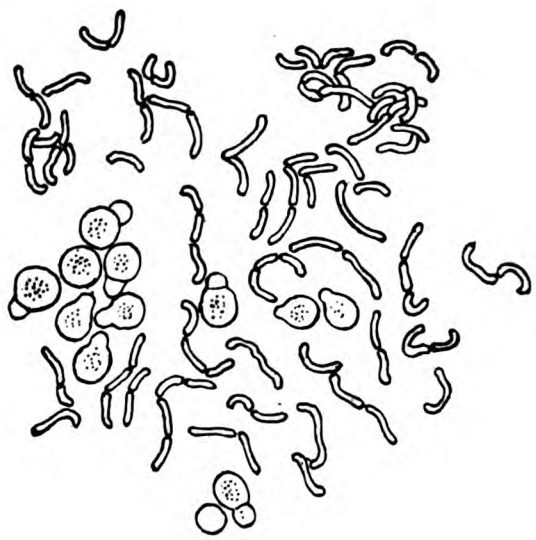
Classification of the Organism.—As the fungus is morphologically yeast-like, it comes under the general heading "Yeast-like Fungi," the classification of which I have briefly described in the first section of this paper.

This yeast-like fungus never shows presence of asci, mycelium is completely absent, the budding takes place by one budding at a time; the organism does not produce a thick pellicle in fluid-sugar media; it should therefore be placed in the genus *Cryptococcus*. The peculiar flask-like appearance often shown by this fungus might be an argument to place it in another genus, the genus *Pityrosporum*, which is said to differ from the genus *Cryptococcus* as follows:

(1) The vegetative cells have a flask-like appearance and do not show a well-marked double contour. (2) It has not been cultivated.

The genus *Pityrosporum* Sabouraud, 1895, contains two species, *Pityrosporum ovale* Bizzozzero, 1882, and *Pityrosporum cantliei* Castellani, 1908. Morphologically the fungus I have isolated is very similar to *P. ovale*, but it differs from it in the fact that it is of smaller dimensions and is cultivable, and, moreover, certain cells may show a double contour. In my opinion the fungus should be placed in the genus *Cryptococcus*.

Bacillus vermiculoides n.s.—This bacillus apparently lives in symbiosis with the *Cryptococcus* I have described; I have separated the two organisms with great difficulty, but I now have pure cultures of both. The bacillus is of rather large dimensions, its length varying between 2 and 6 microns; it is often curved in shape. It is Gram-positive, not acid-fast. The optimum temperature seems to be 37 C., but may grow, though much less abundantly, at much lower temperature, 22 C. and even less.

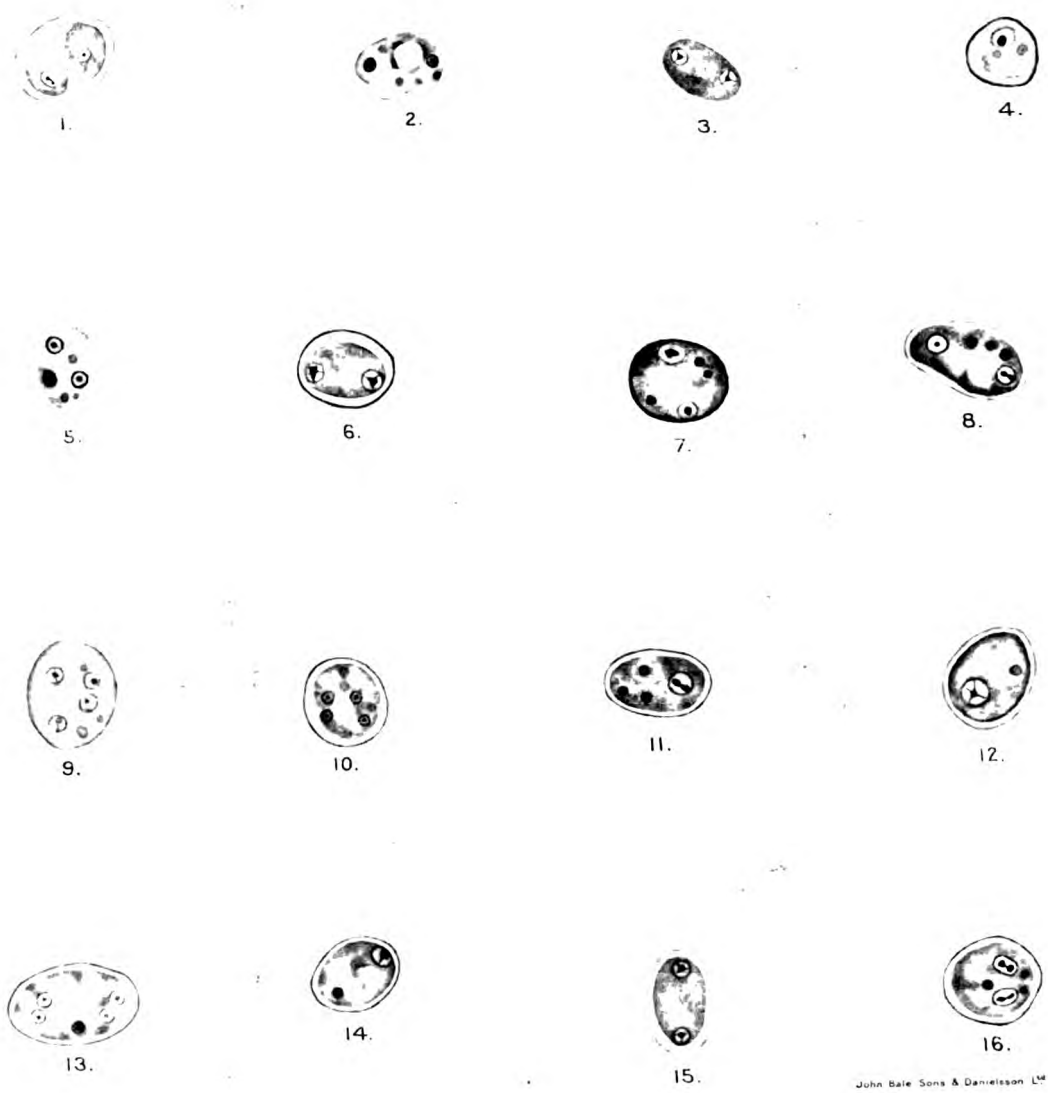


Glucose Agar.— Minute colonies somewhat resembling those of certain streptococci.

Gelatine.—Growth very scanty or absent altogether, no liquefaction.

Serum.—No liquefaction of the medium.

Sugar Peptone Waters.—It produces acidity, but no gas in glucose, levulose, maltose, galactose and lactose. There is usually no change in the other sugar-peptone waters.



Litmus Milk.—The medium is rendered acid and after a time may become clotted.

Symbiosis of *Cryptococcus graciloides* and *B. vermiculcides*. (From glucose-agar culture.)

Biochemical Reaction of the Associated Organisms.—When sugar media are inoculated with a mixed cryptococcus—bacillus culture, acid and gas are produced in glucose and levulose; only acidity in lactose, maltose and galactose; litmus milk is rendered acid and clotted.

Remarks on the Stomatitis from which Cryptococcus graciloides and Bacillus vermiculoides have been isolated.—The appearance of the lesions is quite different from thrush. The patches, which are generally of large dimensions, are hardly raised at all, and are not cream-white; they have the appearance of a thin translucid whitish film covering parts of the oral mucosa, occasionally giving the impression of being patches of incipient diffused leukoplakia, but the microscopical examination of scrapings will clear the diagnosis. The

To illustrate article on "The Cysts of *Tricercomonas intestinalis* Wenyon and O'Connor 1917 found in Human Faeces," by J. G. THOMSON, M.A., M.B., Ch.B., and ANDREW ROBERTSON, M.B., Ch.B.

first two cases of this stomatitis I observed in Central America; very recently I have seen a case of the same, or of a very similar condition, in England, but the investigation of this case has not yet been completed.

THE CYSTS OF *TRICERCOMONAS INTESTINALIS* WENYON AND O'CONNOR 1917 FOUND IN HUMAN FÆCES.

By J. G. THOMSON, M.A., M.B., Ch.B.
Director of Protozoology, London School of Hygiene and Tropical Medicine,
AND
ANDREW ROBERTSON, M.B., Ch.B.
Assistant in Protozoology, London School of Hygiene and Tropical Medicine.

INTRODUCTION.

THE cysts of *Tricercomonas intestinalis* were found in large numbers in the stools of a case convalescent from sprue. The patient was under the care of Dr. P. Manson-Bahr, to whom the authors are desirous of expressing their appreciation of his kindness in giving them access to the material for examination. The patient had returned fairly recently from India, where he had been stationed in the neighbourhood of Madras.

As the cysts of this minute human parasite have been recorded only on four occasions, viz., by Wenyon and O'Connor (1917), Jepps (1921), Lynch (1922), and Boeck (1924), a further description of their morphological characters seems to fulfil a useful purpose, as, owing to their large numbers in the present case, it has been possible to study them carefully, and thus confirm the observations of others. There seems little doubt that many cases of infection with this parasite must fail to be diagnosed, as the cysts especially are small in size and can be easily overlooked.

Wenyon and O'Connor, in their original description of the genus *Tricercomonas*, mentioned cysts which occurred in a case infected with this flagellate, and suggested their association one with the other. Jepps and Lynch both described the cysts in connection with the flagellate, and finally Boeck definitely established the relationship by obtaining the cysts in cultures of the flagellate on Locke's egg-serum medium.

DISCUSSION REGARDING THE GENUS *Tricercomonas* AND CERTAIN DOUBTFUL GENERA AND SPECIES OF FLAGELLATES DESCRIBED AS OCCURRING IN THE INTESTINE OF MAN.

The following free flagellates have been named and described as genera and species occurring in human fæces:—

Enteromonas hominis da Fonseca 1915, *Octomitus hominis* Chalmers and Pekkola 1916, *Monocercomonas* Chatterjee 1917, *Trichomastix hominis* Chatterjee 1917, *Tricercomonas intestinalis* Wenyon and O'Connor 1917, *Diplocercomonas soudanensis* (*Dicercomonas soudanensis*) Chalmers and Pekkola 1919, *Enteromonas bengalensis* Chatterjee 1919.

With the exception of *Enteromonas hominis* and *Tricercomonas intestinalis* the above have been found and described once only, and it is felt that, in view of the extreme difficulty of studying accurately such small flagellates, and the fact that the original descriptions and figures of the various authors are not so convincing as they might be, it is impossible to accept these as true genera and species until further observations of a confirmatory nature have been made. The genus *Enteromonas*, on the other hand, was created by da Fonseca in 1915 for an intestinal flagellate found in the fæces of a woman in Brazil, and since then has been described on several occasions. Chalmers and Pekkola have recorded four cases: (1) in the fæces of a woman in Khartoum (1917), (2) in the case of a British officer at Omdurman (1918), (3) in a Sudanese soldier at Omdurman (1918), and (4) in a male Sudanese convict in the central prison of Khartoum North (1918). Noller (1921) reports one case. Da Fonseca and Chalmers and Pekkola are in agreement that the flagellate is small in size, oval, rounded or irregular in shape with alveolated cytoplasm. The oval forms are about 5·5 microns long by 4 microns broad, while the rounded forms are 4 microns to 4·5 microns in diameter. There are three anterior flagella, two of equal length and one longer, and all are directed forwards. Chalmers and Pekkola describe two blepharoplasts—one, from which the two equal flagella take origin, slightly anterior to the other, which serves as the point of origin of the single long flagellum.

More recently Lynch (1922) described an *Enteromonas* from a guinea-pig (*Enteromonas cavix* Lynch 1922) with three anterior flagella, two shorter ones directed anteriorly, and a third longer flagellum directed posteriorly but not attached to the body, which he was able to compare with a *Tricercomonas* from a human patient. The *Tricercomonas* was somewhat similar in general appearance to the *Enteromonas* in the guinea-pig, but had four anterior flagella, three of which were directed forwards, while the fourth, rather longer than the others, was recurrent, and was attached to the surface of the body for about three-quarters of its length. Lynch succeeded in cultivating both these organisms.

This work of Lynch is of importance because Dobell and O'Connor (1921), from an examination of the literature and the drawings given by the various authors, arrived at the conclusion that *Tricercomonas intestinalis* Wenyon and O'Connor 1917 was identical with *Enteromonas hominis* da Fonseca 1915, and, while accepting the description of Wenyon and O'Connor as the correct one, placed their name *Tricercomonas intestinalis* as a synonym. Dobell and O'Connor have gone still further and have grouped under the name *Enteromonas hominis* the entire list of flagellates given at the beginning of this section. This well-meaning attempt on the part of these authors to simplify the position with regard to this group of flagellates

has really resulted in a greater degree of confusion, and is quite unjustifiable. Until the original preparations on which these genera and species were created are re-examined and redescribed, or until confirmation is arrived at by other means, these genera and species with their descriptions must stand. It is particularly desirable that the original films, if these are still available, should be studied again, as it is quite probable, given that the original descriptions have been inadequate or inaccurate, that the various flagellates might be small races of well-known parasites such as *Trichomonas* or *Chilomastix* or even coprozoic organisms.

This discussion can be concluded by accepting *Tricercomonas intestinalis* Wenyon and O'Connor 1917 as a definitely described intestinal parasite of man, which has been reported, including the present case, on seventy-six occasions. The cysts have been seen in five cases associated with the vegetative forms. *Enteromonas hominis* da Fonseca 1915, *Octomitus hominis* Chalmers and Pekkola 1916, *Trichomastix hominis* Chatterjee 1917, *Monocercomonas* Chatterjee 1917, *Diplocercomonas soudanensis* Chalmers and Pekkola 1919, *Enteromonas bengalensis* Chatterjee 1919, are regarded as doubtful genera and species.

Neither in the paper by Kofoid, Kornhauser and Plate (1919), nor in the one by Kofoid and Swezy (1920), was it stated whether the diagnosis was made on the presence of cysts or free forms.

DESCRIPTION OF THE FREE FORMS.

The morphological characters of this flagellate have been described by Wenyon and O'Connor, and their observations have been confirmed and amplified by Lynch (1922), Jepps (1923), and Boeck (1924). The habitat is probably the lower intestine (*vide* Lynch 1922).

The shape of the body varies according to the angle from which it is viewed. The contour is roughly pear-shaped, the anterior end being rounded and the posterior extremity drawn out to a point, but while one side is convex the other tends to be flattened and possibly has a longitudinal groove. The free forms are extraordinarily active, and, in addition, the body is remarkably mobile, both Jepps and Boeck having described it as extremely amœboid or plastic. The measurements in the long axis have been given as between 4 microns and 10 microns, and probably the largest number are about 7 microns or 8 microns long. The breadth varies from 3 microns to 6 microns.

The nucleus is single, vesicular, spherical or ovoid, and measures from about 1·5 microns to 2 microns in diameter. Jepps, Lynch and Boeck all show in their drawings a centrally placed karyosome, small in size and generally in a single mass, although sometimes it may be divided into two or three granules. Variations in the size of the karyosome have been depicted, but this is possibly due to imperfect differentiation.

Two blepharoplasts have been noted near the nucleus. In one of these, which is situated slightly anterior to the other, three flagella of equal length arise and are directed forwards. The fourth flagellum takes origin from the more posterior of the blepharoplasts, curves backwards and runs along the flattened lateral margin towards the posterior extremity, when it becomes free for a very short distance. According to Lynch this posteriorly-directed flagellum appears to be attached to the body for about three-quarters of the body length, whereas the figures of Wenyon and O'Connor, Jepps, and Boeck seem to indicate that it may be adherent throughout the entire length of the body.

In the present case only a few examples of the free forms were found in stained preparations, and, although these were insufficient for further morphological observations, they were easily identified as the free forms of *Tricercomonas*, and thus could be associated with the numerous cysts present.

THE CYSTS.

In all the specimens examined from this case the cysts were very numerous, and were carefully studied in normal saline, in iodine solution, and in fixed and stained preparations.

They were most commonly oval in outline with a distinct cyst wall, but many distorted forms were seen. They varied in length between 6 microns and 8 microns, and in breadth between 4 microns and 6 microns. The average size was 7 microns by 5 microns. These measurements are in accordance with those of previous observers.

The cytoplasm is finely granular, and may be vacuolated (figs. 2, 4, 7, 8, 10, 11, 13, 14 and 16). In some of the cysts (figs. 1 and 9) the cytoplasm has an appearance suggestive of its being divided into two portions, as if the body substance divided along with the nuclei.

Included in the cysts were certain bodies more or less rounded in outline and highly refractile when examined in the fresh unstained condition, suggestive of chromatoid material (figs. 2, 4, 5, 7, 8, 9, 10, 11, 12, 13, 14 and 16). In iodine solution, however, they became brown in colour. Fixed and stained in Ehrlich's acid or Heidenhain's iron hæmatoxylin they became almost black, but were comparatively easy to decolorize during the process of differentiation, more so than the chromatoid bodies of amœbic cysts. When the specimens stained in Ehrlich's acid hæmatoxylin were differentiated and counte

stained in eosin, it was found that these round bodies had taken up the pink of the eosin more intensely than any other part of the cell. The nature of these inclusions seems to suggest volutin. They were not constantly present, but the majority had a varying number in their cytoplasm, sometimes so numerous as to completely obscure the other contents. Boeck (1924) drew attention to these granules in the cyst, and depicted them in his drawings.

The nuclei, which were situated at the ends of the cysts, numbered one, two or four. The binucleate forms predominated; indeed the uninucleate and quadrinucleate forms were somewhat difficult to find. The nuclei were spherical, vesicular, and had a well-marked nuclear membrane. The karyosome was usually small, rounded, and consisted of a single mass from which fine threads could be made out radiating to the nuclear membrane (figs. 3, 6, 8, 12, 14 and 15). In a fair proportion of the cysts, especially the binucleate forms, the karyosomes were frequently dumbbell-shaped (figs. 1, 7, 8, 11 and 16). This was noted by Wenyon and O'Connor. No nuclear chromatin could be made out apart from the karyosome, but the nuclei were so very small that it is impossible to be certain on this point.

DESCRIPTION OF PLATE.

Cysts of *Tricercomonas intestinalis* Wenyon and O'Connor 1917, stained with Heidenhain's iron hæmatoxylin or Ehrlich's acid hæmatoxylin and drawn at a magnification of 2,000 diameters (approx.).

1. Binucleate cyst. Shows a well-marked dividing line in the cytoplasm, as if the contents of the cyst were differentiated into two parts. One of the nuclei shows the dumbbell-shaped karyosome.

2, 5, 7, and 8. Binucleate cysts showing the peculiar granular inclusions. In 8 one of the nuclear karyosomes is dumbbell-shaped.

3, 6, and 15. Cysts which have each two nuclei in which fine threads, probably of linin, can be made out between the karyosome and the nuclear membrane.

4. Small cyst, uninucleate. Probably an oval cyst seen end on.

9, 10, and 13. Four nucleated cysts each of which show the characteristic inclusions. In 9 the contents appeared to be separated into two portions.

11, 12, and 14. Uninucleated cysts. 11 shows the dumbbell-shaped karyosome. 12 shows the threads radiating from the karyosome. 14 shows the karyosome very eccentrically placed; this is rather unusual.

16. Binucleated cyst with inclusions. Both nuclei have karyosomes elongated and constricted in the middle.

THE TREATMENT OF BLACKWATER FEVER.

By Charles Lewis Trout, M.D.

General Remarks.

The African Inland Mission is conducting missionary work in Kenya Colony, Tanganyika Territory, Congo-Belge and the French Sudan. My work as a medical missionary was in the Belgian Congo under this mission. Within six months of my arrival, I came down with blackwater fever. Thus, the study of this condition was impressed upon me.

From the first, I began to search for a more reliable treatment than the one we were using in our mission. The treatment given in this article is the result.

During my five and a half years of practice in the Congo, four missionaries died from blackwater fever. All these received the Hearsey solution (one-thirtieth grain bichloride of mercury and ten grains of bicarbonate of soda) plus hypodermoclysis and good nursing. Three of these died during the second attack; one during the first attack. The latter had been in the Congo five years and took five grains of quinine daily. The others used quinine about once or twice a week. Our study of the disease covers the history of thirty-four cases with twelve suffering a second attack. Seventy-five per cent. of these patients took quinine daily. All cases had what might be called an exciting cause. One woman came down with hæmoglobinuria after a violent mis-

carriage. The majority gave a history of over-exertion under a hot tropical sun followed by sudden chilling. Most of our cases followed a visit to our main station in the Congo.

This station, Aba, is situated in the northern and eastern part of the Belgian Congo near the English Sudan. The altitude of this station is a little over 3,000 ft. A rocky hill rises some 200 ft. above the surrounding plain. The mission is located upon this hill. Much time and money have been expended in an effort to make the hill mosquito proof. Every prophylactic measure is being used by the missionaries to prevent malaria fever. Nevertheless, Aba continues to be an endemic centre for blackwater fever.

Because of these facts, we thought there might be a specific cause for this malady. All our cases have shown a history of malaria fever usually subtertian in type. All have had a low percentage of hæmoglobin, but we have been unable to discover any specific cause.

Prophylactic Measures.

Personal Hygiene: Clothing.—Dress for the weather and for the time of day. Use silk woollen underwear. Keep the abdomen warm. Put on heavier garments for evening.

Bathing.—Never take cold baths in the tropics. Use warm or hot water. Bathe in the early afternoon and have the room warm.

Sun.—Avoid exposure to the sun during the heat of the day, 11 a.m. to 2 p.m. Wear a good helmet when in the open from sunrise to sunset.

Refrigeration.—Be careful of exposure to weather changes. Change clothing whenever dampened by perspiration from exercise. Guard against getting chilled.

Fatigue.—Avoid over-exertion while walking, overwork and anxiety of all kinds.

Diet.—Do not eat too much meat. The tendency in the tropics is to have meat at all meals. With proper planning vegetables can be had throughout the year in nearly all parts of Central Africa. Have salads of lettuce, cabbage, fruits, once or twice daily. Beets, carrots, squash and potatoes can be grown. Greens can be obtained from the natives. Use fresh fruits in season and have dried fruits on hand.

Malaria.—All evidence now seems to point to malaria as the main cause of hæmoglobinuria. The blackwater fever patient is one whose blood integrity has been lowered by repeated attacks of malaria invariably of the malignant tertian type. The chief contributing factors are over-exertion on safari, exposure to wet and cold, and lowering of vitality by some sudden acute illness.

Every means must, therefore, be used to prevent infection with the plasmodia of malaria. Dwellings should be mosquito tight, traps placed to catch the egg-layers, swamps drained, foliage near living quarters destroyed, and every known means used to exterminate and prevent the breeding of anopheles.

Cases suffering from malaria ought to be isolated in such a manner as to prevent mosquitoes from feeding upon them. Crude oil with some castor oil should be poured over pools that cannot be drained. The individual himself should be careful to have good mosquito boots and to use them, and to have a mosquito proof net in constant service. If one is reasonably sure they have not been bitten it may be all right to take quinine twice a week, but in badly infested areas it is better to take quinine daily. The best time to take quinine is at bedtime, and we advise five grains as the proper dose. Those who have had the blackwater fever should use quinine tannate. Every system of prophylactic quinine treatment has been used, and we have had missionaries develop the subtertian type of malaria even while taking the quinine.

Most important of all is the thorough and systematic Treatment of every Attack of Malaria Fever.

We recommend the following treatment of malaria:

(1) Give the patient one grain of calomel with ten grains of bicarbonate of soda.

(2) Inject intramuscularly five grains of quinine dihydrochloride. Observe strict asepsis.

(3) Give by mouth gelsemium tincture (P. D. and Co.) ten drops in one ounce of water one teaspoonful of this solution every fifteen minutes until the patient perspires or the physiological symptoms appear.

(4) Two hours after the hypodermic injection of quinine, start quinine by mouth. Use this prescription: Take

Quinine sulphate	1 oz.
Phosphate of iron	1 dr.
Sugar of milk	1 oz.

Triturate thoroughly and fill capsules with two grains of the mixture.

Every two hours for sixty consecutive hours give two capsules of the quinine and iron phosphate mixture. At close of this treatment and two hours after the last capsule give five grains of dihydrochloride of quinine intramuscularly.

(5) Take no quinine for five days. During this interval take Fowler's solution, two drops in water, morning, noon and night. On the sixth day, start the quinine and iron phosphate treatment again. This time do not take the intramuscular injections. Start treatment with the calomel and every two hours for sixty consecutive hours take two capsules of the quinine mixture.

Note.—Six hours after the calomel take a large dose of Epsom salts. Keep the bowels open during the treatment. It is well also during treatment to take every night one half-teaspoonful of bicarbonate of soda in water. The success of the treatment will depend upon the faithfulness of the patient in taking the quinine *every two hours for sixty consecutive hours*. This method has seldom failed. It should be repeated at least twice. After all cases of malaria the blood should be examined carefully and means taken to restore the number of corpuscles and the hæmoglobin to normal. Where possible the patient should be removed to a high altitude if the hæmoglobin percentage has fallen very low.

THE PROPER TREATMENT OF EVERY ATTACK OF MALARIA IS UNDOUBTEDLY THE BEST PROPHYLACTIC AGAINST BLACKWATER FEVER.

Patients having malarial fever should have the best possible protection during the period of chilliness. Use hot water bottles, hot drinks, blankets and hot enemata if necessary.

It is well to remember that the transition from the tropics to the temperate zone is trying on the person who has had blackwater fever and that one needs to be cautious about exposure to wet and cold for at least one year after their arrival in their own country.

Drug prophylaxis.—We advise a tonic tablet with the phosphates of iron, strychnia and hydrastin of each $\frac{1}{100}$ grain. This tablet is given after acute illness or whenever the blood is poor. The tablet is preferred in the tropics to liquid tonic as it is more compact and keeps well. Where high altitudes (over 6,000 ft.) are accessible it is best to have the patient, as soon as convalescence permits, removed to the higher elevation. Several of our cases have been sent to stations over 7,000 ft. and have remained on in the tropics for five years and never had any further trouble from blackwater fever. Of course they stayed in the highlands all of this time and were kept free of malarial fever.

TREATMENT IN DETAIL.

General Measures: *Rest.*—Absolute rest in bed. Keep patient quiet. Do not permit him to sit up as there is danger of heart failure. Use bed-pan.

Sick-room.—Keep it clean and well ventilated. Maintain an equable temperature.

Diet.—During the first twenty-four hours give fruit juice sweetened to taste. Orange juice is best. Tea may be given. One method of treatment is to use forty green coffee beans boiled vigorously for twenty to thirty minutes in a pint of water. This is drunk freely and frequently. We inject caffein instead. Give lots of fluids. After vomiting is controlled give liquid nourishment every two hours. Later every three hours. As patient improves, begin return to regular diet. Start first with barley water, then dilute milk (lime-water one part, milk two parts) sweetened to taste. Give orange juice or carbonated water to quench thirst. As stomach grows stronger give beef juice, chicken broth, gruels and solids. During convalescence the diet is also important and should receive study. We give vegetables and salads with a high iron content.

Baths.—To reduce temperature it is sometimes necessary to use wet-pack or blanket bath. These also help to improve the general system by their stimulating effect. Cold enemata may be used to lower fever.

Bowels and Kidneys.—Bowels should be kept open with enemata. For kidneys give plenty of fluids by mouth: barley water, weak infusion of cascarilla or orange juice, lime juice or egg-water. Hypodermoclysis: Salt solution subcutaneously or intravenously. Glucose (one dram to one pint of salt solution) may be given with advantage intravenously. Hot applications to the loins every fifteen minutes when suppression of urine is present.

Stomach.—Vomiting is one of the most troublesome symptoms. Mustard plaster over the pit of stomach. Adrenalin 1 : 1,000 solution two drops in a teaspoonful of water every fifteen minutes for a few doses or tincture of iodine in the same manner or in smaller dose. If unable to control vomiting resort to rectal feeding.

Routine Drug Treatment.—My experience has taught me that the care given in the first twelve hours will largely foretell the ultimate outcome. For sake of description we outline the treatment under the main symptomatic stages.

During Rigor.—Put patient to bed. Keep him quiet. Use blanket and hot water bottles. A hot salt solution enema should be given. At once inject contents of ampoule of any good anti-venom.

(*Note.*—We have used horse serum, anti-venom and bubonic plague serum, in fact any serum available, but our experience would indicate that *if there is any specific remedy it is a serum prepared by immunizing the horse against the virus of the rattlesnake.* A drug-house in New York puts out ampoules of rattle-snake virus in solutions of $\frac{1}{100}$ gr. This diluted virus alone is superior to all ordinary serums but inferior to anti-venom. Cases receiving horse-serum plus the rattle-snake virus (crotalin) showed better response than those receiving the anti-venom. Thus, it would seem that a serum prepared by immunizing the horse against the virus of the rattle-snake would be the ideal preparation.)

Spirits of camphor with small amount of whisky in hot water may be given to help patient over the cold period.

During the Hæmolytic Stage.—It is a debatable question as to how long the hæmolysis lasts, but from the standpoint of treatment it is practical to consider this stage as existing from the start of the chill to the time when the urine clears and ceases to show hæmoglobin. If the horse-serum or anti-venom has not been administered during the chill give it now. In fact the first thing to do when called to see a victim of blackwater fever is to inject the serum. If possible give anti-venom, or if this cannot be obtained give any serum available. If the course of the disease has run itself out and the urine is clear I would not give the serum but examine the blood and institute treatment to replenish it. Now is the time for hypodermoclysis and intravenous injection of salt solution. We use Parke, Davis & Co.'s salt tubes. These are convenient for the ready preparation of salt solution. I usually inject 50 to 100 c.c. of salt solution intravenously and then give more slowly a pint to a quart subcutaneously. After the serum and salt solution have been given wait about an hour and give one ampoule of caffeinæ sodio-benzoatis 0·25 grm. subcutaneously.

If fever is high use drugs and general measures to reduce temperature.

As soon as these measures have been taken we

begin giving cantharides tincture five drops in a half-glassful of water to which a teaspoonful of baking soda has been added. Of this mixture we give two teaspoonfuls every half hour with plenty of water; that is, after the cantharides the patient is urged to drink as much water as he can. Under this treatment the urine often clears within an hour.

During Period of Icterus.—When urine clears and the jaundice develops give small doses of calomel and podophyllum. We follow the calomel with soap suds enemata.

Convalescence.—Use iron tonics and careful diet. Remove patient to the highlands as soon as permissible.

Special Symptoms.—For the heart the best drug is strophanthus tincture or small doses of the alkaloid. For the restlessness good nursing, frequent bathing or alcohol rubs if patient is hot. Intravenous injections of salt solution will help, also use of endocrine preparations, especially thyroid with parathyroid and pituitrin. Where the blood is badly thinned out and patient's condition is low use blood transfusion or intramuscular injections of washed corpuscles. These methods must be understood and proper precautions taken. As a tonic nothing has given us so much satisfaction as the combination of iron phosphate previously mentioned.

Travellers in the tropics should have the following drugs ready for emergencies: ampoules of horse serum, several ampoules of anti-venom (if a serum prepared against the rattle-snake virus or anti-venom can be obtained this is the preparation to have—it might be well to have ampoules of the crotalin on hand as this can be used if the patient is sensitive to horse-serum); cantharides tincture, strophanthus tincture, tubes for preparation of salt solution, hypodermoclysis outfit, good syringe with needles, tablets of the iron, strychnia and hydrastin phosphates.

Several cases in a moribund state receiving this treatment made remarkable recovery. Since giving the serum treatment no case has been lost. One case died but did not receive this treatment. I first started using serums in 1920, in well-selected cases. The results were always good.

Summary of Treatment.—(1) General measures: good nursing, proper attention to kidneys, bowels, heart, &c.; use of-salt solution; hypodermoclysis.

(2) Administer anti-venom or horse serum: one ampoule, repeat in case of relapse. In asthmatics use crotalin $\frac{1}{100}$ gr. if there is sensitivity to horse serum.

(3) Give by mouth plenty of fluids and inject subcutaneously 0·25 grm. caffeinæ sodio-benzoatis.

(4) Administer orally cantharides tincture: prepare as follows five drops in two ounces of water to which add one dram of sodium bicarbonate. Stir this mixture well and give two teaspoonfuls every half-hour until urine is normal.

(5) During icterus give calomel in small divided doses.

(6) During convalescence give iron tonics.

PRESENCE OF SPIROCHÆTES IN THE SPUTUM OF TUBERCULOUS PATIENTS.

By Professor F. Bezançon and Dr. E. Etchegoin.

THE presence of spirochætes in the hæmoptoic sputum of tuberculous patients has, up to the present day, never been recorded by any bacteriologist.

In the course of his researches on spirochætes in general, one of us observed in the hæmoptoic sputum of a tuberculous patient, some spirochætes in the very moment of the hæmoptysis, although these did not exist on the previous days.

This observation was the starting point of our present researches, pursued during our service at the Hôpital Boucicaut as well as at the Institut Pasteur.

The results of this first part of the work have been consigned in a note to the Société de Biologie, published on December 8, 1923.

To-day, the great number of sputa examined (239 examinations) allows us to state the following:—

(1) In sputum of tuberculous individuals, one can never find the type of spirochæte which is observed in the sputum of the same patients during an attack of hæmoptysis.

(2) This type of spirochæte has nothing in common with other spirochætes of the respiratory tracts.

The 239 samples of sputa with which the researches have been carried out are divided as follows:—

Sputa non-hæmoptoic containing bacilli of Koch	140
Sputa non-hæmoptoic not containing any bacilli of Koch	69
Hæmorrhagic sputa without bacilli of Koch from bronchial dilatation	2
Hæmorrhagic sputa containing bacilli of Koch from a slight accident of pneumothorax ...	1
Hæmoptoic sputa from individuals without any doubt tuberculous	27

The results obtained are the following:—

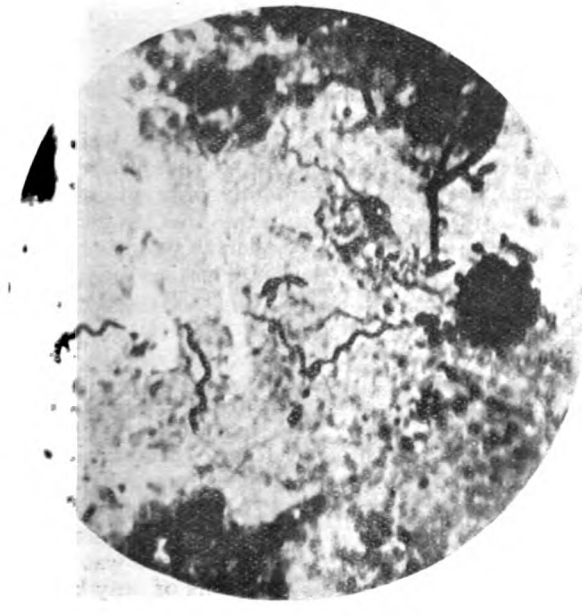
In non-hæmoptoic sputa, with or without bacilli of Koch, we have never found the spirochæte in question, nor any other kind of spirochætes. We have not found it in the hæmorrhagic sputum of bronchial dilatation.

In the case where the hæmoptysis came on as a slight mechanical accident after an injection of azote, during a therapeutical pneumothorax, the spirochæte was also absent.

Out of 27 hæmoptoic sputa of tuberculous origin, we have found spirochætes in 26 cases.

It must be noted that in the only case where the spirochæte was not found, there were no bacilli of Koch, neither at the direct examination, nor after homogenization, although, clinically speaking, the patient was tuberculous.

Let us quote the case of two patients whose sputa had been examined forty-eight hours previous to a hæmoptysis: these presented at the moment of examination five to six bacilli of Koch per field and spirochætes were completely absent; during the attack of hæmoptysis bacilli of Koch were not numerous, on an average one per field, but, on the other hand, one could find spirochætes in the proportion of six to seven per field.



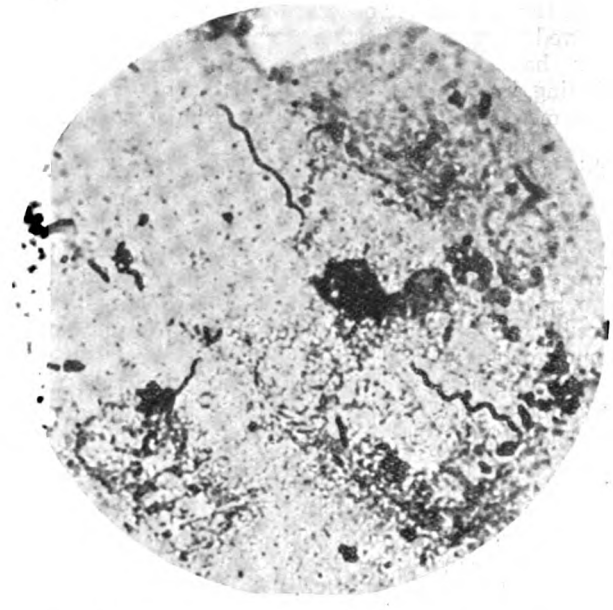
DIFFERENTIATION OF THE SPIROCHÆTA FOUND IN TUBERCULOUS HÆMOPTYSIS.

If the differentiation with the other spirochætes of the respiratory tract is not easy, in certain cases, in stained preparation or impregnated ones with silver, it is very easily made by using the ultramicroscope.

Sputa could be examined with the ultramicroscope, thanks to the following technique.

A small quantity of sputum is put in a tube containing about 1·5 c.c. of physiological salt solution; after shaking it well it is placed in the incubator at 29°, where it has to stay for thirty minutes. The biggest particles of the sputum form a sediment at the bottom of the tube, whereas the spirochætes float on the surface of the liquid.

After it has been taken out of the incubator, *without centrifuging*, a small drop is taken from the surface with the aid of a Pasteur pipette (very fine) and is examined with the ultramicroscope, using the usual technique.



Stained smears clearly show the morphological characters of the spirochæte. Loeffler's method of staining the flagella has given us the best results, but, in the technique of fixation alcohol ether must be used instead of osmic acid.

The microbe which we have found is a spirochæta about seven to fifteen microns in length. The length of the spiral is three microns.

The *Spirochæta dentium* is clearly shorter, narrower, and the spirals are much more close together.

The *S. bronchialis* of Castellani is narrower and has its extremities nearly square; its movements are much more lively; it traverses the field of the microscope within eight to ten seconds, whereas the spirochæte of tuberculous hæmoptysis is much slower; it takes it about thirty seconds to make the same distance. Finally, the spirochæte of the tuberculous hæmoptysis, instead of having jerking motions like the *S. bronchialis*, has an almost rectilinial march.

The *S. buccalis* has its body limited by two brilliant arrows; the central core only is transparent, whereas the spirochæte of the tuberculous hæmoptysis is uniformly brilliant. Morphologically it has no relation whatever with the spirochæte of the symbiosis fuso-spirillosis of Vincent.

We have tried to cultivate the spirochæte in culture media recommended for the spirochæte of the mouth and also for other spirochætes such as the *S. ictero-hæmorrhagia*: we could not obtain any results.

Although the classification of spirochætes be difficult, we think that this spirochæte must be considered as an intermediate type between the "*buccalis*" and the "*bronchialis*" of Castellani.

If the facts so far observed are confirmed and it is proved that the spirochæte which we have observed, can be seen only in tuberculous hæmoptysis, its finding, in the absence of the bacillus of Koch, might become of the greatest interest for the diagnosis.

On the other hand, we cannot yet say what part this spirochæte plays in the causation of the hæmoptysis itself. Is the spirochæte which we have described simply a witness of the hæmoptysis, or is it the cause of certain tuberculous hæmoptysis? We shall not be able to answer this question until we have succeeded in cultivating the spirochæte; a result which we have not yet reached in spite of all our efforts.

We are also investigating the relation that might exist between the presence of the spirochæte and the change of pH of the sputa.

BENEFICIAL ACTION OF RAW PANCREAS IN CERTAIN CASES OF SPRUE. INSULIN IN CASES OF SPRUE COMPLICATED WITH DIABETES.

By Aldo Castellani, C.M.G., M.D., F.R.C.P.
Director of Tropical Medicine and Dermatology, Ross Institute, London.

For many years various pancreatic preparations and extracts have been used in sprue, but I have seldom, if ever, seen any satisfactory results from their administration. Some years ago I tried giving raw pancreas in certain cases of sprue, but the climate of the country in which the experiments were carried out rendered it practically impossible to keep the gland fresh; I then suggested that pancreas should be added to liver in the preparation of the so-called liver soup so often prescribed by practitioners in the East. During the last two years I have carried out some further researches on the administration of raw pancreas in sprue in this country, and the results have been, on the whole, satisfactory.

The routine treatment I now use in most cases of sprue may be summarized as follows:—

(1) The patient is kept at complete rest in bed.

(2) Strict milk diet, diluting the milk at first with Vichy water or plain water.

(3) In most cases, bicarbonate of soda in rather large doses, gr. xxx, or 3i, t.d. or liquor potassæ well diluted.

(4) *Raw Pancreas.*—Sweetbreads from lambs or sheep, or calves are used. They must be absolutely fresh. The gland is minced in a clean bowl or similar receptacle, or may be passed through a mincing machine; the stringy parts are removed. At first a teaspoonful, and later a tablespoonful of the chopped mass including the juice is given once or twice a day; most patients like to swallow it down with a little milk. Provided the gland is absolutely fresh the taste is not nauseating and patients soon get used to it.

When raw pancreas is unobtainable I have tried the pancreas tablets and capsules (whole substance) of Armour and other well-known firms; their action cannot be compared with that of fresh raw pancreas but they seem to be useful. Two or more tablets are given three times daily.

Insulin in Cases of Sprue Complicated with Diabetes.

During the last two years I have had the interesting experience of having three cases of typical sprue presenting at the same time the classical syndrome of pancreatic diabetes. These patients had at times pale, frothy diarrhœa, at other times they were passing bulky solid or semi-solid whitish stools; in all of them the typical sore mouth of sprue was present. In addition to the sprue symptoms, they were passing a very large amount of sugar in the urine; there was polyuria, and severe thirst. The administration of insulin in all three cases made the sugar disappear from the urine while the treatment was kept up. As regards the symptoms of sprue (sore mouth and white diarrhœa) they were slightly benefited in one case (Case I); in the other two cases no amelioration was observed.

A prolonged parathyroid and calcium lactate treatment induced an apparent cure of the sprue symptoms in Case I; practically no improvement in Cases II and III and was discontinued. In Cases II and III the administration of raw pancreas was then resorted to; it induced a slow but progressive improvement, amounting to a clinical cure. I may add that the administration of raw pancreas without insulin never controlled the glycosuria.

Insulin in Sprue not Complicated with Diabetes.

A year ago I tried small doses of insulin in a case of typical sprue without complications. The analysis of the blood did not show any hyperglycæmia, and, therefore, only minute doses (1 or 2 units) were given by subcutaneous injection, and the patient was carefully watched. No untoward symptoms of any kind were noted, but no amelioration took place in the condition of the patient. An observation I made may be put on record: the insulin increased greatly the amount of urine the patient was passing. I must add that later on the patient got quite well, but the cure could not be ascribed to the insulin, as the amelioration began three weeks after the treatment had been discontinued, and the patient was kept on milk all the time. He had neither parathyroid nor pancreas.

Résumé and Conclusions.

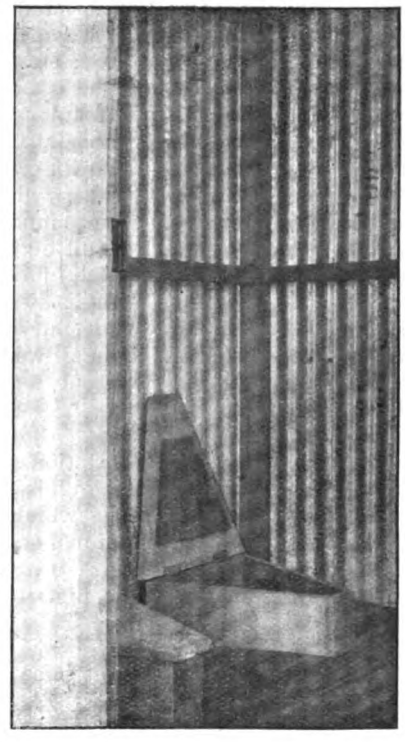
In some cases of typical sprue with copious white motions, sore mouth, &c., the administration of raw pancreas seems to be beneficial. It is true that all my patients were kept on a strict milk diet, and most of them had also an alkaline treatment; but my impression is that the administration of the raw pancreas accelerated the cure.

In three cases of sprue, complicated with typical

diabetes, the administration of insulin induced a disappearance of the glycosuria and polyuria, but had no distinct beneficial action—with the possible exception of one case—on the sprue symptoms. Raw pancreas given by the mouth (Cases II and III) appeared to beneficially influence the sprue condition, but did not control the glycosuria. In such cases, therefore, I advise insulin by subcutaneous injection, and the oral administration of raw pancreas.

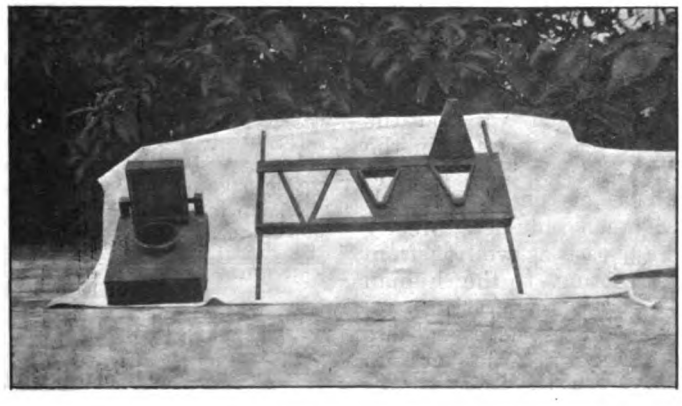
In conclusion, I should like to state that I do not consider the mere administration of raw pancreas to be a specific treatment for sprue, but I have found it beneficial, and I venture to recommend it as an additional therapeutic measure to be combined with the usual dietetic treatments; and I see no reason why it should not be combined also with Scott's parathyroid-calcium lactate method of treatment.

FLY-PROOF LATRINES FOR COLOURED PERSONS.



By G. A. Park Ross, M.D., D.Ph.
Assistant Health Officer for the Union of South Africa.

Most native races adopt the squatting posture with advantage to themselves.



In view of the conservative characteristics of coloured races it is useless providing latrines on European lines and expecting that such will be used.

Further, many native races are careless in their mode of using a latrine, and once such has become fouled it is not used. Also they are rightly particular that their person does not touch any part of a latrine which may have been touched by another person, and if latrines are to be provided which will be of any real service these points must be attended to.

These two patterns to my design are largely used in Natal, specially the pit privy one, the deck for which costs at a large wood-working firm approximately 16s. per aperture.

I attach a photograph showing construction of a pail pattern and the pit privy pattern. In each the receptacle projects some 4½ in. above the floor. In

I find that the essential element in promoting cleanliness is to have some portion of the latrine coming up between the legs and close under the buttocks, and also that when a latrine keeps itself clean there is no difficulty in enforcing its use always provided it is easy of access and close up to coolie lines, &c.

the triangle pit privy pattern the aperture is 21 in. front to back, 3 in. in front and 18 in. behind, and the following instructions are usually sent out with it :—

(*a*) Pits to be made in dry soil to a depth of ten feet or over, but such is not necessary. The bacteriolytic action which goes on in a deep pit is very

effective, and such last for many years without requiring to be filled up.

(*b*) The pit must be completely covered over to prevent access of light. Flies will not penetrate a dark pit.

(*c*) A few spade-fulls of rich leaf mould thrown over the initial deposits of stercus are an advantage in setting up a desirable decomposition.

(*d*) In a large installation (three places or more) I advise a urine trough led to a separate pit.

(*e*) Messrs. Kynoch Ltd., Umbogintwini, near Durban, make a crystalline preparation, di-chlor-benzol, which gives off a heavy gas which is a perfect deodorant. A quarter of a pound of this hung inside the pit keeps the latter full of gas which kills any smell and through which flies cannot penetrate.

(*f*) Should a pit become flooded it must be filled with earth above floor level and some oil waste might be set to smoulder while it is drying out, a procedure which will kill any smell.

(*g*) No disinfectants should be used.

The bucket privy requires no description. I find it useless to arrange for self-closing lids. Natives simply place a stone under the hinge which is lifted off so soon as anyone tries to force down the lid.

When there are no shallow wells and the soil is porous the pit privy is much to be preferred to the bucket.

Studies Upon the Etiology of Dengue Fever (C. W. Duval and W. H. Harris, *Jour. Exper. Med.*, December 1, 1924).—The cultivation of a minute organism is described, upon the special media devised by Noguchi for growing spirochætal organisms, that gives rise to pyrexial and leucocytic reactions in the guinea-pig. The reaction in the animal following the injection of culture filtrate is identical with that induced by the inoculation of human dengue blood. The micro-organisms appear in culture as globoid bodies measuring from 0·1 to 0·3 in diameter and are arranged singly, in pairs, and in short chains. They readily pass through the Berkefeld filter (N and V), and the filtrate gives rise to a characteristic reaction in the inoculated guinea-pig. The filtrate yields in subplants the same globoid bodies of the original culture. Initial cultures have been obtained directly from the blood of the human case as well as from the blood of guinea-pigs reacting to the human material. However, only early generations retain the degree of virulence necessary to cause the experimental reaction, the culture of remote generation failing to infect. As far as is known, this minute organism has characters in common with the globoid bodies of Flexner and Noguchi obtained from cases of poliomyelitis. Examinations of blood specimens for spirochætal organisms in dengue fever patients and experimentally inoculated animals were negative. The minute organism described is frequently found in cultures of blood of human dengue and in animals inoculated with dengue material.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments, either** of subscriptions or advertisements, should be **sent to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, **to avoid delay,** all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these,** with remittance, **is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 ,, ,, ...	1	3	3
200 ,, ,, ...	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 ,, ,, ,,	2	6	0
200 ,, ,, ,,	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

Tropical Medicine and Hygiene

JUNE 15, 1925.

THE JAMAICA HOOKWORM COMMISSION.

THE campaigns of the Jamaica Hookworm Commission, a branch of the International Health Board are conducted with the purpose of employing the control of hookworm disease as a means of educating the people in disease control and especially in sanitation. Thickly populated rural areas are selected

for the campaigns; these are sanitated by the Local Boards of Health several months in advance of treatment; the fly-proof type of pit latrine is generally installed, and in every case the home owner is required to build his own latrine. When a householder constructs his latrine he is much more interested in its maintenance, it has been found.

For the purposes of the treatment campaign an area is divided into districts and an officer of the Commission is given charge of each. Every home is visited, specimens are collected and brought to a central office and laboratory for examination, and the infected are treated in their homes. Educational work is conducted simultaneously with treatment and consists of lectures, illustrated with magic-lantern slides and moving pictures, microscopical demonstrations, and the distribution of public health literature. Emphasis is placed upon the methods of spread of the bowel filth diseases and the necessity for latrine maintenance is stressed. After treatment, each area is provided with permanent sanitary inspectors by the Local Boards of Health.

Routine treatment consists of alternate doses, at weekly intervals, of oil of chenopodium and thymol, with compound jalap powder for the purge. The jalap is mixed and capsulated with equal parts of thymol, just as milk sugar or soda is used, and a maximum dose of 40 gr. of thymol is given; the jalap is placed in the capsule and the oil of chenopodium dropped upon it, the maximum dose being 24 minims of the oil.

Compound jalap powder is used as a preliminary purge in maximum doses of 40 gr. and, being slow acting, can be administered any time after 2 p.m. on the day preceding treatment. Treatment is given in the morning in two parts, at intervals of two hours. By using jalap powder with the chenopodium and thymol the nausea which usually follows treatment is avoided; also the dispenser can administer the preliminary purges and the treatments much quicker and much more conveniently than when Epsom salts is employed as a purgative.

The hookworm campaigns in Jamaica, directed by Dr. B. E. Washburn, have resulted in marked decreases in the number of patients admitted to hospitals for all diseases, and especially in the number of cases of typhoid fever and dysentery. Removal of hookworm infestation has restored many individuals to health and has made it possible for them to perform more regular work, earn more money, and become better citizens.

Annotations.

Stability of Desiccated Beef Heart Muscle Powder for Preparation of Antigens for Conduct of Complement-Fixation Tests in Syphilis (R. A. Kilduffe, *Arch. Dermat. and Syph.*, December, 1924).—The results of the investigation suffice to show that a highly polytropic powder of beef heart muscle can be commercially prepared in large quantities. Such a product is eminently suitable for the preparation of highly antigenic extracts with low hæmolytic and anticomplementary titres according to Kolmer's method of antigen preparation. The powder under ordinary conditions of storage is quite stabile, satisfactory antigens having been prepared from it after eleven months. No special precautions in keeping the powder are required other than to keep the containers tightly stoppered to prevent the absorption of moisture. If the precaution is taken to shake the container frequently and vigorously during extraction, antigens of remarkable potency may be prepared; without special care, the extracts are highly antigenic and quite satisfactory. Beef heart muscle powder may be commercially prepared and stored in large quantities for at least eleven months without fear of undue deterioration.

Relation of Natural Anti-Sheep Hemolysin of Human Serums to Kolmer's Quantitative Complement-Fixation Test for Syphilis (R. A. Kilduffe, *Arch. Dermat. and Syph.*, December, 1924).—Human serum may contain natural anti-sheep hæmolysin in amounts sufficient to exhibit a specific effect in high dilutions. Human serum may contain anti-sheep hæmolysin in sufficient amounts to cause a false negative reaction in complement-fixation tests for syphilis when the serum is used in a dose of 0·025 c.c. The presence of large amounts of natural anti-sheep hæmolysin is not without effect on the reaction in Kolmer's quantitative complement-fixation test for syphilis, even when the serum contains relatively large amounts of syphilitic reagin, and may give rise to false negative results in approximately ten per cent. of hæmolysin-containing serums. The absorption of natural anti-sheep hæmolysin from the serum prior to the performance of Kolmer's quantitative complement-fixation test increases the delicacy of the reaction and may be incorporated as a part of the technique, with definite advantages. The method of Kahn for the absorption of anti-sheep hæmolysin from human serums is rapid, simple and efficacious, and does not appreciably add to the time necessary for performing the test even when large numbers of serums are examined. While Kolmer's method of complement-fixation as originally described has been shown to be superior to the majority of methods in common use, the use of hæmolysin-free serums with this technique definitely improves its delicacy.

A Study of C. diphtheriæ *and Other Members of the Genus* Corynebacterium *with Special Reference to Fermentative Activity* (M. M. Barratt, *Jour. Hygiene*, December, 1924).—In this paper the fermentation reactions and some ancillary characters of 102 strains of virulent *C. diphtheriæ*, 31 non-virulent strains and 150 diphtheroids have been studied. With the possible exception of dextrin which proved to be an unsuitable sub-

stance for biological tests all the strains of virulent *C. diphtheriæ* examined were found to have constant biochemical reactions, fermenting glucose, maltose of galactose and having no action on cane sugar, lactose and mannite. The strains classified as non-virulent *C. diphtheriæ* had the same biochemical characters as the virulent strains and were indistinguishable from them either on morphological or cultural grounds. The diphtheroids examined showed great diversity in their power of attacking the carbohydrates used, at least eleven biochemical groups being recognized. By the use of three carbohydrates glucose, galactose and cane-sugar ninety per cent. of the diphtheroids in this series could be distinguished from *C. diphtheriæ* by the fermentation reactions. In the remaining ten per cent. a clue as to the nature of the organism is often obtained from the character of the growth on agar. Among the corynebacteria examined other than *C. diphtheriæ* no constant relationship was found between source, biochemical, morphological and other characters. Nevertheless, in dealing with members of the genus in pure culture, the morphology, character of the growth on agar and fermentation reactions taken together give useful information as to whether the organism under consideration is *C. diphtheriæ* (virulent or non-virulent) or a diphtheroid.

Pathology of Experimental Pneumococcus Pneumonia in Mice (A. Branch and E. G. Stillman, *Arch. Inter. Med.*, December 1, 1924).—The administration of alcohol produces no evident histological changes in the lungs of mice. Following inhalations of pneumococci the organisms are not visible histologically in the lungs of mice either in the bronchi or alveoli. In partially immunized mice which have been exposed to a pneumococcus spray while alcoholized, true lobar pneumonia not infrequently develops. The primary lesion of such lobar pneumonia in mice is an interstitial inflammation of the alveolar wall and the infection spreads in the interstitial tissue like a cellulitis. A tentative explanation of the lobar distribution of pneumococcus pneumonia is offered.

The Penetration of Bacteria Through Capillary Spaces (Stuart Mudd and Emily B. H. Mudd, *Journal of Experimental Medicine*, November 1, 1924).—The dark-field microscope may be used to observe directly the characteristics of composite films. The liquid phases, one or both of them containing suspended solid particles as test objects (in these experiments bacteria were used), are spread between slide and cover-glass and examined with any desired lenses. The liquid-liquid interfaces appear as bright lines and the solid particles as shining motes. An interfacial kinetic mechanism has been observed in films of all compositions studied. The bacteria are transported along the phase boundary lines in a striking and characteristic manner, and quite independently of movements in the adjoining organic or aqueous phases. These movements in the interface are interpreted as essentially due, according to the composition of the films, to local inequalities in interfacial surface tension, or to minute currents from mixing of the two phases across and along their boundary line, or to both forces acting together. The bacteria (non-motile) reached the interface by Brownian movement or currents or shifts in the position of the boundary line. With liquids which differ markedly in interfacial tension and miscibility with water, these properties may be correlated with the characteristics of the preparation.

The Influence of Different Kinds of Oil, Introduced into the Rectum, on Gastric Secretion (W. N. Boldyreff and J. H. Kellogg, *Arch. Internal Medicine*, November, 1924).—The mineral oils (liquid paraffin oil) do not diminish the appetite, and do not have any harmful effect on gastric digestion. Of the animal oils, butter has no inhibiting action on digestion, because it is not liquid at body temperature, and therefore cannot move into the small intestine. Cod-liver oil inhibits digestion, but in a relatively small degree. The vegetable oils (olive oil and linseed) inhibit very strongly the psychical phase of digestion. The fatty acids are the active substance in the oils. Commercial oils have a stronger inhibitory action, as they contain free fatty acids, but neutral oils also possess this action, though in a less degree. Moreover, the action of neutral oils is slower. The inhibiting action of oils introduced into the rectum consists only in decreasing the quantity of gastric juice; its acidity and pepsin content remain nearly constant.

Mosquitoes and Coconut Palms. A Mosquito Survey of Palm Trees in East Africa and the Problems Resulting Therefrom (W. E. Haworth, *Trans. Roy. Soc. of Tropical Medicine and Hygiene*, October, 1924).—Mosquitoes breed in the crowns of coconut palms. Breeding goes on there with considerable regularity throughout the year, not merely when other potential hatcheries, derived from heavy rainfall, are in existence, but also during times of comparative drought when collections of storm water have subsided, and that in steps in the palms and in rot-holes in other trees has disappeared by evaporation. Within the township areas, in which almost the whole of the investigation was conducted, harmless jungle mosquitoes are in a decided minority, the vast majority of those got from the crowns of the palms being biting mosquitoes, and of these, at all stations, the proved disease carriers predominated. The species most plentiful was not the same at all stations: at Tanga it was *Culex fatigans*: at Dar-es-Salaam it was *Aëdes argenteus*. Until investigation settles the point there appears no reason for concluding that in some places species of *Anopheles* may not

be the most prevalent. Breeding taking place in them at all times of the year, the crowns of the palms act as reservoirs, from which may be stocked other suitable places, whenever such may appear from rainfall or other causes. Imagines are produced in sufficient numbers to prejudice the health of the community. The observations made and facts recorded do not enable the writer to fix a definite figure as the average output per palm per day; but from what has been done and set out, it is considered that it can scarcely be reasonably taken as less than one, and is probably very much higher. The minimum figure does not appear formidable when regarding a solitary palm for a single day, but even it assumes a menacing aspect when—realizing that the life of an imago may extend over many months—it is applied for every day of the year to a township area containing from 4,000 to 70,000 coconut palms.

What has been demonstrated for a portion of the east coast of Africa is probably also taking place throughout tropical lands round the world, wherever the coconut palm flourishes, varying in degree as the conditions may be more or less favourable to the palm, and in species yielded according to their geographical distribution. No antimosquito campaign can be considered otherwise than wanting in thoroughness which neglects to take account of the crown of the palm, since, although it may be found uninhabited, it must ever remain a potential nursery for disease-bearing pests. The natural enemies of the mosquito in all its stages, so far as observed, are inefficient; the harmful species have been found developing from the larval stage to the perfect insect in the presence of *M. brevipalpis* and *L. tigripes* larvæ; and *Aëdes* larvæ have been brought from crowns, the resting places of numerous bats.

Four New Cases of Mycetoma in Tunisia (Ch. Anderson, *Arch. de l'Institut Pasteur de Tunis*, Tome xiv, No. 1, 1925).—These four cases of mycetoma bring the number observed in Tunis up to sixteen. One of the cases here described was due to *Scedosporium apiospermum*, and the other three to a *Discomyces*. The first is the only case of its kind observed in Tunis.

Current Literature.

Bulletin de la Société de Pathologie Exotique.

February 11, 1925.

The Protozoa in Intestinal Intoxication (M. Castex and D. J. Greenway).—614 cases of intestinal toxæmia have been studied clinically and parasitologically by the authors. Protozoa were found in the stools of 415 of these; in 24 other cases protozoa associated with other parasites were seen. *Blastocystis hominis* comes first in order of frequency, followed by *Entamœba histolytica*, *Chilomastix mesnili*, and fourthly *Giardia intestinalis*. Helminthous infections were rare. Clinical symptoms differed in each patient. Investigations prove that intestinal protozoa are an important ætiological factor in chronic intestinal toxæmia. Stovarsol Poulenc and Yatren 105 Behring have given the best results as regards treatment, but are not equally well tolerated by all the patients.

Intestinal Protozoa of Man during the Epidemics of Petrograd (1919•1921) (W. L. Yakimoff and Mlle. W. J. Wassilewsky).—These researches were carried out with stools of patients during the epidemic of cholera and dysentery at Petrograd 1919, dysentery 1920, and cholera and dysentery 1921. The percentages of positive findings of parasites were high, the highest being of *Entamœba coli*. Cases of pure infection in 1919 numbered 27, in 1920, 104; and in 1921, 19. Mixed infections during these years were 36, 95 and 22 respectively. Descriptions of cases are given.

Apropos the Pig Louse: the Pig as Elective Host of Human Lice (P. Delanoe).—Parasitism of the pig by human lice was first reported by Bishopp (1915) in the United States. Pigs are very favourable to the multiplication of human lice; this is easily seen in any pig-sty in Morocco, where the lice are very numerous. They are of a jet-black colour and are thus easily perceptible. In one abandoned pig-sty seen by the author the ground was so thickly covered with lice that it seemed to be moving. Of a total of 1,001 lice taken in a pig-sty only two were dog-lice, all the rest belonged to the species *Pulex irritans* L.

Introduction of "Blue Tongue" in French West Africa (G. Curasson).—Up to the present this disease, which was prevalent in South Africa and carried off numerous victims every year, was unknown in French West Africa. Its appearance has apparently been brought about by imported South African sheep. The disease is more infectious than contagious; it is transmissible by inoculation.

Leprosy in New Caledonia, II. Course of the Disease in the Archipelago (G. Genevray).—Cases of leprosy have been recorded in the Archipelago since 1878, but statistics for the last ten years show there has been a great improvement and the numbers affected have decreased. Unfortunately, however, many cases of leprosy still exist, and everything possible is being done to exterminate the disease.

The Existence of Oriental Sore at Figuig (Eastern Morocco) (L. Leblanc).—A new site of oriental sore has been observed in Morocco; three typical cases are described. The insect incriminated as carrier of the disease is a spider. Although several places near Figuig have been infected some years, this is apparently the first time the disease has been noted there.

Third Note on Sheep Piroplasmosis in Algeria. The true Piroplasma (s. str.) ovis (nov. sp.) compared with Babesiella ovis (F. Lestoquard).—Investigations by the author show that two hæmatozoa exist in the Algerian sheep, belonging to two distinct subgenera: *Piroplasma* and *Babesiella*. Algerian sheep can be infected by five different viruses: *Piroplasma (s.s.) ovis*,

nov sp., *Babesiella ovis* (Babes, 1892), *Gonderia ovis* (Edm. Sergent, Parrot, Hilbert, 1922), *Theileria ovis* (Littlewood 1914), *Anaplasma ovis* (Lestoquard, 1924). The morphological and biological differences are described.

The Pathogenic Rôle of Chilomastix mesnili (M. R. Castex and D. J. Greenway).—From the literature it is seen that authorities on the subject of *Chilomastix* or *Tetramitus* do not agree with regard to the pathogenic properties of this parasite. By some it is considered the cause of colitis, others have attributed little importance to it, and recently cases of chronic diarrhœa presented the parasite in abundance in the fæces. The authors have found *Chilomastix mesnili* 118 times in 614 cases of chronic intestinal toxæmia; sometimes alone, at other times associated with protozoa and helminths. They are of the opinion that the *Chilomastix* in the forty-nine cases of pure infection was the pathogenic factor of the disease and the essential cause of different toxic syndromes.

The Pathogenic Rôle of Blastocystis hominis (M. R. Castex and D. J. Greenway).—*Blastomycystis hominis* is the parasite most frequently found in patients suffering from chronic enterogenous toxæmia. It is sometimes associated with other protozoa and helminths. It is the opinion of the authors that *Blastomycystis hominis* plays an important pathogenic rôle, both from a parasitologic and coprologic point of view, in many cases of enterogenous toxæmia. The *Blastocystis* is easily got rid of by means of Stovarsol Poulenc, and Yatren 105 Behring.

On the Subject of Blastomycosis (W. L. Yakimoff and W. J. Wassilewsky).—Investigations have been made in Russia with regard to the intestinal protozoa of man, 1919-1921, during which time *Blastocystis hominis* has been found 257 times in 1,632 stools examined. Of these cases 223 were pure infection, and 34 were associated with other parasites. Three cases are described in which diarrhœa was due to *Blastocystis hominis*.

The Isolation of the Pathogenic Agent of Blastomycosis of the Lacrimal Ducts (G. Jeaume and M. Dekester).—The organism isolated was named by M. H. Velu (1924) *Cryptococcus mirandei*. The authors have succeeded in making pure cultures on Sabouraud's gelose medium. The culture is rapid; a temperature of 30° F. seems to be the most favourable for its growth. The vitality of the fungus is very great in cultures; even when the cultures are old and have been abandoned for a year, reinoculation has given immediate results.

Correspondence.

To the Editor of the JOURNAL OF TROPICAL MEDICINE AND HYGIENE.

Sir,—I have received from Dr. J. A. Shaw-Mackenzie the following notes on a kennel not far from his home in the North of Scotland. In this kennel which he visited there appears to have been quite a number of cases of reputed cancer in dogs housed therein in the usual manner.

The kennel has been disused for several years on account of the "cancer" mortality among the dogs. As the kennel still remains unoccupied, it would certainly afford an opportunity for ascertaining the true nature of the disease if another dog could be housed for a time under the same conditions in the kennel and become similarly affected. The importance of investigation into incidents of this kind is obvious and the publication probably might bring to light similar experiences.—Yours truly,

W. J. SIMPSON.

31, *York Terrace*,
Regent's Park.
June 5, 1925.

REPORTED CANCER IN DOGS SUCCESSIVELY HOUSED IN THE SAME KENNEL.

The kennel is one of two, separated by a dividing wall and paling. The kennels are of the usual kind for sporting dogs. Each consists of outer court with concrete floor and central drain; and inner roofed division with sleeping shelf. The outside palings are wood on stone wall.

In only one of these kennels has the "cancer" been noted. The back of this kennel is an old wall of a shed which supports the roof of the sleeping compartment of the kennel. This is the only apparent difference in the kennels, the second healthy kennel having its own separate back wall and roof.

A great many dogs housed in the particular kennel have died or been destroyed for "cancer." Half a dozen at least were recalled to memory by the owner, including two retrievers, two or more spaniels and one pomeranian, which latter did not actually live in the kennel but was always about the particular kennel.

The cases have been noted over a long period, the last one a few years back, since when the kennel has not been used, owing to the natural unwillingness of the owner to expose any other of his dogs.

The duration before manifestation appeared to be about nine months.

In the female dogs the breast was affected, in one male dog, the penis, and in another the throat or larynx.

Previous to the last case the kennel was disinfected with lime, lysol and tar; and the floor taken up and re-concreted.

The cases were diagnosed by a well-known veterinary surgeon (since deceased). He had a great reputation in the North and was particularly interested in bacteriology. It is not known if he made any microscopic examinations of sections of the growths, or culture experiments. Whatever the nature of the disease there is no doubt of the successive mortality of the dogs housed in this particular kennel.

There appears to be nothing peculiar in the locality of the kennels.

The woodwork is old, noticeably worm-holed, and affected with dry rot.

In a neighbouring village there is a great deal of cancer, popularly associated with "dry rot."

Original Communications.

SOME REMARKS UPON *SPIROCHÆTA BRONCHIALIS* CASTELLANI, AND BRONCHIAL SPIROCHÆTOSIS.

By Lieutenant-Colonel FROILANO DE MELLO.

Director of the Bacteriological Laboratory, and Professor at the Medical College, Nova-Goa, Portuguese India.

INTRODUCTION.

THE disease which was discovered in Ceylon by Aldo Castellani and termed "bronchial spirochætosis," has also been found by several research workers in almost every part of the world. In all treatises, manuals of parasitology, or tropical pathology, reference has been made either to the disease itself or to its causative agent. For the last two or three years, however, as the area of the geographical distribution of bronchial spirochætosis has been found to be much more extensive than in former days, some scepticism seems to have arisen against what we have, up to now, considered to be based on well-established facts, and the objections which are intended to weaken the creation of this new chapter of human pathology can be combined in two principal groups: (*a*) those concerning the value of *Spirochæta bronchialis* as an independent species, and (*b*) those referring to the disease itself as a clinical and anatomopathological entity.

For the present, I will make some remarks founded chiefly on my own observations, showing the reason why my opinion favours the independence of the *Spirochæta* as a distinct species, as well as the autonomy of the disease as a clinical entity.

IDENTIFICATION OF SPIROCHÆTES.

Before entering on the subject of this paper, some facts must be considered in order to discuss the value of the methods employed by the protozoologists for the identification of spirochætes. A large number of these organisms cannot be cultivated, and *Spirochæta bronchialis*, as well as some of its allies, belongs to this group. If some blood and tissue-invading spirochætes can be differentiated by inoculation and by some immunity tests, the same cannot be done with species whose habitat is in open cavities of the body, together with a large and variable bacterial flora.

The movements of spirochætes vary to a large extent with the same species, according to various factors, viz., the temperature and chemical composition of the spirochæte-containing medium, the time elapsed after the material has left the infected body, &c.

The cytological study gives very little help for the specific characterization, and often various details of structure given as generic distinctions have been discovered further as belonging also to allied genera. Hence the tendency of certain protistologists to include all the species in two or three well-defined genera.

Under the circumstances, the only elements we possess for the identification of such spirochætes as I am discussing here are those concerning their morphological character. This point must be emphasized, and I fully agree with the following words of Scott Macfie, which still live fresh in my mind [1]: "For diagnostic purposes a morphological criterion is still urgently needed."

METHODS EMPLOYED BY THE WRITER FOR THE IDENTIFICATION AND CLASSIFICATION OF NON-CULTIVABLE SPIROCHÆTES.

The methods I employ at present for the specific determination of such non-cultivable spirochætes are strictly morphological and subordinate to the following points [2]:—

(*a*) A detailed cytological study of the parasite on smears stained, with and without wet fixation, by various dyes in order to let us know the colour reactions and the structure of the spirochæte; (*b*) the length of the spirochæte taken on at least 100 individuals drawn at camera lucida in order to know not only the maximum and minimum length, but also the percentages of the variations comprised between these extremes; (*c*) the number of coils taken on the same 100 individuals and disposed of in the same way; (*d*) the diameter (= breadth taken on stained slides, noting always the stain used for this purpose, as the breadth varies largely according to the chemical composition of the stain: thus the spirochæte seems narrower with Romanowsky than with phenicated solutions (when on a slide such as from dental parasites, there appear to be many species of spirochætes, the breadth is an important element for a primary differentiation of the species); (*e*) the ratio: length divided by number of coils, taken on the average of these elements from all the spirochætes drawn using the camera lucida, or more simply by dividing the total length by the sum of the number of coils of these 100 spirochætes. This ratio, which replaces with more efficiency the so-called average dimensions of spirals given by some authors for some spirochætes, has been named in my studies as the "index of morphological identification."

HOW I CAME TO USE FOR DIAGNOSTIC PURPOSES THE INDEX OF MORPHOLOGICAL IDENTIFICATION.

By a careful study of the spirochætes of the dental region in Portuguese India, I have seen [3]:

(1) That the spirochætes constitute the normal fauna of all the mouths examined.

(2) That their number increases enormously in cases of pyorrhœa alveolaris—a disease very common in this country.

(3) That these spirochætes can be divided at first into two groups:

(*A*) Those having a breadth from 0·4 to 0·8, even 0·9 micron, with large spirals, and whose number seems to be in a constant relation with the length of the spirochæte.

(*B*) Those with a breadth from 0·2 to 0·5 micron, having narrow spirals and whose number seems to be also in constant relation with the length of the spirochæte.

A careful study in a large number of cases showed me that these characters were found in every one, and that with the spirochætes of group *A*, the relation referred to above was equal or above to 2, and that with spirochætes of group *B* it was subject to oscillations varying from 1 to 1·33, being always below to 1·50.

The first spirochæte is the *S. buccalis* Cohn; the second, *S. dentium* Koch.

Ever since we described these elements in the morphology of the spirochætes, and in the description of *S. bronchialis* found in two cases of Oporto and Braga (Portugal), we have pointed out the following, besides the structure, forms of division, &c.: that the breadth on wet slides fixed by Bouin, Flemming, and sublimate alcohol and stained by Heidenhain's iron hæmatoxylin, was from 0·15 to 0·35 micron, and that on slides fixed by heat and stained by carbol fuchsin the breadth was from 0·25 to 0·45; minimum length 4, maximum 18 to 20; the majority (85%) between 5 and 12; minimum number of spirals 2, maximum 12. Ratio (length divided by number of coils) was 1·63 in the first case, 1·18 in the second case. As the ratio was so different in both cases, a question arose as to whether this element could be made use of as in the case of the spirochæte of the mouth for the identification of *S. bronchialis*. Evidently, a settlement of this point would necessitate further study, which would determine the same ratio in many cases of *S. bronchialis* in order to certify if it was its polymorphism that accounted for the variation [4].

Can these Methods be Employed for the Identification of other Species of Non-cultivable Spirochætes?

In Angola, having a large material for such studies, I intended to decide if the methods I tried on mouth spirochætes had any value for the identification of other species of non-cultivable spirochætes [5].

I identified the following spirochætes of the mouth in natives of Angola: *S. buccalis*: breadth 0·5 to 0·8, to even 1 micron; sometimes rudimentary undulant membrane; length, minimum 5, maximum 18, majority (72%) between 10-15. Number of coils, minimum 3, maximum 14, majority (85%) between 4-7. Ratio (length divided by number of coils) 2 (2·24). *S. dentium*, breadth 0·20 to 0·40, no trace of undulant membrane. Length, minimum 5, maximum 16, majority (89%) between 6-12. Number of coils, minimum 4, maximum 15, majority (91%) between 6-11. Ratio (length divided by number of coils) 1·4.

I found also two intermediary types, from which Type II was considered as a thinner variety of *S. buccalis*, and Type I as an intermediate. The following table shows the morphological characters: —

Mouth Spirochætes in Natives in Angola.
(Measurements in microns).

Species	Breadth	Minimum	Maximum	Majority	Minimum	Maximum	Majority	Ratio (index)
buccalis	0·5 to 1	5	18	72 per cent.—10-15	3	14	85 per cent.—4-7	2·24
dentium	0·2 to 0·4	5	16	89 per cent.—6-12	4	15	91 per cent.—6-11	1·4
intermedium (type I)	0·4 to 0·7	5	23	72 per cent.—8-15	4	16	83 per cent.—5-11	1·49
Var. *buccalis* (type II)	0·2 to 0·4	4	26	72 per cent.—8-15	2	11	86 per cent.—3-7	2·3

The same methods applied to intestinal spirochætes gave me the opportunity of identifying the organisms of *Eurygyrata* type with the following characteristics:—

Intestinal Spirochætes of Eurygyrata Type in Man and Animals in Angola.

Species	Breadth	Length* Min.	Length* Max.	Majority	Number of coils Min.	Number of coils Max.	Majority	Ratio (index)
Man	0·20	3	11	80 per cent.—4-7	2	11	87 per cent.—3-7	0·9 to 1·2
Horse	0·2 to 0·4	4	11	92 per cent.—4-8	3	7	92 per cent.—3-6	1·4
Mule	0·2 to 0·4	4	12	93 per cent.—6-11	3	8	87 per cent.—3-6	1·7
Guinea-pig	0·2 to 0·4	3	10	88 per cent.—4-8	2	6	96 per cent.—3-6	1·58
Rabbit	0·2 to 0·4	3	10	98 per cent.—5-8	2	7	98 per cent.—3-6	1·3
Ox	0·3 to 0·7	4	15	74 per cent.—5-10	3	10	90 per cent.—4-8	1·4
Goat	0·25 to 0·40	4	15	90 per cent.—5-10	3	14	79 per cent.—5-9	0·96
Sheep	0·25 to 0·40	3	14	89 per cent.—5-10	2	8	91 per cent.—3-6	1·7
Cat	0·25 to 0·50	3	10	88 per cent.—5-8	2	7	96 per cent.—3-6	1·4
Dog	?	4	13	94 per cent.—5-10	3	9	86 per cent.—3-6	1·3
Pig	?	3	10	85 per cent.—5-8	2	7	84 per cent.—3-5	1·6

* In one case a large type belonging to an animal type, possibly goat.

In conclusion, I think that the morphological methods are useful for the identification of non-cultivable spirochætes and that the ratio (length divided by number of coils), termed by me the *index of morphological identification*, gives a valuable element, much more advantageous than the so-called average dimension of the spirals formerly cited.

Morphological Characters of the S. bronchialis Castellani.

A very careful study of the *S. bronchialis* in six cases of broncho-spirochætosis in Portuguese India has given me the following elements [6]: (*a*) in

hanging-drop active movements of the progression on both extremities; helicoidal movements; frequent lysis; (*b*) in stained slides: well stained by aniline dyes, less, however, than the mouth spirochætes, especially of *buccalis* and *intermedium* type; breadth 0·2 to 0·6, with carbol fuchsin or phenicated gentian violet. No peculiarities on the structure: ends generally pointed, very rarely a rudimentary undulant membrane, visible only on the coils, room-chambered structure, transverse division, coccoid bodies.

The lengths and the number of coils are given in the table below:—

Another point which calls for attention is that I cannot accept as proved that all spirochætes found on phagædenic ulcers in association with fusiform bacilli are *ipso facto S. vincenti*. Having had a large material at my disposal in Angola, I have seen [7]: (*a*) that even in cases where there is only one species of spirochæte, I can morphologically identify at least two types:—

Type I.—Breadth, 0·40 to 0·70. Length, minimum 7 to 11; maximum 30 to 42; majority (74 to 84%) between 15 to 26. Number of coils, minimum 3; maximum 13 to 16; majority (81 to 94%) between 4 to 10. Index 2·6 to 2·7. This type is perhaps the same as *S. schaudinni* Prowazek, which I do not believe to be the same as *S. vincenti*.

Type II.—Same breadth; length, minimum 5 to 10; maximum 24 to 25; majority (73 to 83%) between 9 to 18. Number of coils, minimum 3, maximum 10, majority (83 to 84%) between 4 to 8. Index, 2·2 to 2·3. One or two flagella on each point.

(*b*) That in the majority of the ulcers there are more than one species of spirochætes, whose rôle, if pathogenic or saprophytic, cannot be found out by microscopic examination only. Only in two of these cases I found a type identical with a spirochæte met with in an undoubted case of Vincent's angina.

Type III.—Breadth, 0·25 to 0·40. Length, minimum 5 to 6; maximum 20 to 28; majority (67 to 75%) between 8 to 15. Number of coils, minimum 3 to 4; maximum 11 to 15; majority (79 to 80%) between 4 to 10. Index 1·4. However, this spirochæte cannot be considered absolutely pathogenic, as in ulcers having only one species of spirochæte I have sometimes found just the spirochæte that was in association with this Type III.

(*c*) In two cases Type II was found and in other cases the following types:—

Type IV.—Length, minimum 8 to 10; maximum 30 to 35; majority (68 to 81%) between 13 to 24. Number of coils, minimum 2, maximum 8 to 11; majority (75 to 88%) between 3 to 8. Index 3·0 to 3·7.

Type V.—Length, minimum 10, maximum 25; majority (61%) between 14 to 20. Number of coils, minimum 3, maximum 14, majority (78%) between 6 to 11. Index 2·1.

In conclusion, my opinion is that many species of spirochætes produce the so-called fuso-spirochætic symbioses in phagædenic ulcers, and that it is a mistake to identify all these spirochætes as *S. vincenti* on account of their association with fusiform bacilli.

MORPHOLOGICAL CASES OF S. BRONCHIALIS IN SIX CASES OF BRONCHO-SPIROCHÆTOSIS.

Case	Length			No. of coils			Index
	Minimum	Maximum	Majority	Minimum	Maximum	Majority	
I	5	24	80 per cent.—7 - 13	?	?	?	?
II	5	24	81 per cent.—7 - 13	3	10	81 per cent.—4 - 7	1·9
III	4	20	81 per cent.—6 - 11	2	11	95 per cent.—4 - 9	1·13
IV	4	19	80 per cent.—6 - 11	3	16	89 per cent.—4 - 10	1·2
V	6	19	80 per cent.—7 - 12	3	15	89 per cent.—4 - 10	1·36
VI	5	18	87 per cent.—7 - 12	4	12	92 per cent.—4 - 9	1·3

This leads me to define *S. bronchialis* with the following characters: extremities generally pointed, sometimes one blunt, breadth varying between 0·2 to 0·6 on slides stained by carbol fuchsin, length between 4 to 24 microns, and excepting some rare giant forms, the majority, or more than 75%, between 5-12 microns. Number of spirals varying between 3 to 18 and making the same restrictions for some rare, very long and narrow coiled forms, the majority, or 90%, showing 4 to 9 spirals. The ratio (length divided by number of coils) varies from 1·2 to 1·9, and the species shows a great polymorphism, possessing specimens of large and narrow spirals, which suggest the existence of perhaps more than one type or variety in this species. Cytological constitution is without special characteristics; some individuals show a rudimentary undulant membrane; room-chambered structure, transverse division; coccoid bodies.

Is S. BRONCHIALIS Identical with other Species of Spirochætes?

Some authors believe that *S. bronchialis* is not a valid species and must be identified with one of the following: (*a*) *S. vincenti;* (*b*) dental spirochætes.

(*a*) As regards *S. vincenti*, I must point out that the principal point in favour of the identification between *S. bronchialis* and *S. vincenti* is that *S. bronchialis* is at times associated in sputum with the fusiform bacillus, as in the case of Vincent's angina. The presence of the fusiform bacillus cannot be used for the diagnosis of different species of spirochætes, as many of them show the same association. The dental spirochætes, for example, are constantly seen together with fusiform bacilli, and in every case I examined, especially when there is pyorrhœa alveolaris, I have seen such association. Nobody would identify on account of this fact the dental spirochætes with *S. vincenti*.

Having discussed the value of this association for the purpose of specific diagnosis of spirochætes, I am obliged to state with Fantham [8] that little is known of the morphology of *S. vincenti*, a name given by Blanchard in 1906 without any description of the parasite. This name is, however, so widespread in the medical nomenclature as characterizing the agent of the well-known Vincent's angina, that it is our duty to describe it better, from well-defined cases of the above-mentioned disease.

Nowadays a protozoologist would be in serious difficulties to identify as *S. vincenti* a spirochæte found in fuso-spirochætic association, as the dimensions given for this species vary according to the authors (Castellani and Chalmers, 10 to 22 microns; Neveu Lemaire, *idem;* Brumpt, 5 to 12 in " Précis de Parasitologie "; 8 to 20/0·2 to 0·4 in Roger Widal, Teissier's " Treatise on Medicine "; Macfie quotes Bosanquet, giving 10 microns, Mackie noting even 40, Castellani and Chalmers 10 to 25, Fantham 9 to 23; Gonder 14 to 16, with 3 to 5 micron coils).

Only once have I been able to study a *S. vincenti* from a definite case of Vincent's angina. It had the following characters: Breadth, 0·25 to 0·75, showing in the last case a kind of undulant membrane. Pointed tips, rarely one blunt. Does not stain well with the common aniline dyes; stains violet pale with Romanowsky. Transverse division, binary and multiple. Coccoid bodies. Length. minimum 8, maximum 29, majority (75%) between 10 to 20. Number of coils, minimum 4, maximum 15, majority (85%) between 6 to 11. Index 1·5. Evidently it would be necessary to study many more clear cases of Vincent's angina to see the morphological variations to which the spirochæte is subject.

Based on therapeutic lines also, I have reasons to classify *S. vincenti* as a distinct species from *S. bronchialis*. Novarsenobenzol has given brilliant results in Vincent's angina and in the phagædenic ulcers, while on two of my patients with broncho-spirochætosis with hæmoptoic symptoms novarsan has proved absolutely useless, giving negative results both from clinical as well as from parasitological points of view (0·30, 0·45, 0·4, 0·60).

In conclusion, the identification between *S. bronchialis* and *S. vincenti* is far from being proved. The arguments I produce against this identification are: (1) *S. vincenti* is not well defined and the presence of *Bacillus fusiformis* cannot be used to characterize any species of spirochætes, as its association with many other species, even with common dental spirochætes, is constant; (2) the only definite *S. vincenti* I have seen stains weakly or not at all with common aniline stains in opposition to *S. bronchialis;* (3) novarsenobenzol, which gives so brilliant results on Vincent's angina and phagædenic ulcers, is without effect on *S. bronchialis*.

The opinion of some authors who consider *S. bronchialis* as a variety of *S. vincenti* is a mere hypothesis without any strong point to support it.

Some authors claim that *S. bronchialis* is one of the dental spirochætes. Indeed, there can be cases where the invasion of the ærial viæ by mouth spirochætes is possible, but two facts must be pointed out in connection with this hypothesis, when generalized, in order to demonstrate that *S. bronchialis* is from such an origin (I have already said that dental spirochætes stain more intensely and more easily than *S. bronchialis* with common aniline stains):—

(1) It is really curious that, when buccal spirochætes exist more or less abundantly in every mouth, only such an infinitely small percentage of persons suffer from bronchial spirochætosis. Certainly, I do not refer to some rare spirochætes found sometimes on a slide during the examination of the sputum for T.B. bacillus, and evidently coming from dental contamination. Broncho-spirochætosis is characterized generally by the presence of numerous spirochætes, and in spite of the fact that their number may be occasionally small, especially when the sputum is hæmoptoic, the spirochætes are seen in every microscopic field and their total number in a slide is far greater than the rare spirochætes found in ordinary sputum. (2) I have shown, dealing with *Intestinal human spirochætosis*, that mouth spirochætes may sometimes invade the intestinal tract and that they keep in the intestine their buccal characters [9]. So a comparison of *S. bronchialis* from a case with its own dental spirochætes will be full of interest. I have made this study completely in two cases, following my morphological methods; the summary is given in the following table:—

CASE IV.—COMPARISON OF S. BRONCHIALIS WITH MOUTH SPIROCHÆTES OF THE SAME CASE.

Species	Length Min.	Length Max.	Length Majority	Breadth	Number of coils Min.	Number of coils Max.	Number of coils Majority	Index
bronchialis	4	19	80 per cent.—6 - 11	0·2 to 0·5	3	16	89 per cent.—5 - 11	1·2
buccalis	5	25	73 per cent.—10 - 10	0·5 to 0·8	3	11	82 per cent.—4 - 6	2·78
dentium	5	18	76 per cent.—6 - 11	0·25 to 0·40	5	20	82 per cent.—6 - 11	1·02
Type *intermedium*	5	18	77 per cent.—7 - 13	0·4 to 0·8	4	13	84 per cent.—6 - 11	1·3

CASE V.

Species	Length Min.	Length Max.	Length Majority	Breadth	Number of coils Min.	Number of coils Max.	Number of coils Majority	Index
bronchialis	6	19	80 per cent.—7 - 12	0·2 to 0·5	3	15	89 per cent.—4 - 10	1·36
buccalis	6	19	89 per cent.—8 - 16	0·5 to 0·9	2	10	91 per cent.—4 - 7	2·1
dentium	5	16	79 per cent.—6 - 11	0·25 to 0·40	5	18	89 per cent.—7 - 13	0·87
Type *intermedium*	5	27	84 per cent.—8 - 15	0·4 to 0·8	3	19	84 per cent.—7 - 12	1·17

Before analysing these tables I must say that in Portuguese India, at least, the dental spirochætes are seen on a slide in the following comparative frequency: *buccalis, dentium, intermedium,* the last being comparatively rare. I take as *buccalis* the large spirochæte with large wavy spirals, *dentium* the narrow-coiled spirochæte, and *intermedium* the large narrow-coiled spirochæte.

Now analysing the tables, we can see that *S. bronchialis* can be immediately differentiated from *S. buccalis*. Certainly there are among specimens of *S. bronchialis* some large coiled forms, but I have never seen parasites with a breadth such as attained by *S. buccalis*, and I do not understand why the large forms would disappear in the bronchi.

S. bronchialis can also be differentiated from *S. dentium* on the above lines, being a more narrow-coiled species.

The differentiation with *S. intermedium* is more difficult, but besides the breadth of *S. intermedium* being greater than *S. bronchialis*, I must state that this dental species is less abundant than its two allies and that it can hardly be conceived why it should proliferate in the bronchi. For all these reasons I think that *S. bronchialis* is a distinct species, very polymorphous, possessing perhaps more than one type or species, which complicates the problem of its polymorphism.

Considering the disease from a clinical point of view, I must confess that anatomopathological data are wanting as well as many other elements corresponding to the principles of Koch-Henle's postulatum.

Many other well-defined diseases do not fully satisfy this postulatum, and it is not for these reasons that we are allowed to deny the autonomy of the broncho-spirochætosis. I will not refer to all clinical forms described by Castellani, but only to the chronic type on which I have sufficient experience. Clinical facts are and have always been most important, and all of us must recognize: (*a*) that, normally, the sputums practically do not contain spirochætes; (*b*) that in some cases the sputums show an enormous number of spirochætes.

The persons belonging to this second group show some alterations in their pulmonary apparatus, signs of bronchitis, some more or less inconstant râles, more or less hæmoptoic sputum. It is known to all of us that pathognomonic signs are not always found in pulmonary diseases, and I cannot certify that the various signs described by the authors in spirochætosis may not belong to some other associated causes; but what does not seem justifiable is the hypothesis that these spirochætes make their appearance on account of the blood existing in sputums: in cases of spirochætosis the agents are present, and sometimes in much larger number, even when the sputum is free from all blood; on the other side so many diseases with hæmoptoic sputums do not show any spirochætes at all.

Another point to be considered in these chronic patients is that they are subject to remittances on their clinical evolution, and it is just when the clinical signs reappear that the sputums show large quantities of spirochætes; hence, it is evident that a certain synchronism exists between the clinical evolution and the spirochætic discharge.

I am convinced that the disease discovered by Aldo Castellani is autonomous and that, if anatomopathological data are wanting, it is because the disease is not lethal and has not given occasion for full research work, in which the histopathology would certainly occupy the first place.

Before finishing, reference has to be made to two interesting publications in the literature at our disposal: a paper by R. Pons [10] and the book of Professor Delamare [11]. In the first paper the author states that in eight-tenths of the people at Saigon the dental spirochætic fauna is poor and in two-tenths very rich, owing certainly to carious teeth. His nine patients belong to the latter class. In Portuguese India the pyorrhœa alveolaris shows patients of the so-called rich fauna, and this disease is widely spread, as is shown by the following numbers: Children (3-12 years), 20% affected; young people (12-21) 56%; adults (over 21), 80%; native Christians, 83%; Hindus and Mohammedans, 80%; men, 80%; women, 30%.

The relative percentage of spirochætal infestation in normal and pyorrhœic persons can be appreciated by the following numbers (examination of 100 microscopic fields):—

Case	Normal per field	Pyorrhœa per field
I	0·34	93·41
II	0·31	111·42
III	0·47	89·18
IV	0·81	62·08
V	0·39	103·35

In spite of this large distribution of pyorrhœa, the cases of bronco-spirochætosis registered in Portuguese India since 1918 do not reach a dozen. Moreover, one of my last cases was found in a child where pyorrhœa alveolaris and its consequent rich fauna were not present.

As far as it concerns the distribution of the spirochætes in different parts of the mouth, my studies show that in the rhino-pharynx there are practically very few or no spirochætes, in the palate very few, their number increasing gradually as one approaches the dental region, which is the habitat *par excellence* of the spirochætes. The following numbers will give an idea of this distribution (100 microscopic fields):—

Case	Dental region	Saliva	Palate	Tonsils	Rhino-pharynx
I	21 spirochætes per field	6 spirochætes	0·01 spirochætes	0·01 spirochætes	0·02 spirochætes
	17 fusiform per field	2 fusiform	0·0 fusiform	0·03 fusiform	0·03 fusiform
II	16 spirochætes per field	6 spirochætes	0·02 spirochætes	0·19 spirochætes	0·05 spirochætes
	9 fusiform per field	5 fusiform	0·0 fusiform	0·07 fusiform	0·0 fusiform
III	31 spirochætes per field	5 spirochætes	0 01 spirochætes	0·05 spirochætes	0·04 spirochætes
	14 fusiform per field	3 fusiform	0·0 fusiform	0·07 fusiform	0·0 fusiform

I agree with Pons that disinfection by antiseptics does not decrease sensibly the rate of infestation of the different parts of the mouth, and it is recommended only to avoid particles retained in dental regions contaminating the sputum. Indeed, if the only passage of the sputum by mouth was enough to contaminate it with so many spirochætes as we see in that disease, I do not understand why every sputum sent for analysis should not show spirochætes, at least in such a large number as in pure saliva: we all know that among sputums sent for examination of Koch's bacillus, only a small percentage show a very minute rate of spirochætes that are certainly provenient from dental contamination. In my cases, distinction is very easily made between *S. bronchialis* and *S. buccalis;* some doubts may exist for the differentiation with other mouth species, especially with *S. intermedium*, but I hardly conceive how Pons obtained such a high index in three of his cases (2·56, 3·7, 4·1). His spirochætes must have been extraordinarily largely waved, and this fact will perhaps suggest new problems concerning the plurality of the types or species causing spirochætosis of the ærial viæ.

Professor Delamare in a very interesting communication shows that *S. bronchialis* can be morphologically differentiated from the common mouth spirochætes *S. buccalis* and *S. dentium*, the distinction being more difficult with *S. intermedium*. To his remarks I may be allowed to present some objections: (*a*) first of all, I do not find justification from a protistological point of view for the distinction he makes between *Spironema* and *Treponema*. The designation *Spironema* Vuill. 1906 is preoccupied by a fossil Gasteropod Meek 1864 and by a flagellate (*Spironema multiciliatum* Klebs 1892). Moreover, it seems that Delamare indicates under the name *Spironema* spirochætes of large waves, as he calls *Spironema buccalis* in contraposition with his narrow-coiled ally, which he designates as *Treponema dentium*. This sense, which the author employed also in designating the intestinal spirochætes [12], cannot be accepted, as we know that the term *Spironema* Vuill. was proposed for the spirochæte of syphilis, being in consequence synonymous of *Treponema*, whose type species is *T. pallidum*. (*b*) Stating that there are cases of pulmonary gangrene which evidently must not be regarded as broncho-spirochætosis of Castellani, Professor Delamare compares *S. bronchialis* with *S. vincenti*. The arguments pro and con can be resumed as follows: (1) absolute similarity of the majority of bronchial spirochætes with the spirochætes of Vincent's angina (Delamare). I will remark that in the only case of Vincent's angina I was able to study, the spirochætes did not stain well with common stains and required Romanowsky. The same happens with many types of spirochætes found in phagædenic ulcers. (2) Frequent symbiosis with fusiform bacillus (Delamare). I have already said that their association is found with many other spirochætes, even with common mouth species. (3) The absence of fusiform bacillus in some cases of broncho-spirochætosis does not necessarily indicate for Delamare that they are not present in the lesion, as occasional disappearances of and oscillations in their number have been observed. And it is on these arguments that Professor Delamare concludes that " il faut bien se décider á rayer *S. bronchialis* de la nomenclature," giving it a synonym of *S. vincenti*, constituting, perhaps, on account of its adaptation to the bronchi, a race particularly apt to be free of its habitual symbiosis with fusiform bacillus, and accepts the name *S. vincenti* var. *bronchialis*. It seems to me that this is a mere hypothesis unsupported by any solid reason.

For all these arguments I am of opinion that *S. bronchialis* Castellani is a distinct species and that broncho-spirochætosis is a clinical entity of its own.

Nova-Goa, April, 1925.

FURTHER OBSERVATIONS ON VAGINAL MONILIAS AND VAGINAL MONILIASES.

By Aldo Castellani, C.M.G., M.D., F.R.C.P.,
Director of Tropical Medicine and Dermatology, Ross Institute, London,

and

Frank E. Taylor, M.D., B.S., M.A., M.Sc. F.R.C.S.,
Lecturer on Bacteriology, King's College, London.

When microscopic examination is made of stained smear preparations of vaginal discharge, large round or oval bodies usually described as yeasts or yeast-like cells are frequently observed.

These are present in addition to an extensive bacterial flora which is always observed. As a rule the presence of these yeast-like bodies is straightway ignored on the presumption that they are of no clinical significance. Whether this presumption is justified or not yet remains to be proved. In the normal vaginal secretion they are present, if present at all, in extremely scanty numbers, being found neither in smears nor in cultures. On the other hand, they are often present in large numbers in cases of vaginitis associated either with an increased amount of vaginal secretion or with membrane formation.

Cultures of these organisms can readily be obtained by smearing a swab moistened with the vaginal discharge over the surface of a glucose-agar or a maltose-agar plate. By fishing and subculturing from the thick, creamy-white colonies that develop on the glucose-agar or the maltose-agar plates, pure cultures may be obtained without very great difficulty. Further study and investigation of the organisms so obtained shows them to belong to the genus *Monilia* Persoon 1797 of the class Fungi Imperfecti.

Under the name Fungi Imperfecti, Finckel gathered together all the forms of fungi, the complete history of which was unknown, and made this class in contradistinction to his other class of Fungi Perfecti, so that there is some ground for the naive remark of Lafar in his " Technical Mycology " that the Fungi Imperfecti are so called, not because the fungi in this group are themselves imperfect, but because our knowledge of them is imperfect.

They may be defined as follows: Fungi, almost invariably minute, but much larger than bacteria, in which asexual reproduction takes place by means of conidia produced on conidiophores which are either enclosed in perithecia, placed on discs, or unprotected.

The fungi thus defined were divided into two groups by Vuillemin, viz., the DEUTEROMYCETES and the HYPHALES. It is to the subclass Hyphales that the monilias belong, and the Hyphale of Vuillemin may be defined as Fungi Imperfecti with the hyphæ more or less developed, less or more or less compact, superficial or subsuperficial or more rarely as in man, vertebrates and insects, endoparasite conidiophores never situate in closed or open receptacles. Reproduction by means of spores isolated or in groups, situate on isolated or fasciculated hyphæ. The monilias are included in the family Oosporaceæ in the subclass Hyphales; and the relationship to the other genera of this family—the *Oospora* and the *Oidium*—is seen in the following classification:—

A. Hyphæ thin, short, simple, or nearly simple, terminating in chains of spores—*Oospora*, sugars not fermented with gas production.

B. Hyphæ not thin, often long and branched.

1. Sporophores simple and subsimple, typically with disjunction apparatus. Glucose completely fermented, gas being produced. Numerous budding forms in culture—*Monilia*.

II. Sporophores simple, septate, often with disjunction apparatus. Glucose not completely fermented, gas not being produced. Budding forms rare in culture—*Oidium*.

According to this classification the botanical definition of the monilias is as follows:—

Sporophores simple or subsimple, producing by constriction at their extremities a chain of large lemon-shaped conidia, often provided with a dis junction apparatus.

The usual definition, however, is as follows: Oosporaceæ, possessing *in situ* budding forms and mycelial threads, which later are often long and branched; in cultures mostly budding forms but sometimes filaments in which thallospores of the blastophore type are found. Glucose and often other carbohydrate media are fermented with the production of gas.

Very closely allied to, and at present often included in this genus are the *Zymonema* of de Buermann and Gougerot, 1909, including the *Zymonema gilchristi*, more commonly called *Cryptococcus gilchristi*, which causes American blastomycosis, the *Parasaccharomyces* of de Buermann and Gougerot, 1909, and the *Parendomyces* of Querat and Laroche, 1909.

The genus *Monilia* is widely distributed in nature, a number of species having been found growing on dead leaves, fruits and decomposing wood. That a number of species may affect man was first pointed out by Castellani, who has shown their importance as the ætiological agents of thrush, bronchomycosis (*pro parte*), and some dermatomycoses; whilst Ashford attributes the causation of sprue to a monilia—*Monilia psilosis*, which is probably merely a synonym of *Monilia enterica* Castellani.

The classification of the monilias has been the subject of much confusion. Morphological grounds do not suffice for a classification, but by means of their biochemical reactions a fairly satisfactory classification has now been reached. By means of the sugar reactions it is possible to divide the species of *Monilia* into groups: (1) by the use of the following carbohydrates: glucose, levulose, maltose, galactose, saccharose, lactose, inulin.

1. *Balcanica group.*—Gas produced in *glucose* only. *Monilia balcanica* Castellani. *Monilia parabalcanica* Castellani.
2. *Krusei group.*—Gas produced in *glucose* and *levulose*. *Monilia krusei*, Castellani. *Monilia parakrusei*, Castellani.
3. *Pinoyi group.*—Gas produced in *glucose*, *levulose*, *maltose*. *Monilia pinoyi* Castellani. *Monilia nabarroi* Castellani.
4. *Metalondinensis group.*—Gas produced in *glucose*, *levulose*, *maltose* and *galactose*. *Monilia metalondinensis* Castellani. *Monilia pseudometalondinensis* Castellani.
5. *Tropicalis group.*—Gas produced in *glucose*, *levulose*, *maltose*, *galactose* and *saccharose*. *Monilia tropicalis* Castellani. *Monilia partropicalis* Castellani. *Monilia pulmonalis* Castellani. *Monilia nivea* Castellani, *Monilia*

insolita Castellani. *Monilia enterica* Castellani.

6. *Guillermondi group.*—Gas produced in *glucose, levulose, saccharose* and *raffinose. Monilia guillermondi* Castellani. *Monilia pseudo-guillermondi.*
7. *Macedoniensis group.*—Gas produced in *glucose, levulose, galactose, saccharose* and *inulin. Monilia macedoniensis, Monilia macedoniensoides.*
8. *Pseudotropicalis group.*—Gas produced in *lactose* and *other carbohydrates. Monilia pseudotropicalis.*[1]
9. *Pseudolondinensis group.*—Gas produced in *dextrin* in addition to other carbohydrates. *Monilia pseudolondinensis* Castellani. *Monilia pseudolondinoides,* Castellani. *Monilia africana,* Macfie.
10. *Zeylanica group.*—No gas produced in any sugar.

In the vaginal discharge of cases of vaginitis, monilia belonging to groups *balcanica, pinoyi, metalondinensis* and *tropicalis* have been found in certain parts of the tropics, in the Balkans, in Italy and in England. More extended investigations will probably reveal other members of the genus in this condition. The members of Group 1 found were *Monilia balcanica* and *Monilia parabalcanica;* of Group 3, *Monilia pinoyi* and *Monilia nabarroi;* of Group 4, *Monilia metalondinensis;* and of Group 5, *tropicalis.* The principal characters of these organisms, together with other monilias, are set forth in the accompanying table.

In searching the literature we find several references to this subject; thus: Littauer described an aphthous vulvitis due to *Oidium albicans.* He believed that this condition begins as a primary vaginitis and is rarely found in children, but is common in diabetes and in the aged. He also mentions the cases of Plant in Hamburg, in which vaginal thrush and vaginal pruritis were associated with fungi of similar nature.

Von Herff has also recorded the occurrence of monilias in the vagina in cases of vaginitis and of vaginal pruritus, considering, however, that they were all comprised in the species *albicans* and *candida.* Loeser found saccharomyces among the microbic flora of the normal vagina and in cases with cervical catarrh with the formation of erosions, whereas Frank considers that in a perfectly healthy vagina only vaginal bacilli and comma variabile are found in the spread, and as the vagina approaches the pathological, more and more of the bacteria appear. Cases of vaginal thrush have also been described by Guilini, Hausmann, Vleemann, Mettenheimer and Panfilowicz.

[1] It is important to note that many monilias after a few transplantations lose some of their fermentative characters or these are altered. Hence the determination of species is possible only when using recently isolated strains.

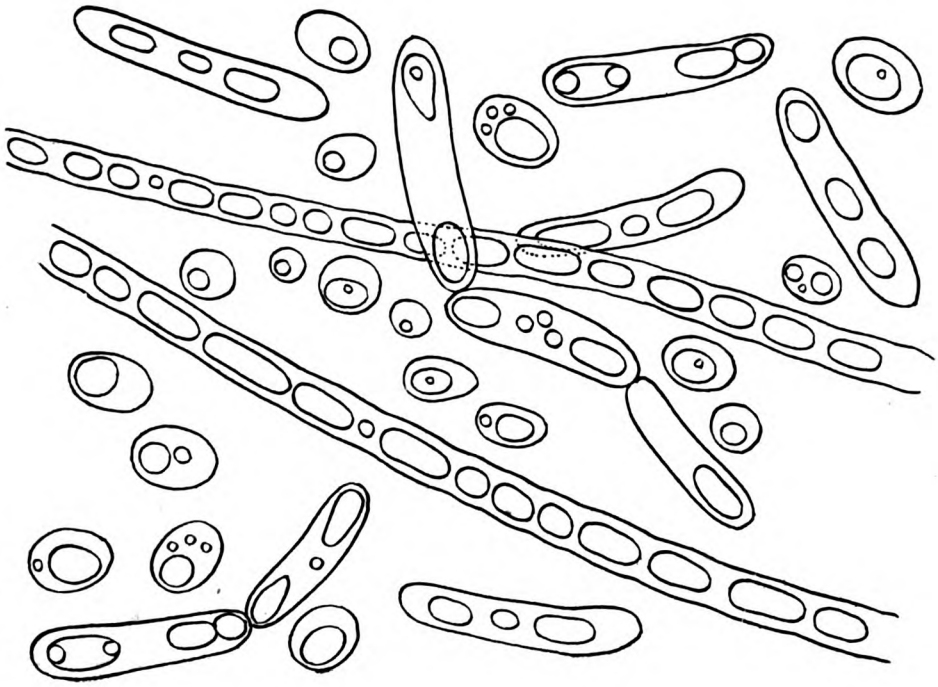
in the first or membranous type, thrush-like patches of membrane are present on the mucosa (the so-called vaginal thrush); in the second or purulent type no such patches are present, but the secretion is thick and purulent. Where laboratory facilities do not exist cases of the purulent type of vaginal moniliasis are not rarely mistaken for gonorrhœa. The following illustrative case, which occurred in Ceylon, may be quoted: The surgeon in charge of the Colombo Lying-in Home had a case in which a pelvic operation was urgent; a thick purulent discharge was, however, noted, and active gonorrhœa was suspected, and he felt inclined to postpone the operation. A specimen of the discharge was sent to one of us for examination. No gonococci were found, but an enormous number of Gram-positive mycelial and conidial elements were present. Further investigation revealed the fungus to be *Monilia pinoyi*, Castellani.

Attention may also be directed to the presence of very numerous monilias in certain cases of chronic vaginal pruritus associated with muco-purulent discharge, although we cannot say whether the monilias really play a rôle in the causation of the pruritus. In these cases abundant irrigations of iodine (tinct. iodi ʒj, aq. ad Oij) have answered exceedingly well, especially after a preliminary short course of hot bicarbonate of soda irrigations. We might also call attention to a variety of pruritus vulvæ and pruritus ani described by one of us (C.), caused by localization of fungi of the genus *Epidermophyton* in the ano-perineal region and on the external surface of the labia majora, without any objective symptom pointing to an epidermophytic or trichophytic infection. In such cases the fungus remains dormant, and apart from the pruritus, give rise to no symptoms, although on close examination not rarely a few red patches may be seen. The condition may be compared to the pruritus interdigitalis pedium caused by the localization to the skin of the toes of the same epidermophyton. Fungi in that localization, too, remain dormant, causing pruritus but no objective sign pointing to an epidermophytic condition.

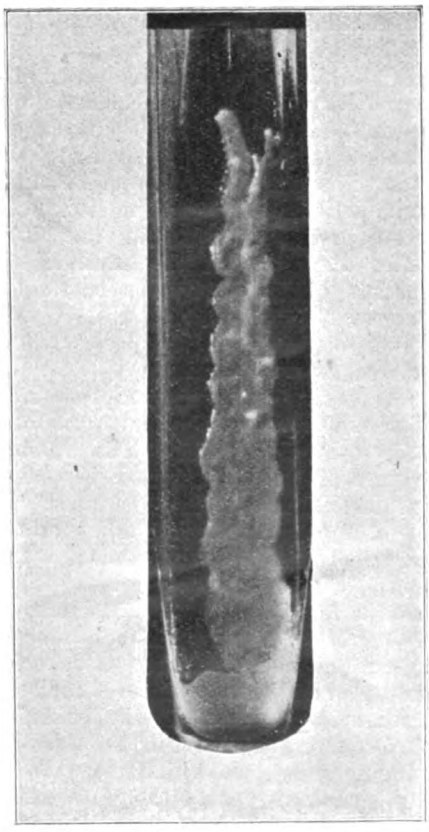
Recently we have come across a most interesting case of extremely severe pruritus ani, pruritus vulvæ and pruritus vaginæ in an elderly spinster, of some years' duration, which had been treated by different medical men in various ways without any distinct amelioration resulting. In the perianal region, on the perineum and on the labia majora a very few small reddish patches were seen, which it was thought might be due to a secondary pyogenic infection produced by scratching. There was an abundant purulent vaginal discharge and a very similar discharge from the anus, with symptoms of proctitis. A complete mycological and bacterial investigation was carried out, with the following results:—

1. From the scrapings of the perianal region and from the labia majora a fungus was grown with the characters of ***Epidermophyton cruris*** Castellani, 1905, the fungus which is the commonest cause of dhobie itch and pruritus interdigitalis pedium.

2. In the vaginal and in the rectal discharge enormous numbers of monilias were present, with very few bacilli; cultivations showed the fungus to be a strain of *Monilia pinoyi* Castellani.

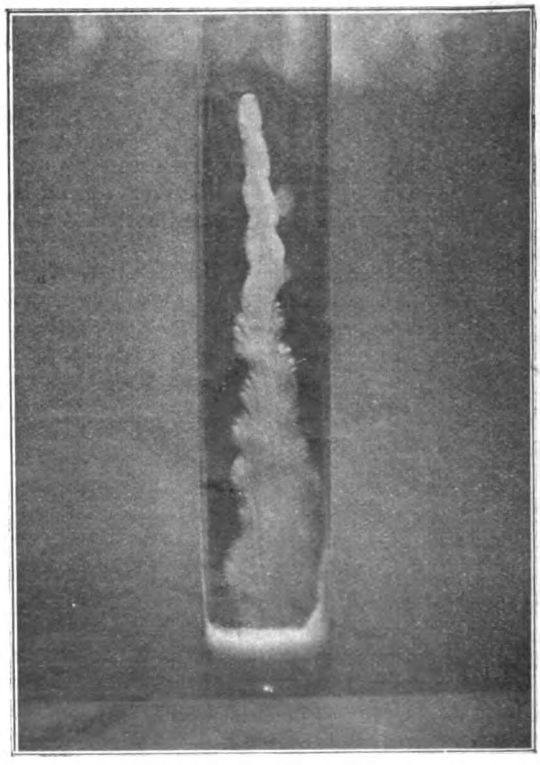


The following treatment was given: creosote was administered by the mouth. Tinct. iodi, which in this case did not give rise to any local pain or irritation, was freely applied once a day to the anal-perinal region, the perineum and the external surface of the labia majora. For the first three days hot alkaline irrigations (two ounces of bicarbonate of soda to two pints of hot water) were given; afterwards, twice a day with iodine irrigation (tinct. iodi ʒj, aq. ad Oij). Within two weeks the lady was completely free from the ano-perineal and vulvo-vaginal discharge, and the purulent rectal discharge had ceased entirely, whilst the vaginal discharge had decreased but had not quite disappeared. The monilias present had diminished enormously in number, but had not disappeared completely.



Monilias in the Identification of Certain Carbon Compounds.

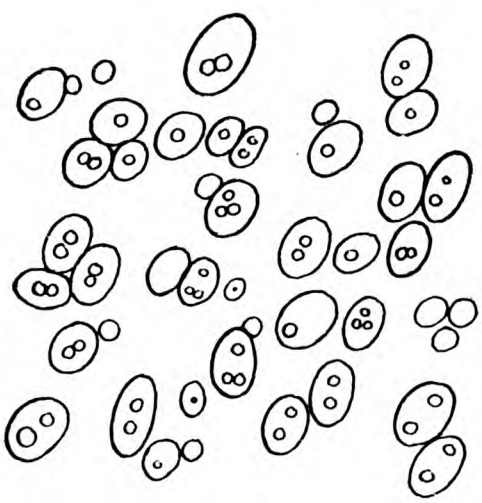
Detection of Lactosuria.



Certain species of monilia, some of which were isolated from the vagina, have been employed by us in association with other micro-organisms as reagents in a new method of mycological analysis of carbohydrates and other compounds of carbon, theoretically devised by one of us (C.) in Ceylon some years ago. The differentiation, for example, of the various Fehling-reducing substances present in urine is readily accomplished by the application of this mycological method. By its use we have been able to recognize the following carbohydrates in urine, viz., glucose, lactose, galactose, saccharose, maltose, pentose, glycerol and inosite. It forms a ready and convenient method for recognizing the presence of lactose in the urine of pregnant and puerperal women, and for differentiating this substance from glucose and other Fehling-reducing substances. The technique of the method may be found in papers published by us in the *British Medical Journal*, 1917, vol. xvi, No. 5. We will limit ourselves to describing very briefly the detection of lactosuria.

Lactose, as is well known, reduces Fehling's solution, and not infrequently lactosuria has been mistaken for true glycosuria. The detection of lactose by purely chemical methods is difficult for an ordinary medical man. In most textbooks it is stated that if a urine reduces Fehling and is not fermented by ordinary baker's yeast (so-called German yeast), the presumption is that the reducing substance is *lactose*. There are, however, two important sources of error. First, in our experience, quite a number of specimens of baker's yeast ferment lactose in addition to glucose, maltose, and other sugars; second, even if the baker's yeast should not ferment lactose this is not the only Fehling-reducing substance which may not be fermented by baker's yeast—the pentoses, for instance. If a urine which reduces Fehling is not fermented by ordinary yeast we cannot therefore

TUBE 1.—*Monilia Tropicalis* Castellani.



TUBE 2.—*Monilia Pinoyi* Castellani.

come to the conclusion that it is a case of lactosuria. Our mycological or myco-bacterial method, on the other hand, renders possible the detection of lactosuria in a very easy manner.

The urine is collected aseptically, or if this is not feasible, is distributed into sterile tubes (each containing a small fermentation tube) as soon as passed, and then sterilized in Koch's stove for thirty minutes on two or three consecutive days, or the urine may be filtered through a sterile Berkefeld filter. It should never be autoclaved, as this procedure not rarely alters the chemical structure of the sugars. Two or three tubes of the aseptic urine to which one-third or the same amount of sterile sugar-free peptone water has been added, are inoculated with certain monilias and other micro-organisms as follows:—

(*a*) No. 1 tube is inoculated with *Monilia pseudotropicalis*. No. 2 is inoculated with *Monilia tropicalis*. The two tubes are placed in the incubator at 37° C. for three days and then the results are read.

If No. 1 tube (*Monilia pseudotropicalis*) contains gas, and No. 2 (*Monilia tropicalis*) does not, we can come to the conclusion that in all probability the urine contains lactose. This is easily explained by keeping in mind the biochemical reactions of *Monilia tropicalis* and *Monilia pseudotropicalis*. These two monilias differ only in regard to lactose and maltose, *Monilia pseudotropicalis* fermenting maltose but not lactose; a substance, therefore, which is fermented by *Monilia tropicalis* must in all probability be *lactose*. This is represented by the following mycological formula:—

Monilia pseudotropicalis	+	= Lactose.
Monilia tropicalis	0	

(*b*) No. 1 tube is inoculated with *Bacillus neapolitanus* Emmerich. No. 2 tube is inoculated with *Bacillus pseudoasiaticus* Castellani. If after two days in the incubator at 37° C., No. 1 tube (*Bacillus neapolitanus*) contains gas and No. 2 tube does not contain gas, we can come to the conclusion that the urine contains lactose. The explanation lies in the fact that *Bacillus neapolitanus* and *Bacillus pseudoasiaticus* differ only in lactose as regards sugars and other carbohydrates found in pathological urines.

B. neapolitanus	+	= Lactose.
B. pseudoasiaticus	0	

(*c*) Tube 1 is inoculated with *Bacillus coli*, tube No. 2 with *Monilia metalondinensis*. If after 48 hours there is fermentation in No. 1 tube and no gas in No. 2 tube, we can come to the conclusion that lactose was present, provided Fehling was positive.

Fehling	+	
Monilia metalondinensis	0	= Lactose.
B. coli Escherich	+	

(*d*) In practice, the following procedure is very convenient. No. 1 tube is inoculated with *Bacillus coli* Escherich, No. 2 tube with *Bacillus paratyphosus* B Schottmüller. If fermentation occurs in tube No. 1 (*coli*) and does not occur in tube No. 2 (*paratyphosus*) we may come to the conclusion that the urine contained lactose, provided Fehling was positive. This is easily understood by remembering that *Bacillus coli* and *Bacillus paratyphosus*, besides lactose, differ in their action on raffinose and salicin, but raffinose and salicin are not Fehling-reducing.

Fehling	+	
B. coli Escherich	+	= Lactose.
B. paratyphosus B Schottmüller ...	0	

Further details on the method may be found in our publication in the *Annales de l'Institut Pasteur* (November, 1922).

Vaginitis associated with Fungi other than Monilias.

In addition to fungi of the genus *Monilia* Persoon, we may add that one of us (C.) has found occasionally in the vaginal secretion of native women suffering from very chronic vaginitis in the tropics, fungi of the genus *Oidium* (Link), *Aspergillus* (Micheli), *Sporotrichum* (Link), *Chladosporium* (Link), *Sterigmatocystis* (Cramer), *Cryptococcus* (Kützing, 1883), *Willia* (Hansen), *Vibriothrix* (Castellani), and others. Recently we have observed two such cases in European women in England, in one of which an aspergillus was grown, in the other a hemispora.

Vaginal Aspergillomycosis.—The case observed was an old woman, who complained of brownish-black vaginal discharge. The microscopical cultural examination revealed the presence of an aspergillus very similar to *Aspergillus fumigatus*. Irrigations with a weak solution of lysol cured the condition.

Vaginal Hemisporosis.—A young married lady contracted in the East a mycosis of the tonsils which, during the acute stage, was at first considered to be diphtheria. After the acute symptoms disappeared a greyish-whitish patch remained on the right tonsil. When she came to see one of

us in London, on her return from the tropics, she had had it for five months. She was complaining also of feeling discomfort in the vulva. The examination of her genital organs revealed a greyish patch on the inner surface of the right labium, somewhat similar to that present on the tonsil. From both the patch on the tonsil and the patch on the right labium a fungus was grown with all the characters of *Hemispora rugosa*. Local application of diluted tincture of iodine cured the condition, both on the tonsil and the labium.

Hemispora rugosa Castellani belongs to the Hemisporales Vuillemin 1910, the definition of which is Hyphales, with the mycelium, composed of abundant hyphæ, thin, but more than one micron in diameter, septate and

Hemispora rugosa.

branched conidiophores ramified basally, each branch terminating in a protoconidium, preceded by a constriction produced by a brown, rigid thickening of the wall. The protoconidium is transformed completely or partially into deuteroconidia, but occasionally it elongates, forming a new conidiophore, or puts out branches which are capable of becoming conidiophores. As regards classification, there is only one genus, *Hemispora* Vuillemin, 1906, the definition of which is mycelial filaments, thin, hyaline, septated, ramified. Each conidiophore terminates into an ampulliform structure (protoconidium), which later divides into several spore-like segments (deuteroconidia). Three species are known: *Hemispora stellata* Vuillemin, *Hemispora rugosa* Castellani, *Hemispora pararugosa* Castellani, Douglas and Thompson. The latter is probably only a variety of *H. rugosa*.

HEMISPORA RUGOSA.

Name of fungus	Motility Gram	Gelatine	Serum	Litmus milk	Lactose	Saccharose	Dulcite	Mannite	Glucose	Maltose

Abbreviations used in the Tables.—A = acid; C = clot; G = gas; S = slight; vs = very slight; O = negative result, viz., non-production of acid or gas in

Hemispora rugosa Castellani, 1910 (*Syn. Monilia rugosa* Castellani, 1910.)

Definition.—Hemispora growing on all ordinary media, with a crinkled surface without asteroid colonies.

Remarks.—The growth on glucose agar is abundant, crinkled, or at times somewhat cerebriform; and in colour is amber, yellow, or brownish. Grows well on gelatine, which it liquefies very slowly, so much so that at first it was believed to be a non-liquefier. Gram-positive. Milk is not changed as a rule, but occasionally it undergoes a certain degree of peptonization, with a very small coagulum at the bottom of the tube. For sugar reactions see the table.

Hemispora pararugosa Castellani, Douglas and Thompson differs from *H. rugosa* in being a rapid liquefier of gelatine. *Hemispora stellata* Vuillemin is characterized by its asteroid colonies, and moreover, after a time glucose agar cultures develop a black pigmentation.

Conclusions.

1. In the normal vagina monilias and other fungi appear to be constantly absent.

2. In certain cases of vaginitis, vulvo-vaginitis, and of vulval vaginal and ani-perineal pruritus, monilias are abundantly present and may perhaps play some rôle in the ætiology of such cases, or at least produce the associated purulent or muco-purulent discharge.

3. Two principal types of vaginitis are associated with the presence of monilias, namely (*a*) the membranous type, presenting white patches of membrane on the vaginal mucosa, the so-called "vaginal thrush," and (*b*) the purulent type, with thick purulent vaginal discharge containing enormous numbers of monilias and sometimes simulating gonorrhœal infection.

4. Monilias, along with other micro-organisms, are employed in the authors' mycological method of identification of carbohydrates and other carbon compounds. This method is especially useful in the detection of lactosuria.

5. Attention is also directed to the presence of several genera of fungi other than the monilias in the vaginal secretion of cases of chronic vaginitis. A case of vaginal aspergillomycosis and a case of vulvar hemisporosis have been briefly described.

THE CESTODE GENUS *HYDATIGERA* LAMARCK, 1816, SPECIES *REDITÆNIA* SAMBON, 1924.[1]

By C. W. Stiles,

Professor of Zoology,

and

Mabelle Orleman,

Laboratory Aide, Hygienic Laboratory, U.S. Public Health Service.

Sambon (1924, Journal of Tropical Medicine and Hygiene, 165) has recently proposed *Reditænia* as a new genus of Cestoda, with *Tænia tæniæformis* of cats as type species, and he differentiates the larval stage, *Cysticercus fasciolaris*, found in the liver of rats and mice, from other cysticerci under the new name *Strobilocercus*. The generic characters are:—

Tæniidæ, *Tæniinæ*: Rostellum massive, columnar, armed with double row of hooks and resembling an actinia (coral). Suckers prominent, set at base of rostellum and pointing forward and outward. Neck absent; segmentation begins immediately caudad of suckers. Adults in intestine of carnivorous mammals. Larva a "*Strobilocercus*" Sambon, 1924, J.T.M.H., 165 (i.e., a segmented cysticercus, in which the head is in the anterior end; bladder reduced, very small, at caudal end; body more or less segmented; the proglottids occasionally with genital primordia). Tod. *Tænia crassicollis* of cats (larva is *Cycticercus fasciolaris* of rats and mice).

---

[1] Approved for publication by the Surgeon-General.

This newly proposed genus is of interest in human medicine from two points of view, namely:

(*a*) As parasites of man:—

I. *Tænia infantis* Bacigalupo, 1922 (*Semana med.*, 302-305, figs. 1-5), has recently been described as a new parasite of man in Argentine. It bears a remarkable resemblance to *T. tæniæformis* of cats, and if it is a valid species it is to be classified in the same genus with the tapeworm from the cat.

II. *Tænia crassicollis* Rudolphi, 1810a, is synonymous with *T. tæniæformis*. On account of a folk custom of eating chopped liver of mice in case of retention of urine, this worm has long been under suspicion as a possible parasite of man (but its occurrence in man is as yet doubtful).

(*b*) Because of the concurrence of cancer in the liver of rats with the presence of *Cysticercus fasciolaris*.

Whether or not the characters advanced by Sambon will be accepted as of generic value will depend largely upon individual conceptions of taxonomy. Conservatively they might be accepted as of subgeneric rather than of generic value, but admittedly this is a subjective opinion.

Attention may, however, be invited to the point that if *Tænia tæniæformis* is accepted as representing a genus or a subgenus distinct from *Tænia* (*Tænia*) type *T. solium*, and *Tænia* (*Tæniarhynchus*) type *T. saginata*, the new generic name *Reditænia* falls into synonymy, for it is antedated by two other names, *Megacephalos* and *Hydatigera*, both based upon the same species as genotype.

Megacephalos Goeze, 1782a, 42, was based upon the larval form *Tænia vesicularis fasciolata* (= *Cysticercus fasciolaris*) of the rat. The question arises, however, whether this name is available in nomenclature. The nomenclatorial practices of Goeze, 1782, are so confusing and subject to such subjective interpretation that the senior author of this paper circularized a number of helmintholo-gists about thirty years ago with the proposition that Goeze, 1782, be eliminated from consideration in nomenclature because of the inconsistencies. Several of Goeze's names had, however, become current, and the proposition did not meet with favourable response. Accordingly, he bowed to the view of the majority and accepted Goeze's names. To recognize *Megacephalos*, 1782, at present might produce confusion in other groups, the extent of which cannot be immediately foreseen. The following technical names of the same derivation have been proposed: *Megacephala* Latr., 1802, coleopt.; *Megacephala* Meig., 1824 (supergeneric), dipt.; *Megacephalidæ* Lap., 1834 (supergeneric), coleopt.; *Megacephalon* Temm., 1844, aves; *Megacephalon* Gray, 1846, aves; *Megacephalus* Fitz, 1843, rept. Partly on the basis of the principle that current nomenclature should not be disturbed unless the necessity therefore is clear under the International Code, and partly on the premise that we have grave misgivings as to the availability (under the International Rules) of Goeze's name *Megacephalos*, we are unwilling to assume the responsibility of accepting it.

Hydatigera Lamarck, 1816b, 153-154, was proposed to contain: (1) *Cystercus fasciolaris* of rodents, (2) *C. fistularis* of the horse, and (3) *C. cellulosæ* of man, &c. The first species, *C. fasciolaris*, was later definitely designated as genotype. *Hydatigera* is on a different basis from *Megacephalos*, and under Articles 25 and 26 of the International Code this name undoubtedly takes precedence over *Reditænia*.

The purpose of inviting attention to this point is to prevent, if possible, the use of the generic name *Reditænia* in medical literature with the certainty in view that it would have to be changed later. If the new taxonomic unit proposed is accepted by authors as of either generic or subgeneric value the correct name will be *Hydatigera*, with *Reditænia* as synonym.

NOTES ON NON-GONORRHŒAL URETHRITES.

By Aldo Castellani, C.M.G., M.D., F.R.C.P.

Director of Tropical Medicine and Dermatology, Ross Institute, London.

Very recently I was consulted by a planter on leave from an Eastern country, who informed me that he was suffering from chronic gonorrhœa, for which he said he had been treated with gonococcus vaccines without any benefit for a long period of time. On examination I found that there was a thick whitish discharge from the urethra. The microscopical examination showed absence of gonococci or of cocci and bacilli of any kind; instead numerous yeast-like cells were present; some glucose agar tubes were inoculated and a monilia was grown. I came to the conclusion that it was a case of mycotic urethritis, several types of which I described some years ago. I put him on creosote and potassium iodide and gave him also large doses of bicarbonate of soda; locally injections of mercury perchloride, 1 in 20,000, and instillations of diluted glycerine of borax on alternate days. All the symptoms disappeared within two weeks.

In connection with this case it may perhaps be of some interest to give a short general account of non-gonorrhœal urethrites, a subject which has hitherto attracted very little attention.

Some years ago I classified these conditions as follows:—

(1) Traumatic urethritis.

(2) Urethritis associated with protozoa.

(3) Urethritis associated with animal parasites higher than protozoa.

(4) Urethritis associated with fungi.

Another group of urethrites might be added; bacterial non-gonorrhœal urethrites, various cocci and diphtheroid bacilli having been described as capable of producing urethritis, but in my experience these organisms are usually secondary invaders.

Traumatic Urethritis.

In certain individuals prolonged marching or any other exercise or exposure to prolonged vibration, such as a long railway journey, seems to cause

symptoms of urethritis. One, of course, is rather sceptical in admitting such a type of urethritis, and practically all the cases of so-called "porter's urethritis" which I saw in Africa were cases of gonorrhœa. However, it must be admitted, in my experience, that in soldiers and porters doing long marches day after day, a slight urethritis with scanty mucous discharge, very seldom, if ever, purulent, may develop, even in individuals who apparently have never suffered in the past from gonorrhœa.

Urethritis associated with Protozoa.

The following varieties may be distinguished:—

(1) *Spirochætic Urethritis.*—This type of urethritis, first described by Macfie and due to *S. urethralis* Macfie, is occasionally met with. The discharge may be abundant and frankly purulent, and contain an enormous number of spirochætes. It must be noted, however, that spirochætes are not rarely found in the normal urethra, as shown by many observers and in the tropics by Mendelson.

(2) *Treponema Urethritis.*—The discharge is muco-purulent and contains a large number of treponemas (*Treponema urethrale* Castellani), without any cocci or bacilli. The organism is very delicate, stains purplish or pinkish, with Giemsa's, has numerous small spirals, all practically of the same size; length of the parasite 6 to 12 microns. The patient has no sign of syphilis and Wassermann is negative. Urethral irrigation of a 1 in 20,000 solution of hyd. perchlor. cures the condition. I have seen only two cases of this condition.

(3) *Urethritis associated with Amœbæ.*—Several cases have been recorded, the amœbæ being apparently of the *histolytica* type.

(4) *Urethritis associated with Flagellates.*—The flagellates found belong to the genera *Trichomonas* Donne, *Cercomonas* Dujardin, *Prowazekia* Hartmann and Chagas. It is doubtful, however, whether the flagellates found are the true ætiological agents of the discharge.

(5) *Urethritis associated with Ciliates.*—In a case of urethral discharge in a Singalese man in Ceylon, Chalmers and I found a *Balantidium*-like ciliate which we had previously observed in the vaginal secretion of several native women.

Urethritis associated with Animal Parasites higher than Protozoa.

These are generally due to larvæ of flies and chance parasites setting up an inflammation of the urethra.

Urethritis of Mycetic Origin.

Ætiologically these urethrites may be grouped as follows:—

(1) Associated with so-called *yeast-like* fungi, viz., fungi belonging to the genera *Saccharomyces* Meyen 1838; *Cryptococcus* Kützing 1833, *Monilia* Persoon 1797, *Endomyces* Rees 1870, and allied genera.

(2) Associated with fungi of the genus *Nocardia* Toni and Trevisan 1889.

(3) Associated with fungi of the genus *Oidium, sensu* Pinoy.

(4) Associated with fungi of the genus *Hemispora.*

(5) Associated with fungi of the genera *Aspergillus, Penicillium,* and allied genera.

(6) Associated with fungi of the genus *Cladosporium.*

(7) Associated with fungi which have not yet been classified.

The botanical description of these fungi may be found in the chapters on fungi in Castellani and Chalmers' "Manual of Tropical Medicine," third edition.

As regards the principal species of the genus *Monilia,* these are found in the paper on "Vaginal Moniliasis" by Taylor and myself in this number of the Journal.

In practice it is of advantage to use a clinical classification based on the colour of the discharge, viz.:—

(1) Mycotic urethrites with white or white-yellowish discharge.

(2) Mycotic urethrites with red discharge.

(3) Mycotic urethrites with black discharge.

Mycotic Urethrites with white or yellowish discharge.

Ætiologically two groups of cases may be distinguished: (*a*) those in which yeast-like organisms are found in the great majority; (*b*) those in which *Nocardia*-like fungi are present, very rare.

In cases of the first group, the fungi belong generally to the genera *Monilia, Saccharomyces* and *Cryptococcus;* the secretion is whitish or yellowish, generally scanty but occasionally abundant and macroscopically indistinguishable from gonorrhœal discharge. In certain cases signs of balano-posthitis due to the same fungi may be present, with or without thrush-like white membranes.

Cases of the second group, of *Nocardia* origin, are in my experience extremely rare. I have had two cases only: in both the discharge was yellowish, in one small yellowish granules composed of masses of bacillus-like fungus were present. *Nocardia* fungi were grown from both cases. I may add that potassium iodide given in large doses cured both cases.

Illustrative Case (mycotic urethritis with presence of yeast-like fungi).—In addition to the case I have mentioned in opening this paper, I could quote at least another half-dozen cases, but I will limit myself to saying a few words on a case I observed in the Balkans during the Great War:—

A young Serbian officer in Macedonia consulted me for a fairly abundant purulent urethral discharge. The patient was greatly distressed; he was engaged and believed he was suffering from gonorrhœa, though he denied having exposed himself to infection. I examined the secretion: no gonococci present; instead a large number of yeast-like cells and a few mycelial filaments could be seen. The cultural investigations showed presence

of a monilia very similar to *Monilia krusei*. I prescribed a mixture containing pot. iod., soda bicarb., glycer., syr. of tolu, and irrigations with a solution of perchloride of mercury 1 in 20,000. The discharge disappeared completely within ten days.

Mycotic Urethrites with black, greenish-black or brownish-black discharge.

The urethral discharge is black or greenish black or dark brownish, and may be very scanty; at times there is a yellow purulent discharge, in which small black or greenish-black granules are seen. The fungi found generally belong to the genera *Cladosporium*, *Aspergillus*, *Penicillium*, and closely allied genera. Very often, in addition to the fungi, various cocci and bacilli are found. In one case I grew a *Nocardia* producing a black pigmentation.

Illustrative Case.—An old Tamil coolie came to the Colombo Clinic in January, 1906, complaining of black urethral discharge dating from several months back. He stated that he had not had sexual contact for several years. The secretion was blackish and contained numerous small granules, which on microscopical examination were seen to consist of mycelian threads and spore-like bodies. Various sugar-media were inoculated and a fungus was grown, producing a black pigmentation, and very similar also in other characters to *Cladosporium mansoni* (Castellani). In two other clinically similar cases, one in a native and the other in a European, I found aspergillus-like fungi.

Mycotic Urethrites with red or pink discharge.

In these cases red pigment-producing fungi are found of the genera *Cryptococcus*, *Torula*, *Monilia*, *Saccharomyces*. At times two organisms are found; a higher fungus such as a monilia, living apparently in symbiosis with a red pigment-producing coccus or bacillus.

Illustrative Case.—A little Singalese boy, six years old, was brought to my clinic in Colombo by his parents because they believed he was passing blood from the urethra. The discharge, examined microscopically, consisted of leucocytes and numerous budding cells. Several sugar-agar tubes were inoculated and a red pigment-producing cryptococcus was grown. The child was given an alkaline mixture, and instillations of diluted glycerine of borax were carried out. This, however, did not improve the condition. Urethral injections of a solution of perchloride of mercury, 1 in 20,000, were then made, and a speedy cure resulted.

Primary and Secondary Mycotic Urethrites.

As is the case with so many other mycoses, the urethral fungoid infection may be *primary or secondary*. Practically all my cases seemed to be primary, but I observed once a monilial infection of the urethra developing in a case of chronic gleet.

RÉSUMÉ AND CONCLUSION.

(1) Non-gonorrhœal urethrites are not of frequent occurrence, but it would appear from my observations that they are not so exceedingly rare or non-existent as some authorities would seem inclined to believe.

(2) Non-gonorrhœal urethrites may be classified into three groups: (*a*) of traumatic origin, (*b*) of protozoal and metazoal origin, (*c*) of mycetic origin. Those of the first group are exceedingly rare and from a practical point of view may be omitted altogether; as regards the second group several of them are doubtful, the flagellates and some of the other protozoa found probably not being the true causative agents. The urethrites of the third group are the most important from a practical point of view, as there is little doubt that the fungi found are in a certain number of cases the true causative agents, but as is the case in so many other mycoses (bronchomycoses for instance) there is primary and secondary mycotic urethritis.

(3) Mycotic urethrites may be classified ætiologically according to the botanical position of the fungi observed or they may be classified clinically into three subgroups according to the colour of the discharge: mycotic urethrites with black discharge, mycotic urethrites with white-yellowish discharge, mycotic urethrites with red discharge. The urethrites of the first subgroup are generally associated with so-called yeast-like fungi (*Monilia*, *Cryptococcus*, *Saccharomyces*). Those of the second subgroup are mostly associated with the presence of *Cladosporium*, *Aspergillus* and *Penicillium* fungi; those of the third group with red pigment-producing yeast-like fungi or with apigmented yeast-like fungi together with red pigment-producing cocci and bacilli.

(4) Practically all the protozoa and fungi found in non-gonorrhœal urethritis of the male have been found also in cases of vaginitis and vulvo-vaginitis, and it is not, therefore, very improbable that in certain cases and under certain circumstances these affections may be transmitted by sexual intercourse, as I suggested some years ago.

The botanical description of these fungi may be found in the chapters on fungi in Castellani and Chalmers' "Manual of Tropical Medicine," third edition.

LITERATURE.

CASTELLANI (1920). Milroy Lectures, delivered before the Royal College of Physicians of London, *Lancet*.

The Therapy of Amœbic Dysentery (P. H. M. Travaglino and R. M. Soedjono, *Geneesk. Tijdschr. v. Nederl.-Indie*, vol. 64, No. 4, 1924).—The writers give their experience in about 359 cases among the population of a lunatic asylum in Java. Of the drugs administered yatren ranks the highest; emetine injections gave favourable results. Emetine bismuthius iodide was not so effective, but the dosage administered was only about one-seventh of the usual. Tannin injections were very painful. Cane-sugar enemas, ipecac. powder in salol-coated pills, bismuthous preparations *per os*, or simply diet and rest were not successful, nor were quinine enemas. A native drug called "setjang" appeared to give satisfactory results.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is MESSRS. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings** per annum, may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

A WHITE AUSTRALIA: IS IT A POSSIBILITY?

By SYDNEY J. SKERTCHLEY, J.P.

(*Continued from page* 210.)

CHAPTER XV.

CONCLUSIONS.

The Four Great Principles Deduced from this Investigation.

I WILL now give a concise summary of the results of this investigation. Some of them may appear startling; some are new; all of them I believe to be profoundly important to the actual and prospective denizens of Australia.

(1) The course of human history has been reviewed from a novel standpoint: that of race, instead of that of politics. For this purpose the human species was dealt with on broad lines, as comprising the White, Yellow, and Black Races. The White Race was further subdivided into two sub-races—the Fair Whites and the Dark Whites. The former originated in the Baltic region, and are what are often called the Anglo-Saxon, or Germanic, stock. The latter are the swarthy folk of the Mediterranean area. It is with the Fair Whites—ourselves—we are chiefly concerned.

(2) The emigrations, immigrations, the conquests of these races, have been traced in broad outline. The evidence is abundant, and extends over thousands of years. It unmistakably points to a great law underlying the distribution of race. This law may be thus expressed:—

No race has ever permanently established itself on foreign soil.

(3) This conclusion, so directly contrary to the common view, is demonstrated over and over again. Thus, the Roman Empire was confined within ethnographic boundaries: the Rhine—Danube and the Tigris—Euphrates. Again, by the fifth century the Fair Whites had conquered all Europe and North Africa. They could not hold it, and their blood has vanished almost entirely from all but the native soil.

(4) This law involves a corollary. *The autochthonous blood tends to reassert itself and become again dominant.* Both these cases are illustrated by abundant evidence. Extermination alone prevents this rehabilitation of native races; but for us in Australia the matter is only of academic interest; our black-fellow is being exterminated.

(5) Another important law is also established. *Natural increase cannot be maintained by immigration.* The parent countries cannot stand a continuous drain of population; and Europe is now demonstrating this fact. The immigrants must multiply faster on the new soil than their predecessors die out, or the population does not naturally increase.

(6) The first tendency on a congenial soil is to raise the birth-rate above the normal, and to enhance the physique. After about three generations this impulse wastes itself; the birth-rate sinks below the normal, and the physique is impaired.

(7) Another highly important and unexpected law has been brought to light. *Improved conditions of life* (among immigrants) *do not raise the birth-rate; they only reduce the death-rate.* In other words, a child has a better chance of seeing old age, but more children are not born to enjoy this blessing.

(8) If this were not so we should find the birth-rate (and with it the natural increase) invariably raised as improved conditions made themselves felt. This is not the case. In the United States the natural increase is declining in an alarming manner. In Australia the decline is even more rapid.

(9) The conclusion which cries aloud from all the facts of history, and which must make itself heard, is that *it is almost impossible for any race to permanently occupy alien soil.*

(10) The fertility or healthiness of a country has little to do with its habitability by alien races. The United States, much of Asia, Australia, &c., are quite healthy; yet never has there been a case of permanent occupation by the whites, whether Fair or Dark.

(11) I said "almost" impossible. The one and

only possible exception is Canada, so far as time gives us sufficient grounds for coming to a definite conclusion. Australia (the truly extra-tropical part) may be another, but it is too soon to know, and *up to the present Australia is in a worse plight than the United States.* And in the United States the Fair White blood is rapidly dying out.

(12) The humid tropic land of Australia will never be truly colonized by white man, dark or fair, or all the history of every tropic land for four hundred years has no lesson for us. We may occupy it as overlords, we may be sojourners there for part of our lives, but we shall never work the land and live. We shall never bequeath our fee-simple to our heirs, for there will be no heirs to inherit.

(13) For the rest of Australia there may be hope; but hope can only lead to success if we intelligently and deliberately face the great problem of how to increase our rate of natural increase.

(14) We have traced two causes for the decline of our birth-rate; the abnormal aggregation in cities, and the severity of the woman's lot who "goes bush." Mitigate these evils and the birth-rate may be raised. Whether it can be so raised as to reverse the downward current that has so universally checked colonization time alone can show. I hope it is not mere hope that it may be so here in Australia. But the dream of a White Australia, as generally understood, is but a dream, and a foolish dream that is contradicted by every daylight fact from before the dawn of civilization to our year of jubilee.

(15) The facts and arguments I have set forth must be met fearlessly and intelligently; declamation will not alter them; political bias will not shift them a hair's-breadth, be they never so unsavoury to the palate. I have written in all seriousness after a long life of travel, observation and study. Let me close with the words of Cicero, now two thousand years old, words that will still be true two thousand years hence, when the question of a White Australia will have solved itself.

"History is the witness of the times, the torch of truth, the life of memory, the teacher of life, the messenger of antiquity."—*Or.*, ii, 15.

And again:—

"Who does not know that the primary law of history is that it should not dare to say anything false: next that it should dare to state the truth; that there should be no suspicion of favour nor yet of hatred in its words."—*Or.*, ii, 21.

And so I say sincerely and not unhopefully—

"ADVANCE AUSTRALIA."

THE END.

Annotations.

Autumn Stomatitis (H. Jamin, *Arch. de l'Institut Pasteur de Tunis*, Tome xiv, No. 1, 1924).—This condition is observed in a great number of the people in Tunis at the beginning of autumn, and occasionally at the beginning of spring. The patient complains of pain and a hot sensation of the buccal mucus, which is increased by movement of the tongue in speaking, and more still when food is taken into the mouth. The clinical picture is described. The whole mouth, gums, cheeks, &c., and tongue are covered with a light exanthema, and small red papules. The lesions of the mouth clear up before those of the tongue. Sometimes the tongue alone is affected.

Reinoculations in Infection due to a M. melitensis, especially after the Experimental Malady of the Guinea-pig (Et. Burnet, *Arch. de l'Institut Pasteur de Tunis*, Tome xiv, 1925).—Guinea-pigs infected with *M. melitensis* react to subcutaneous reinoculation by a thermic reaction. With peritoneal reinoculation they die, if the dose is strong enough, with formation of an abundant exudate and congestion of the abdominal organs, especially of the spleen and uterus. The reinoculation provokes a local reaction analogous to the phenomenon of Koch. In the case of *M. melitensis*, this reaction is characterized by the *abscess* more than by the necrosis. The phenomenon is less intense than in tuberculosis. In the reinoculation of *M. melitensis*, as in the reinoculation of tubercule bacilli, one can distinguish, in the "Koch phenomenon," the toxic reaction and the phenomenon of Arthus, although the two conditions are not quite independent of each other. In the guinea-pig infected with *M. melitensis* and reinoculated, the melitine reaction is more pronounced than the local reaction. The reinfections do not aggravate the *M. melitensis* infection; this should encourage trial of vaccinotherapy in Mediterranean fever. The microbes of reinoculation rapidly disappear from the organ already infected. They are not eliminated from the liver and the kidneys with the bile and urine; they are seized and destroyed by the phagocytes. The reactions of hypersensibility and the application which was made for the diagnosis, constitute a striking analogue between the melitococcus and tuberculosis.

On the Preservation of Marrow for Antirabic Treatment (Et. Burnet, *Arch. de l'Institut Pasteur de Tunis*, Tome xiv, No. 1, 1925).—The conclusions of this paper may be given as follows: Glycerine is universally used in the preparation of antirabic vaccine; but the preservation of the virulence of rabic marrow in glycerine is not unlimited. It is the rule, in antirabic institutes, not to use marrow which has been in glycerine, in the glaciere, more than 14 days. According to Remlinger, on account of the weakening of the virulence in the course of the passages, this limit of 14 days has become too much; it should be reduced to 8 days. The writer's investigations were carried out with Pasteur virus and maintained by passage, and with two days' marrow, preserved in glycerine in an ordinary glaciere. In glycerine, the shortest time of preservation observed was 20 days; virulence has also been observed after 27 and 62 days. Marrow whose virulence was preserved 20 days and up to 28 days killed the rabbit. Rabbits

have also been killed with marrow of 62 days' duration. On some media (olive-oil, &c.) marrow retains its virulence for a longer period, but these media cannot be used in antirabic treatment for reasons described. The duration of the preservation is not the same with all marrow; it depends on the richness of the virus. These results show that it is not necessary to change the limit of 14 days. Even with fixed virus having passed the 2,000th passage good results have been obtained in glycerine.

On Some Lesions of the Nervous System Provoked by Antirabic Injections (Dr. Pamboukis, *La Grèce Médicale*, December, 1924).—Cases have been recorded, since about 30 years ago, of complications ensuing the treatment for rabies. Two new interesting cases are described, the first a patient bitten by his dog in 1912. Fever set in after the seventh injection, and after the ninth he had spasms in the upper limbs; he had begun to feel numbness of the limbs after the third injection, which had increased the following days. Treatment was discontinued after the seventeenth injection as the symptoms were worse. The eighteenth day after the commencement of treatment the patient was suffering from facial paralysis and other severe symptoms. He was almost completely cured by electrical treatment of forty days' duration. Ten years later the same patient was bitten again, and paralysis of the right side of the face ensued the treatment; he was cured eventually without treatment. The second case, a lady, was bitten in 1922 on the hands and legs by a cat: two days later the cat bit this lady's daughter, who afterwards died. The mother was in a nervous state and often suffered from an intense cephalitis. After the fourteenth injection, she was attacked with this cephalitis and severe pains in the back of the neck and first thoracic vertebra. The pains got worse and after the sixteenth injection the treatment was stopped. The pains continued, however, and were insupportable. There was unilateral facial paralysis, which is a rare complication. The patient was eventually cured. This is probably the only case reported of polymyelitis with slight spinal meningitis.

The Histogenesis of the Hydatid Parasite (Tænia echinococcus) in the Pig (H. R. Dew, *The Medical Journal of Australia*, January 31, 1925).—This experimental study of the early stages of the development of the hydatid cyst leads to the following conclusions. The hydatid hexacanth embryo finds its way to the liver by means of the portal vein, and there is evidence to show that the liver barrier is by no means a perfect one. The time taken for the embryo to reach the liver is very short and sections show it in the liver lobules within twelve hours. The embryo tends to come to rest in the substance of the liver lobules and has a predilection for the subperitoneal lobules. By the local reaction of the liver tissue a hydatid follicle is rapidly produced. In the second week vesiculation commences. There is a very striking local eosinophile cellular accumulation and also much cellular reaction in the periportal zone, which brings this infestation into line with that of other helminths. There is evidence that in some cases the cellular reaction on the part of the host tissue overcomes the parasite in the earlier stages with the production of an aborted follicle. The adventitious capsule by organization becomes avascular and fuses intimately with the surrounding liver tissues. This fusion precludes any possibility of total enucleation of the whole cyst at operation. A remarkable feature is the persistency of patent biliary channels in the fibrous adventitia even close up to the parasite itself. This no doubt explains the frequency of complications in liver cysts due to the entry of bile and so forth. The cyst grows as a rule in a spherical form, but it also tends to take the line of least resistance so that pouching is not uncommon. This pouching is determined by the local resistance of bands of fibrous tissue, large blood-vessels or bile-ducts. At the end of five months the cyst may reach a diameter of one hundred millimetres, but there is no trace of the formation of blood capsules at this stage.

Studies in Scarlet Fever II. Studies on the Use of Convalescent Scarlet Fever Serum and Dochez' Scarlatinal Antistreptococcic Serum for the Treatment of Scarlet Fever (Konrad E. Birkhaug, *Bulletin of the Johns Hopkins Hospital*, February, 1925).—In the study of thirty-seven cases of scarlet fever treated by intramuscular injections of 15 to 85 c.c. of serum from convalescent cases of scarlet fever, it was found that:—Convalescent scarlet fever serum causes a rapid improvement in the general symptoms and a slight fall in temperature and pulse-rate, but produces no effect upon the general rash, and does not shorten the convalescence or reduce the incidence of septic complications during convalescence. A comparative study of thirty-one cases of scarlet fever showed that the intramuscular injection of Dochez' scarlatinal antistreptococcic serum in amounts of 40 c.c. administered during the first three days of the disease caused a prompt disappearance of the toxæmia, a critical fall in temperature and pulse-rate, prompt fading of the general exanthema, rapid reduction in leucocytosis and rapid disappearance of the glandular enlargement. The Schultz-Charlton rash extinction phenomenon can be obtained with samples of serum withdrawn from patients treated with Dochez' serum shortly after its injection. A therapeutic dose of 40 c.c. of Dochez' serum was sufficient to bring about a clinical cure in moderately severe cases of scarlet fever. The incidence of septic complication was low in the cases treated with Dochez' serum prior to the fourth day of the disease. The cases presenting septic complications yielded slowly and irregularly to Dochez' serum.

Alastrim (M. Brelet, *Gazette des Hôpitaux*, January, 1924).—Alastrim is an infectious, contagious and epidemic disease, its essential symptom is an eruption

very much like the exanthema of small-pox and chicken-pox. It chiefly attacks the black races, possibly because they have a greater receptivity and their conditions of living are unhygienic, rendering contagion easy. It is not known whether alastrim is contagious before the eruption appears, or the length of time that the disease is contagious, but in any case the matter of the vesico-pustules, the nasal mucus, the saliva and sputum must be considered as contagious. The symptoms of the disease are described by the author.

Investigations on Pulmonary Tuberculosis in Cochin China (Lasnet, *Bulletin de l'Office International d'Hygiene Publique*, January, 1925).—The writer gives the results of his investigations during the past two years in Cochin China. The form of tuberculosis most frequently seen is the pulmonary form, and the affection is carried from one person to another. Sero-diagnosis proved of great value. With the aid of the Government and the Service d'Hygiene of the Pasteur Institut of Saigon, general conditions have been improved and prophylactic measures carried out.

Abstract.

THE PROPHYLAXIS OF SLEEPING SICKNESS.[1]

By Professor EMILE BRUMPT.

SINCE the discovery of the sleeping sickness trypanosoma, by Castellani, and the hypothesis set forth by Sambon and myself on the transmission by tsetse flies, and the definite experiences of Bruce and Nabarro, of Kleine and of Tante, it is now possible to fight against the spread of sleeping sickness. Nevertheless, in spite of all efforts made till now, results obtained have not been very encouraging, because we do not know entirely yet which are the domestic and wild animals able to bear in their blood the two species of trypanosoma found in man. Sleeping sickness, so common in equatorial Africa, may only exist in an endemic or epidemic state if there are: (1) Sick people and infected animals; (2) glossinas or tsetse flies; (3) healthy people.

So, as in the case of malaria, we must study those various epidemiological elements during at least a whole year, in a determined region, before ordering effective prophylactic measure.

We shall examine first of all the reservoir of virus to appreciate the frequency of the disease. For this purpose, natives of the same village are gathered together and trypanosomes are sought for in blood smears and in the fluid extracted from enlarged lymphatic glands. This microscopical examination necessary to discover sick people at the first period, is useless later on, diagnosis being then evident. Enlargement of lymphatic glands is not so frequent as enlargement of spleen in malaria, for it misses sometimes in the case of sick people, and exists in healthy ones. That is why lymphatic puncture and microscopical examination are necessary. In those conditions, presence of trypanosomes allows us to maintain the diagnosis. When we have examined the greater part of the population of a region, we can establish: (1) The endemic index in each locality; (2) frequency of infection according to age, sex, occupation; (3) the relation between presence of trypanosomes in blood and enlarged lymphatic glands; (4) the relation between parasitical index and lymphatic index.

To complete the study of man's pathogenic trypanosomes in nature, it is necessary to look for them equally in the blood of domestic and of wild animals. Unfortunately till now this has never been entirely done, no differentiating test existing for animals' and man's trypanosomes. So all studies on that subject will not be of great value until it will be possible to do otherwise than to inoculate a virus into a receptive man, as has been done by scientists to themselves or to noble willing men.

We must study now the second element of endemicity, the *Glossina* of tsetse flies. It is by the knowledge of the glossina's biology that we may fight successfully against them. As in malaria, the measures are different according to each case. For instance, for a traveller having to cross endemic zones atoxyl preventive injections and protection from tsetse bite are the only things to be done, but in villages situated in regions swarming with glossinas, the surroundings must be deforested and the haunts destroyed. Fighting *Glossina morsitans* in savanahs by bush fires is not the same as fighting *Glossina palpalis* living in forest glades, to which it is impossible to set fire before cutting trees. After having deliberately chosen the most practical method, the difficulty consists in having measures executed and controlled. This is the affair of the Colonial Administration.

The principal administrative measures to take are:

Division of an unhealthy country into zones under the direction of a doctor with an auxiliary staff.

Compulsory declaration of disease by the native chiefs of villages.

Reconstitution and grouping of native villages in flyless regions.

The issue of sanitary passports.

Regulations made to prevent native travelling.

Creation of stations of inspection, or "filtrating stations" as we call them, where sick people are kept and nursed.

Improvement of the economic conditions of natives.

Work organization and inspection of workmanship undertaken by colonial societies.

Making the ground healthy by various processes.

All the European colonizing nations must participate, by scientific means and application of improved knowledge, in the eradication of this dreadful African plague, which commercial or military expeditions have contributed to spread from infected regions over healthy countries swarming with transmitting tsetse.

and

E. T. Thompson,
Senior Bacteriological Assistant, Ministry of Pensions Hospital, Orpington.

One of us, since 1905, has called attention to the comparative frequency of cases of subacute and chronic bronchitis, clinically simulating tuberculosis, but in reality due to totally different organisms: fungi, protozoa and worms. In previous publications we have described cases of broncho-moniliasis, broncho-oidiosis, broncho-hemisporosis, broncho-anaeromysis, occurring in England. In the present paper we propose to touch briefly upon the subject of mixed mycotic infections, in which probably two species of fungi, and not one only, play an ætiological rôle. We will limit ourselves in the present paper to discuss only one mycotic association: the monilia and anaeromyces association. It may, perhaps, be advisable to first say a few words on broncho-moniliasis and broncho-anaeromysis, although we have fully described these conditions in other publications.

Broncho-moniliasis.—This term is used to denote bronchial conditions associated with the presence of monilia fungi in the sputum. Three varieties of bronchial moniliasis may be distinguished:—

(1) Primary moniliasis.
(2) Secondary moniliasis.
(3) Saprophytic moniliasis.

In *primary broncho-moniliasis* the monilia is the actual causative agent of the condition: in *secondary broncho-moniliasis* the monilia is a secondary invader, like the streptococcus in pulmonary tuberculosis; in *saprophytic moniliasis* the monilia is merely a saprophyte with no pathogenic action whatever. In the case of true primary moniliasis, the monilia, isolated from the sputum, when injected intrapulmonarily into rabbits will produce a peculiar nodular condition of the lungs; in the case of secondary broncho-moniliasis, the monilia injected intrapulmonarily will not produce any nodular condition of the organ, but a general monilial septicæmia will ensue, and the rabbit will die within a few days, or be very ill. In the case of saprophytic moniliasis the intravenous and intrapulmonary injection of the isolated monilia will give rise to no symptoms whatever, and the rabbit will remain quite well.

Pathogenic monilias belong generally to the types *krusei*, *pinoyi*, *metalondinensis*, *tropicalis*. It must be noted that at times two monilias may have identical sugar reactions, but one is pathogenic to rabbits and guinea-pigs, and the other is not. According to Redaelli, the original strain of *Monilia krusei* Castellani, when inoculated intravenously into guinea-pigs, localizes itself only to the lungs, and at the post-mortem mycotic nodules are found only in these organs.

It must be noted also that a number of monilias, after several transplantations, lose some of their biochemical characteristics, and therefore their classification can be satisfactorily carried out only by using strains recently isolated. The biochemical reactions of certain monilias, however, are permanent; for instance, *Monilia krusei*, *Monilia tropicalis* and *Monilia macedoniensis*. We have strains of these three monilias several years old, and their sugar reactions have always been the same in regard to the production of gas, although the production of simple acidity may somewhat vary. As an example we may quote *Monilia krusei* Castellani. One of the strains we have is fourteen years old; it has always produced, and is still producing gas in glucose and levulose and no other carbohydrate, but occasionally may produce a slight acidity in maltose and galactose. In the classification of monilias at the present time, therefore, we take into consideration only the production or absence of gas.

Determination of Group and Species.—One of us some years ago suggested the following grouping of monilias, based on the action of these organisms on glucose, levulose, maltose, galactose, saccharose, inulin and dextrin.

Group I (*Monilia balcanica*). — Gas produced in *glucose only.*
Principal species: *M. balcanica*, *M. parabalcanica.*
Group II (*Monilia krusei*).—Gas produced in *glucose* and *levulose.*
Principal species: *M. krusei*, *M. parakrusei.*
Group III (*Monilia pinoyi*).—Gas produced in *glucose*, *levulose*, and *maltose.*
Principal species: *M. pinoyi*, *M. nabarroi.*
Group IV (*Monilia metalondinensis*). — Gas produced in *glucose*, *levulose*, *maltose*, and *galactose.*
Principal species: *M. metalondinensis*, *M. pseudometalondinensis*, *M. albicans* (clots milk and liquefies gelatine).
Group V (*Monilia tropicalis*).—Gas produced in *glucose*, *levulose*, *maltose*, *galactose*, and *saccharose.*
Principal species: *M. tropicalis*, *M. paratropicalis*, *M. pulmonalis*, *M. nivea*. *M. insolita*, *M. enterica.*
Group VI (*Monilia guillermondi*).—Gas produced in *glucose*, *levulose*, and *saccharose.*
Principal species: *M. guillermondi*, *M. pseudoguillermondi.*
Group VII (*Monilia guillermondi*).—Gas produced in *glucose*, *levulose*, *galactose*, *saccharose*, and *inulin.*
Principal species: *M. macedoniensis*, *M. macedoniensoides*, *M. chalmersi*, *M. parachalmersi.*
Group VIII (*Monilia pseudotropicalis*). — Gas produced in *lactose, in addition to other sugars.*
Principal species: *M. pseudotropicalis.*
Group IX (*Monilia pseudolondinensis*).—Gas produced in *dextrin in addition to other sugars.*
Principal species: *M. pseudolondinensis*, *M. pseudolondinoides*, *M. africana.*
Group X (*Monilia pseudotropicalis*). — Gas produced in *lactose in addition to other sugars.*
Principal species: *M. pseudotropicalis.*
Group XI (*Monilia zeylanica*).—Gas is *not* produced in any sugar.
Principal species: *M. zeylanica* (yellow), *M. zeylanoides* (white, no darkening of lead agar), *M. macroglossiæ* (lead agar darkened).

When the isolated monilia has been placed in one of the above groups, the determination of species is not difficult, having recourse to the complete table of monilias, published by one of us in several previous papers, and which may be found also in Castellani and Chalmers' "Manual of Tropical Medicine," pages 1082 to 1083. We give in next column an abridged table.

Broncho-anaeromycosis.—We introduced this term to indicate a chronic bronchitic condition, often hæmorrhagic, associated with the presence of minute fungi in the sputum, which show intermediate characters between organisms of the genera *Nocardia* (Toni and Trevisan) and *Cohnistreptothrix* Pinoy of the family Nocardiaceæ (Castellani and Chalmers), and the genera *Mycobacterium* (Lehmann and Neumann) and *Corynebacterium* (Lehmann and Neumann) of the family Mycobacteriaceæ Miche. We created a new genus for it: *Anaeromyces* Castellani, Douglas and Thompson.

The organisms of the group Anaeromyces are very closely related to the genus *Corynebacterium* (Lehmann and Neumann) (diphtheria and diphtheroid bacilli), and the genus *Nocardia* Toni and Trevisan (*Actinomyces* Harz, *Discomyces* Rivolta, *Streptothrix* Rossi-Doria, *Oöspora* Sauvegeau and Radais, *Cohnistreptothrix* Pinoy *pro parte*); but in contrast to the former branching is much more marked, and they are strictly anaerobic, and in contrast to the latter the mycelium is very much less developed, the growth is moist and not dry and crinkled, and they never give rise to actinomytic granules in the lesions. They are Gram-positive, non-motile, and not acid-fast. These germs, or similar ones, were found in cases of bronchitis in 1904, by Chalmers and one of us, and were referred to at the time as "bronchial anaerobic diphtheroid bacilli," but the observation attracted very little notice. They are also somewhat similar to *Bacillus vitulorum* Flügge.

Clinically, the condition can hardly be distinguished from either pulmonary tuberculosis or hæmorrhagic broncho-moniliasis.

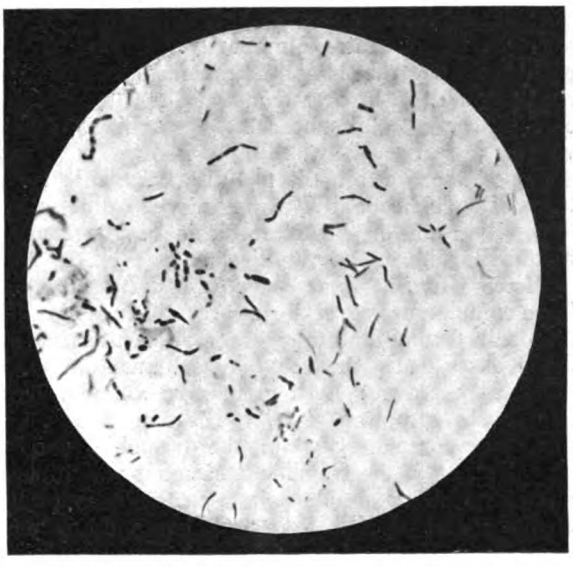
Anaeromyces bronchitica Castellani, Douglas and Thompson, 1922.—*Morphological and staining characteristics.*—The organism is bacillus-like, 3 to 5 microns by 0·3 micron, and resembles in shape a diphtheroid bacillus, but branching is much more marked. It is Gram-positive and not acid-fast, and by staining by Neisser's method no metachromatic granules are seen.

Motility.—The organism is non-motile.

Relation to Oxygen.—The organism is an obligate anaerobe.

Cultural Characters.—Provided a strictly anaerobic technique is used the germ grows well in any of the usual laboratory media. The growth on glucose and other sugar media is not very characteristic; gelatine and serum are not liquefied.

Biochemical Reactions.—There is no formation of acidity or gas in any carbohydrate with which we have experimented, viz., glucose, levulose, maltose, galactose, saccharose, lactose and inulin. Milk is not clotted.



Pathogenicity.—This organism does not seem to be pathogenic to guinea-pigs or rabbits, even when

injected in large doses, either subcutaneously, intravenously, or intrapulmonarily. Although non-pathogenic to the lower animals we came to the conclusion that the organism was the causative agent of certain cases of hæmorrhagic bronchitis, because a vaccine prepared with the fungus induced in them the disappearance of all the symptoms. This type of hæmorrhagic bronchitis can hardly be differentiated clinically from either tuberculosis of the lungs, or hæmorrhagic broncho-moniliasis.

Mixed Monilia and Anaeromyces Infection.—We have come across several cases of what we consider a true mixed monilia + anaeromyces infection. In these cases both the monilia and anaeromyces are constantly grown: both germs are abundant while the severe symptoms last, to become scanty or to disappear completely when the bronchial condition improves, or is cured. The treatment which usually answers well in simple primary moniliasis (iodides, creosote and monilia vaccines) has only a partial success in these cases. The treatment which is generally very successful in simple anaeromycosis (anaeromyces vaccine) does not induce a cure, but only an improvement. These cases are frequently completely cured by combining the two treatments.

We quote the following illustrative case: Mrs. N., aged 41. Married. Nothing of importance in the family history. Had some of the usual children's diseases: whooping-cough and measles. Went to Southern India in 1903, and after a few months was married there. Enjoyed good health until 1917, when she began complaining of a slight cough with scanty mucous expectoration, the cough got gradually worse and she occasionally brought up blood. She consulted a local practitioner, who put her on arsenic and gave her some balsamics. During the next two years her condition became gradually worse, and she was sent home in 1920 with the diagnosis of probable pulmonary tuberculosis, though no tubercle bacilli had ever been found. The lady came to consult one of us. She was extremely emaciated and looked very anæmic. She was complaining of a severe cough and a feeling of great lassitude. Very slight serotine fever. The sputum was muco-purulent with usually a certain amount of blood. The physical examination of the chest revealed coarse, dry and moist râles, but no patches of dullness and no crepitations.

Microscopical and Bacteriological Examinations.—The sputum was examined thirty times for T.B., using also the antiformin method, with negative results. Cuti-reaction and ophthalmo-reactions negative. The direct microscopical examination of the sputum never revealed presence of mycelial or conidial bodies except on one occasion. The cultural investigation carried out, by using aerobic and anaerobic methods, showed on every occasion the presence of both a *Monilia* and a strain of *Anaeromyces*. The *Monilia* produced gas in glucose, levulose, maltose and galactose. It did not liquefy either gelatine or serum, and did not clot milk; it belongs therefore to the type *Monilia metalondinensis*. Inoculated intrapulmonarily into a rabbit, it produced a generalized nodular condition of both the inoculated and non-inoculated lung, the invasion of the non-inoculated lung taking place, apparently, via the bronchi. The histological examination of sections of the smaller nodules shows in the centre, masses of small cells, both polymorphs and leucocytes. Further out the cells are fewer in number. This corresponds to the area of degenerating expanded bronchiole. Still further out there is a ring of endothelial cells; many of them are phagocytes, containing smaller white cells, and there are a few large multinucleated giant cells, and also in this ring there is a large number of eosinophile cells. The same nodular cells in the centre are markedly degenerated and are becoming caseous. The sections stained with Gram show only a very few mycelial segments and very scanty spores so stained. Between the nodules there is a certain degree of congestion but no true pneumonia; there is a considerable increase of endothelial cells. In the small arteries one notices that the intima is greatly thickened.

Strain of Anaeromyces isolated.—This strain does not produce any lesion in rabbits or guinea-pigs when inoculated either intrapulmonarily or intravenously, but this is the case with all other strains of anaeromyces with which we have experimented.

Course and Treatment.—During the first two months the treatment was carried out only for the moniliasis: potassium iodide, creosote, glycerophosphates and monilia vaccines. The result was satisfactory, the general condition improved enormously the expectoration greatly decreased in amount, but did not disappear completely, and now and then a trace of blood was present. Injections of an autogenous anaeromyces vaccine were then given, one every other day, and the cough and expectoration disappeared completely within six weeks. The patient was feeling and looking very well and all treatment was discontinued. For two months the lady felt well, then again she began coughing, with hæmorrhagic sputum, and again she began losing weight. We started the anaeromyces vaccine without giving potassium iodide and creosote. The blood disappeared from the sputum almost completely, but the expectoration remained fairly abundant, muco-purulent occasionally slightly tinged with blood, and the general condition did not greatly improve. We then gave the iodide and creosote in addition to the anaeromyces vaccine and the condition cleared up completely, and the lady has since been in apparently perfect health.

Conclusions.

From observations and researches carried out during the last four years, we have come to the conclusion that a true mixed monilia + anaeromyces infection exists, in which each of the two organisms plays an ætiological rôle. We base our opinion, not on the fact that in these cases both organisms are found in the sputum, as one of them might play only a saphrophytic rôle, but principally on the fact that in such cases the specific treatment for simple broncho-moniliasis (iodides, creosote) and the specific treatment for anaeromyces (anaeromyces vaccine

given alone are not sufficient to induce a cure, while this is obtained by combining the two treatments.

In a future paper we propose dealing with other mixed mycotic infections.

TREATMENT OF CHOLERA AND ITS COMPLICATIONS.[1]

By S. K. Ghosh-Dastidar, M.B., D.T.M.

Assistant Surgeon, General Hospital, Cuttack, Demonstrator of Medicine, Pathology and Bacteriology, Orissa Medical School, Cuttack, India.

The treatment of cholera depends chiefly upon the stage of affection, so it is better to recapitulate the *different stages* briefly.

According to the classical textbooks cholera has three stages, but I prefer to describe four stages, as the patients do not enter the collapse stage after the premonitory diarrhœa (though some of them really do); the intervening or the transitional stage is known as "true cholera."

1.—*Preliminary or Premonitory Diarrhœa.*—It is characterized by the frequent passage of bile-coloured diarrhœic stools, sometimes with vomiting; specific gravity of blood is not affected.

2.—*True Cholera.*—During this stage there is frequent passage of rice-water stool, vomiting, pains and cramps in the muscles of the extremities and abdomen; urine is scanty and highly coloured, and specific gravity of blood gradually rises with depletion of fluids from the system through evacuation and vomiting. With Indians the normal specific gravity of blood varies between 1052 and 1054; in Europeans it is between 1054 and 1056.

3.—*Collapse.*—In this stage there is very low blood-pressure, about 70 mm. Hg, very feeble or collapsing pulse, markedly high specific gravity of blood, subnormal temperature, suppression of urine, &c.

4.—*Reaction.*—This stage is reached when the system is trying to come back to normal, by improvement in the general condition shown by vasomotor equilibrium, passage of urine, &c.

[1] Read at the November meeting of the Orissa Medical Association, Cuttack, India.

Now concerning the treatment, the most important thing to be borne in mind is *the value of time*, the sooner it is begun, the better for the patient, and the more so for society as the sporadic cases often lead to epidemics.

No present treatment is specific in the true sense, it is only symptomatic based on general physiological principles. The indications of treatment are as follows:—

(1) To replace the lost fluid in the system.

(2) To relieve the painful cramps.

(3) To lessen the activities of the absorbed toxins.

(4) To lessen the number and multiplication of cholera vibrios in the intestine.

For the first two, saline injections are required; the third factor is aimed at by measures that are required to dilute the concentrations of toxins in the system and help the free urination, either by administration of sufficient fluids, alkalies, or improvement in circulation. We have got very little means to prevent multiplication of the cholera vibrios, which is approached by administration of oxidizing agents (e.g., potassium permanganate), or the mild antiseptic and hepatic stimulant (e.g., hydrargyri subchlor.) and at the same time without stopping evacuation, which is really Nature's attempt to eliminate microbes and their toxins.

The composition of salines (Rogers) which I will often have to refer to is given below:—

1. *Hypertonic saline.*

Sodium chloride	120 gr.
Calcium chloride	4 gr.
Aqua distilled	Oj

2. *Isotonic saline.*

Sodium chloride	90 gr.
Aqua distilled	Oj

3. *Hypotonic saline.*

Sodium chloride	60 gr.
Sodium bicarb.	160 gr.
Aqua distilled	Oj

For the preparation of the hypotonic saline, first mix sodium chloride with water and boil it; when it is boiling put out the stove and mix at once fresh and clean sodium bicarb.—never boil after the addition of sodium bicarb. Often in treatment hypertonic has to be poured into the flask from which hypotonic is flowing; in that case let the hypotonic flow out from the flask leaving the smallest quantity possible with safety, otherwise $CaCl_3$ of the hypertonic mixes with sodium bicarb. of the hypotonic to form inert and insoluble calcium carbonate (chalk).

For the *specific gravity of blood* mixtures of glycerine and water in different proportions (specific gravity ranging from 1050 to 1070) are used. The saturated solution of magnesium sulph. can be conveniently used for the same purpose (Dr. D. N. Bannerjee); its specific gravity is 1220; of this take 5 c.c., mix with it 15 c.c. of clean sterile water, and the resultant solution has the specific gravity 1060 always. The magnesium sulphate solution can be made at any

place and at any time; moreover, the treatment can be guided more or less in the right path by noting the drop of blood ejected from the pipette at the mid-level of the solution in a one-drachm phial; if the drop is stationary, the specific gravity of blood is 1060; if it floats up, the specific gravity is less; if it sinks down, the specific gravity is more; by careful observation a rough estimate of specific gravity can be made from the rate of rapidity of the blood, either in floating up or in sinking down. This method is of much service for those who cannot always keep a fresh supply of glycerine mixture. I have often used it and it has never failed me.

Now let me divide *the treatment* according to the stage of infection.

In the Premonitory Stage the disease can often be cut short by administration of simple astringent mixtures or powder, if infection is not virulent and the bile is present in the stool.

℞	Pulv. cretæ aromat.	20 gr.
	Bismuth carb.	10 gr.
	Mucilage	q.s.
	Spt. ammon. aromat.	10 min.
	Spt. chloroform	10 min.
	Tinct. caro. co.	20 min.
	Aqua menth. pip.	ad 1 oz.
	mft. mist. Every 4 hours.	

Or,

℞	Tinct. opii or chlorodyne	15 min.
	Acid. sulph. dil.	15 min.
	Aqua menth. pip.	ad 1 oz.
	mft. mist. Every 4 hours.	

There is some objection to the second mixture as there is no knowing whether the progress of the disease will stop here; if it does, well and good; but if it does not, is it advisable to push the opium preparations, which irritate the kidneys by their excretion, only to pave the way for the so much dreaded uræmia, which is in fact a fatal complication of cholera? Another factor might creep up unconsciously. Suppose a patient is given the second mixture every four hours, and slowly passes to the collapse stage at which there is no absorption from the stomach, but the medicine is still given regularly, as often happens; now, if the patient ever reaches the reaction stage, there will be sudden absorption of a huge quantity of opium preparation only to produce the toxic effects of it.

The patient is never to be purged when there is any apprehension, especially during the outbreak of an epidemic, with salines which denude the intestinal mucous membrane only to make it an easy prey to the disease.

In the Stage of Cholera and Collapse.—Blood-pressure and specific gravity of blood are to be taken carefully and regularly for the guidance of treatment; the total quantity of urine passed should also be noted.

(*a*) If blood-pressure is 70 mm. Hg or below, give intravenous saline, not less than two pints, to bring up the pressure for efficient circulation.

(*b*) If specific gravity is over 1060, inject Oj hypertonic for each degree of rise above 1060, but not more than four or five pints at a time.

(*c*) If blood-pressure is low and specific gravity is 1060, at least three pints of hypertonic are needed.

(*d*) When specific gravity is 1054 or thereabout, and the injections are indicated, isotonic saline is to be given instead of the hypertonic to correspond with the tonicity of blood.

Intravenous saline injections are also given for the relief of cramps and restlessness, which are due to the small amount of fluid in the system. To combat toxæmia and suppression of urine plenty of sodium bicarb. is to be given, preferably in the form of hypotonic saline by intravenous method. To quote Sir Leonard Rogers, "the alkalinity of blood is nearly always much reduced in severe cases of cholera, and that the early and repeated administration of sodium bicarbonate intravenously has lowered the mortality from uræmia to the fourth of its former rate; it is now clear that the rule I have adopted of giving alkalies intravenously in all cases of cholera with each saline injection after the first, as well as with the first injection in late admission with deficient urinary secretion, is a sound one, which should never be neglected."

Therefore it is advisable that the first pint should always be hypotonic saline (sodium bicarb.) whenever it is required to increase the alkalinity of blood, as rigor may set in at any time and prevent further intravenous administrations.

Repetition of intravenous injection is called for when (1) blood-pressure is very low, the patient is pulseless and restless; (2) there is suppression of urine; (3) specific gravity of blood is high.

It is better to add adrenalin or pituitrin, 1 c.c. to every injection to stimulate the broken-down vasomotor system. When the system loses fluid very quickly by copious evacuation or vomiting after each intravenous injection, *subcutaneous injections* are needed: the latter method of administration is also needed if the person is very obese or the vein is very small.

INTRAVENOUS INJECTION.

Advantage.	*Disadvantage.*
Quick, sure absorption of known quantity of saline; painless, no chance of abscess formations, less asepsis required in comparison with the subcutaneous method.	Embolism.

"The cyanotic, algid, pulseless, breathless creature with shrunken, wrinkled features, sunken lustreless eyes, and the whole aspect of a moribund, will, as if from a deep sleep, arouse himself and tell the delighted doctor he feels vastly better."

As regards the *rate of injection*, the first pint should take about 7-10 minutes; later 10-12 minutes per pint. If there is any cardiac or respiratory trouble the patient is to be carefully watched and the rate of injection should be very slow. Very rapid injections often cause œdema of lungs or acute heart failure.

The *temperature of salines* to be administered intravenously should be regulated carefully for fear of severe reaction. If the rectal temperature is normal, or below normal, the salines should be at 100° F.; if the rectal temperature is 102° F. the salines should be at 90° F. or thereabout.

In young children the saline cannot often be administered intravenously owing to the fine calibre of the veins; subcutaneous method is substituted, accompanied by the continuous administration of isotonic rectal saline (with sodium bicarb. gr. 160 and 5 per cent. of glucose per each pint). The isotonic rectal saline is stored in a thermo flask at 37° C., and from this the saline flows slowly drop by drop high up into the rectum through a rubber catheter; the flow is so regulated that one drop falls per second. By these methods the required quantity of fluid is sufficiently given.

SUBCUTANEOUS INJECTION.

Advantages.	*Disadvantages.*
No operative difficulty, no chance of embolism.	Chance of abscess formation; slow absorption and painful, at one site not more than Oj can be given.

Intraperitoneal methods have been used with success by some authors.

Rectal injections of 10 oz. of isotonic saline with sodium bicarb. 160 gr. to Oj should be given as a routine measure every two hours; 5 per cent. of glucose may be added to it conveniently. This rectal saline lessens the need of intravenous saline injections.

As a routine measure, too, a hypodermic injection of atropine $\frac{1}{100}$ gr. and digitalin $\frac{1}{100}$ gr. given twice daily gives good results, as very little drug is absorbed from the stomach in such conditions.

Potassium permanganate pills (2 gr. with kaolin) are given every fifteen minutes till 20 gr. are given and then two pills every half hour till colour of steel changes to green; but this treatment increases nausea and the patient feels worse. Hydrargyri subchlor. is generally given in fractional doses $\frac{1}{6}$ or $\frac{1}{4}$ gr. every half hour till 2 to 3 gr. are administered.

For vomiting, small pieces of ice are given to suck; tincture iodine in minim doses every fifteen minutes for two hours answers well in some cases. Fifteen minims of adrenalin may also be administered.

For tympanitis, fractional does of either calomel, menthol, thymol or camphor, or a combination of them, is given every half hour; paralytic distension responds to pituitrin only.

Stage of reaction, especially after an intravenous administration. Temperature should be brought down; it should be taken every fifteen minutes for two hours, and necessary steps to be taken on the first apprehension, i.e., only one bed sheet to cover the body, ice caps, cold sponging, &c. Many lives are lost due to inefficient management in this stage for hyperpyrexia.

Diarrhœa is never to be checked unless severe, as it eliminates toxin. When urine is free, but the stool is frequent and less formed:—

℞ Bismuth subgallate ... ... 15 gr.
Tanalbin ... . 10 gr.
Pulv. cretæ aromat. ... . 1 dr.
mft. pulv. Every four or six hours.

Kaolin Treatment.—One school favours it much, though in my experience it proved to be a failure. About a tablespoonful is required mixed with half a tumblerful of water into a uniform mucilaginous suspension, which is administered per mouth every four hours and *per rectum*, too, at intervals, till the patient passes kaolin in each stool. For acidosis sodium bicarb. is administered by mouth; when there is much loss of fluid, the isotonic saline is administered intravenously. The aim of treatment is to protect the denuded intestinal mucous membrane, and at the same time to check the multiplication of the vibrios. The Vienna school gave satisfactory reports of this product, but it did not prove useful in the hands of experts in India.

Complications.—(1) Tympanitis.—It has been dealt with previously; hot turpentine stupes and long flatus tube may be tried. Sometimes, in spite of all possible efforts, severe tympanitis persists for five or six days, and with the improvement of the condition it slowly disappears.

(2) *Uræmia.*—The administration of sufficient fluid and sodium bicarb. in the system diminishes its possibilities. When there is sufficient fluid in the system and specific gravity is below or about 1056, one pint of hypotonic saline or isotonic saline with 160 gr. of sodium bicarb. per pint often relieves the condition by causing free urination. Alkaline should be given per mouth too. I saw one case having no other sign but exhausting uræmic hiccough; sufficient alkali was given, the specific gravity of blood was 1054, and the blood-pressure fairly normal, but he was constipated and passed little urine; he was given an ounce and a half of castor oil every day for three or four days; the hiccough disappeared later on and the patient was quite well within a week.

Sometimes tinct. apocyanaci and caffeine sodium of benzoas give marvellous results.

(3) Œdema of lungs may be present, due to the rapid administration of salines or in failing hearts. Atropine $\frac{1}{50}$ gr. should be given intravenously immediately, and the administration of intravenous saline should be stopped. If fluid is at all necessary subcutaneous injection is to be given.

(4) Pneumonia, hypostatic or septic should be treated on general principles. If this condition sets in early the case is hopeless; here subcutaneous saline can be given very cautiously in urgent needs.

(5) Corneal ulcer is treated on general principles. For the prevention of it during the collapse stage the eyes should be washed with boric acid lotions at intervals and a mild antiseptic ointment such as ung. hydrargyri oxidi flava ($\frac{1}{2}$ per cent.) applied.

(6) Gravid uterus cannot stand the affection; it either ends in abortion, miscarriage or death of the fœtus.

(7) Septic infections might occur at the site of injections due to bad management.

(8) Sudden heart failure during the convalescent stage has been seen by me when the case was about to be discharged from the ward as there was nothing clinically abnormal.

(9) Relapse, though rare, should not be entirely forgotten; this might occur through injudicious diet.

(10) Local vasomotor spasms might occur during administration; atropine, $\frac{1}{50}$ gr., associated with gentle

massage of the veins of the upper arch from below upwards relieves after a few minutes. Sometimes this is often mistaken for clot, either in the canula or vein; this error can be easily avoided if a glass connection is interposed just before the canula; in any doubt clamp the rubber tubing on the proximal side of the glass connection, when the blood will flow into the glass piece, showing thereby the absence of clot (*vide* author's note in *Indian Medical Gazette*, September 23). In this condition the veins in the upper arm stand out prominently like whip-cord.

Diet.—In acute stage nothing but plenty of cool green coconut-water or thin barley-water with lemon-juice is to be given in sips. When the acute stage is over, add whey to the diet list. Later on, during convalescence, when the patient is passing formed or semiliquid bile-coloured stools, citrated milk or Horlick's may be given; slowly and very cautiously normal diet may be taken.

Hygienic measures are to be adopted in the disinfection and disposal of the excreta and clothes. They are to be well soaked in 5 per cent. carbolic acid lotion for three to four hours, and then boiled before being sent away for washing. The convalescents are to be examined before they leave hospital for the persistence of cholera vibrios in their excretions, because some of them eventually are cholera carriers. These cholera carriers are really a menace to society, especially if they have to handle food-stuffs. They respond to the vaccine treatment.

Prophylaxis.—During the outbreak of an epidemic Haffkine's prophylactic treatment with vaccine is useful.

All attention should be directed to the water supply for efficient chlorinization with bleaching powder. Segregation of the patients should be carried out immediately.

Croonian Lectures on Researches on Leprosy and their bearing on the Treatment of Tuberculosis. Lecture IV, "The use of Chaulmoogrates and Morrhuates in the Treatment of Tuberculosis" (Sir Leonard Rogers, *The Lancet*, June 26, 1924).—From this interesting paper it is seen that while chaulmoogra oil derivatives have proved of great value in the treatment of leprosy, the morrhuates in small subcutaneous doses have proved both safer and more effective in tuberculous disease. This has been confirmed by several experts; although it has sometimes been found that sodium morrhuates have given negative results in cases of advanced disease and cases with poor resistance, but the number of these is inferior to the number of cases which have greatly benefited by the treatment. The complete disappearance of tubercle bacilli from the sputum has been obtained in a certain proportion of advanced cases, some of whom had resisted sanatorium treatment. The results of sodium morrhuates in surgical tuberculosis leave much to be desired, but are not without promise. These investigations have proved to be a valuable contribution to general medical science.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments, either** of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which **is Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part **resident** abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are **entitled to 25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these,** with remittance, **is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 ,, ,, ...	1	3	3
200 ,, ,, ...	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 ,, ,, ,,	2	6	0
200 ,, ,, ,,	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

THE JOURNAL OF

Tropical Medicine and Hygiene

JULY 15, 1925.

THE VINCENT D'ANTONI HOSPITAL IN HONDURAS.

WE have on several occasions called attention to the rapidly increasing importance which is given at the present time in the United States to the study of tropical medicine and investigation into tropical problems.

A very important feature of the moment is the interest taken in the subject by private concerns and corporations. Some of these concerns have complete medical services of their own. The United States Fruit Company, for example, has a tropical medical service admirably organized by Dr. E. Deeks, with branches in several Central American countries. At the head of each branch or division there is a principal medical officer with an adequate medical and nursing staff.

A magnificent hospital has been recently erected in Ceiba, Spanish Honduras, by the well-known American firm of Vaccaro Brothers of New Orleans, U.S.A., as a memorial to Vincent D'Antoni, Local Manager of the Company, who was a man beloved by all classes of the native population and during his short lifetime greatly contributed to the welfare of the native population and to the progress of the whole country.

The Hospital is of the pavilion type and constructed of hollow tile and stucco, with a red Spanish tile roof. It is ideally located at the foot of a high ridge of mountains where the climate is pleasant throughout the whole year. It is well equipped with receiving wards, accident room, laboratories, X-ray rooms, operating rooms, private rooms, offices and library; all windows and verandas are completely screened. The furniture throughout the Hospital is of metal finished in mahogany colour.

One of the chief activities of the institution is the out-patient department. The Honduras Government has arranged to conduct an intensive campaign against ankylostomiasis and malaria and other tropical diseases of Honduras, under the auspices of the Rockefeller Foundation working in conjunction with the National Health Department. The Vincent D'Antoni Hospital has been selected as the headquarters for this work. The treatment for these diseases in the out-patient department will be free of charge to all natives.

A somewhat unusual feature of the staff organization in a tropical hospital is the provision for an honorary staff upon which any distinguished physician or surgeon may be placed on the recommendation of the superintendent, who was until recently Dr. William H. Walsh, an expert on hospital organization. The first members appointed were the professors of the National Medical School of Honduras, the representatives of the Rockefeller Foundation, the director of the National Health Department, and certain foreign physicians and surgeons resident in the United States and Europe, who have consented to hold clinics at the new hospital from time to time.

The hospital is provided with a complete and up-to-date dental department which is in charge of a native visiting surgeon, a graduate of an American dental college. A resident dentist will be appointed at an early date.

The cost of building and the entire equipment of the hospital has been defrayed by Vaccaro Brothers; the firm also gives a very large annual grant for the upkeep of the institution.

The Vincent D'Antoni Hospital is an institution which not only gives the best modern treatment and care to the sick, but is fast becoming a centre of research and medical education in Honduras.

Annotations.

A Clinical and Experimental Investigation of Arsphenamin Poisoning (Soma Weiss, *Journal of the American Medical Association*, Feb. 21, 1925).—Cats were used in experiments designed to study the gross and microscopic tissue changes produced in the liver, spleen and kidneys by arsphenamin. by arsphenamin together with mercuric salicylate, and by arsphenamin administered after chloroform. The doses of arsphenamin, corresponding to massive therapeutic doses, produce small areas of necrosis, fatty infiltration, congestion with round-cell infiltration, and occasionally cloudy swelling in the liver cells, with the evidence of fatty degeneration in the tubules of the kidneys in some cases. The poisons produced no changes in the spleen. This tissue injury was not increased or modified when arsphenamin was combined with mercuric salicylate in amounts corresponding to therapeutic doses in man. Arsphenamin does not appear to increase the injury produced by chloroform.

Immunity in Rocky Mountain Spotted Fever (Charles L. Connor, *The Journal of Immunology*, July, 1924).—The investigations carried out show that the behaviour of the virus in the tick and in laboratory animals is contrasted. The fact that there are so few organisms in the blood may be the reason why the virus in this situation is not amenable to attenuation. It has been shown that in tick tissues and in the tissues of guinea-pigs the virus may be attenuated by drying in the cold, and that after keeping for from five to thirty days at a below zero temperature, the tissue is no longer virulent, but will produce immunity. Several methods of using combinations of virus and immune serum have been tried. The most effective seems to be where virus is given in rather large dose and allowed to grow for twenty-four hours, when a dose of serum is given to stop the infection. Another method which is successful under limited conditions is the giving of large doses of mixture of virus and serum. It is shown that an immunity may be achieved which equals that following an attack of the disease. The same mixtures heated to 60° for twenty minutes have been ineffective. The virus serum mixtures are applicable for the present to guinea-pigs only. It is questionable whether the same amount of immune serum which will protect a guinea-pig against a certain amount of virus will protect a larger animal, and whether the same amount of virus that will produce immunity in the guinea-pig will do the same for a larger animal. A virus that is much more concentrated is desirable, and one that may be calculated as to its minimum infectious dose prior to administration. The fact that immunity depends only on the amount of virus given is brought out, the immune body having nothing to do with the production of immunity in another animal.

Study of the two hundred and two Cases of Hay Fever (G. Piness, *Journal of the American Medical Association*, Feb. 21, 1925).—The author discusses in detail the technique of the various procedures employed in the diagnosis and treatment of 202 cases of seasonal pollen hay fever, 1923. The results of these observations are, that a thorough botanic survey of all the air-borne plants is necessary before one can intelligently diagnose and treat hay fever. The method of collecting pollens and their preservation, as described in this article, is the most satisfactory one at hand. A correct diagnosis is essential for good results, and is simplified by a thorough study of the history in each individual case, in connection with a local pollen survey and plating, if necessary. The scratch method (cutaneous method) gives as good reactions as does the intracutaneous method, with less liability to constitutional reaction. The treatment on the assumption of group reaction is not as satisfactory as treatment based on tests. Preseasonal desensitization is a method of choice, and gives the best results when properly administered. Multiple sensitization is common in the vicinity studied. At least 87 per cent. of series were of that type. Bermuda grass (*Cyndon dactylon*) is the most frequent offender in the South-west. Reactions incident to treatment occurred most frequently in the patients who obtained the greatest amount of relief. The results obtained by preseasonal immunization compare favourably with those of other workers, and are quite uniform in that the average obtained by all workers is about 23 per cent. complete relief. From the results obtained by all the workers, much hope and promise of relief may be offered to the hay fever sufferer.

The Identification of the Organism of Rocky Mountain Spotted Fever in the Blood (Ch. L. Connor, *The Journal of Infectious Diseases*, vol. 35, No. 6, December, 1924).—The organism of Rocky Mountain spotted fever may be found in the blood and cell-free serum of infected guinea-pigs by dilution and prolonged centrifugation. Staining for more than four hours in Giemsa's stain, and differentiation in 95% alcohol, seem necessary to bring it out properly. The organism may be found by recovering infected blood from the peritoneum of a normal guinea-pig two days after the intraperitoneal inoculation. The fact that it has been found in the blood and serum does not completely dispense with speculation as to the real form of the organism in this situation. The small numbers found may be present from broken-down cells, and be quite accidental and transient. The unusual virulence of the blood (0·001 c.c. often being infectious) seems somewhat incompatible with the exceedingly small number of organisms found.

The Rôle of the Domestic Cow in the Epidemiology of Undulant Fever (J. T. Duncan, *Trans. of the Royal Soc. of Med.*, February, 1925).—From these studies it is clear that the strain " B " isolated from a case of Rhodesian undulant fever described is a *Brucella* of serological Group I (Feusier and Meyer). The cultural tests, as far as they showed any differences between *B. abortus* and *B. melitensis*, showed strain " B " to resemble *B. abortus*. The weight of evidence tends to point to *B. abortus* as the cause of Rhodesian undulant fever, and to the cow as the source of infection, but experimental proof that *B. abortus* from the Rhodesian cattle disease is pathogenic for man has not yet been supplied, nor is there available any trustworthy test to distinguish *B. abortus* from *B. melitensis* of Group I (Feusier and Meyer).

The Activation of Yeast-Absorbed Complement with Heated Sera (Roscoe R. Hyde, *The American Journal of Hygiene*, March, 1922).—Yeast-absorbed guinea-pig complement can be activated with minimal amounts of heated human or guinea-pig serum (56° 30′) in which a sufficient amount of sensitizing sera (approximately 5 units) is employed, provided the corpuscles are added after the other reagents have been added to the tubes. The zone of hæmolytic activity begins in the tubes containing approximately 0·04 c.c. of the heated sera and spreads to the tubes containing 0·1 c.c. If the number of sensitizing units is increased, covering a range from 5 to 100, the prezone practically disappears and the hæmolysis may extend to the tubes containing 0·005 of the heated serum. In those sets containing the same reagents, but in which the addition of the corpuscles and heated serum is interchanged, no hæmolysis occurs. If the sensitizing serum is reduced to less than 5 units the hæmolytic zone may shift to the tubes containing heated serum ranging from 1 c.c. to 0·1 c.c. In this case the hæmolytic action begins in the tubes containing approximately 0·5 c.c. and spreads to the other tubes in this zone. In this case the quantity of sensitizer can be adjusted so that hæmolysis results within this zone in those sets to which the corpuscles were incubated with the other reagents, before the addition of the heated sera, but not in the control set, in which the order of addition of the corpuscles and heated serum is reversed.

The Reaction Product which inhibits Reproduction of the Trypanosomes in Infections with Trypanosoma lewisi, with special reference to its Changes in Titre throughout the Course of the Infection (F. A. Coventry, *The American Journal of Hygiene*, March, 1925).—The presence of the reaction product which inhibits reproduction of the trypanosomes could not be demonstrated in the blood of infected rats on the fifth day of infection. The reaction product must be present before the fifth day, because the rate of reproduction is declining by that time. There is a sudden, very great, increase in the titre of the reaction product between the fifth and sixth days of the infection. There is

a gradual action in the titre of the reaction product between the seventh and, approximately, the thirty-fifth days of the infection. There appears to be a decrease in the titre of the reaction product from about the thirty-fifth day to the end of the infection.

The Treatment of General Paralysis by Inoculation with Malaria. A First Report (H. A. Bunker and G. H. Kirby, *The Journal of the American Medical Association*, Feb. 21, 1925).—Between June, 1923, and November, 1924, 53 unselected patients with general paralysis, in the male service of the Psychiatric Institute, have been inoculated with tertian malaria. Of the 53 patients inoculated, 11 have been treated too recently to allow an expression of opinion; 2 received a course of malaria on two separate occasions, and 1 failed to acquire the infection after repeated inoculation. Of the 39 patients remaining, 6 died during the actual treatment (5) or within a month of its completion (1), and 1 died eight months subsequent to treatment, after a slight remission of five weeks' duration. Three of the group of 6 died as a direct result of convulsions; in the case of the other 3 death may have been hastened, but was hardly directly caused, by the malaria. Of the 32 patients now alive at the end of from three to thirteen months from the conclusion of treatment, 14 are considered as either unimproved or more or less improved (only 1 of these 14 is definitely worse), and 18 are considered as much improved, and may be regarded as exhibiting fairly complete remissions with a residual mental defect, save in the case of perhaps 2 patients, either undemonstrable or of the slightest possible degree. Seventeen of these patients were discharged from the hospital from one to ten months ago, and 14 have returned to their occupations. These results, completely confirmatory of the data of similar type already published, lead to the belief that treatment of general paralysis with malaria is unquestionably a method of value. The authors believe that in the proportion of cases in which the disease appears to be brought to a standstill, as judged by clinical criteria, in addition to the proportion in which a striking degree of mental improvement comes about, is in itself not without possible significance.

Chronic Roentgen-ray Dermatoses as seen in the Professional Man (H. N. Cole, *Journal of the American Medical Association*, March 21, 1925).—The author believes that Roentgen-ray dermatoses in physicians and technicians are far more numerous than the literature would lead us to believe. Many cases, even severe ones, have probably never been reported. In six of the cases reported, a clinical diagnosis of malignant degeneration was made, and was confirmed microscopically in three. Two of these physicians have had a finger removed because of malignant change, and one has undergone several major operations, lost a thumb, had glands dissected out, and finally recovered through this and the use of electro-coagulation and radium. Roentgen-ray and radium, when used properly and with care, are not a danger to the patient or the operators. The author advises the adoption of the measures recommended by the Royal College of Physicians and the American Roentgen-ray Society for protecting the operators.

Mercurochrome-220 Soluble and Gentian Violet. Bactericidal Efficiency by Intravenous Route (I. C. Brill and H. B. Myers, *Journal of the American Medical Association*, March 21, 1925).—Clinical observations were made on three cases of bacteræmia and two cases of local gonococcal infections treated by intravenous injections of mercurochrome and gentian violet. These observations, which were carefully controlled by cultural checks, seem to indicate that in these five cases the intravascular injection of the dyes in no way interfered with the progress of the infection. Experiments on the effect of dilutions of mercurochrome and of gentian violet on the growth of staphylococcus, streptococcus and *B. coli in vitro* seem to indicate that there was no direct bactericidal action on those organisms from three hours' exposure to mercurochrome and gentian violet in concentrations of 1:10,000, representing the maximal advisable concentration of these dyes in the circulation.

Clinical Studies of the Kahn Reaction for Syphilis. III. The Test with Spinal Fluids (H. L. Keim and R. L. Kahn, *Journal of the American Medical Association*, March 21, 1925).—A comparative study was made of the Kahn precipitation test and two separate Wassermann tests, based on 1,000 spinal fluid examinations. The cases included: 222 of general paresis, 124 of tabes dorsalis, 387 of the diffuse type of neurosyphilis, 250 cases of syphilis with apparently no neurolgic involvement, and seventeen cases that showed central nervous system involvement of a non-syphilitic nature. The results indicate that the Kahn precipitation test compares favourably in specificity and sensitiveness with the Wassermann test.

On the Value of the Estimation of the Ionic Calcium of the Serum in the Diagnosis of, and as a Gauge of Progress in Sprue (H. H. Scott, *Annals Trop. Med. & Parasitology*, March 31, 1925).—The conclusions of this interesting paper are as follows: Sprue is a disease which is constantly associated with a fall in the amount of ionic calcium in the serum, whereas the total remains at or about normal. A rise and fall of the ionic calcium coincides with improvement and relapse. Absorption of calcium is little, if at all, interfered with, but calcium metabolism is upset. Consideration of this fact, and of some of the other symptoms of sprue, especially the cramps and tetany in severe or advanced cases, points to interference with the function of the parathyroid glands. Amelioration

of symptoms, followed by cure, is obtained by oral administration of suitable salts of calcium and a pure and active preparation of parathyroid in adequate doses. The period needed for cure by these means is much shorter than by previous methods, the main systems clearing up in some cases within a few days. The administration of the parathyroid must, however, be maintained to stabilize the amelioration, but no ill-effects have been found to occur if it be continued longer than is actually necessary to bring about this result. In the light of the above, it is interesting to note that most of the old empiric remedies contain lime as an important constituent.

Malaria Parasites in the Placental Blood (B. Blacklock and R. M. Gordon, *Annals Trop. Med. and Parasitology*, March 31, 1925).—Of twenty-six placentas of native women examined in Sierra Leone twelve, i.e. 46 per cent., were infected with *Plasmodium falciparum*. The infection in many of these placentas was massive. Examination of the peripheral blood of twenty-three of these cases revealed only four, i.e., 17 per cent., infected. In the placental blood, sporulating parasites were numerous, and also young and half-grown forms. Definite differences were observed in the number of merizoites produced by the parasites of different cases; these differences may influence the rapidity of onset and the course of the disease. Crescents were never found in the placental blood in any of the cases examined. No case of congenital malaria was encountered. Some evidence is produced which suggests that malaria infection of the mother predisposes to accidents during pregnancy or at birth.

A Disease of Fowls in Palestine characterized by Leucocyte Inclusions (S. Adler, *Annals Trop. Med. and Parasitology*, March 31, 1925).—A disease of fowls in Palestine characterized by various forms of chromatic inclusions in the leucocytes is described. The inclusions appear to be identical with the leucocytic inclusions described and figured by Macfie from Eket, Nigeria. The disease in Palestine is considered to be the chronic form of the disease described by Macfie. It can be transferred to healthy fowls by blood inoculation. The inclusions appear five to six days after the inoculation of infected blood; they are considered to be true parasites belonging to the Chlamydozoa. Transmission experiments with *Argas persicus* were unsuccessful, but the experiments are not conclusive.

The Eradication of Helminthiasis from the Egyptian Army (Major B. H. H. Spence, *Jour. Roy. Army Med. Corps*, May, 1925).—Fourteen per cent. of the soldiers treated in the Egyptian Army General Hospital in Cairo, in 1923, were admitted primarily for parasitic worm infestation. Twenty-nine per cent. of the men invalided in 1923 from the same hospital were invalided for the effects of chronic infestation with parasitic worms. Large numbers of "fit" men in the Egyptian Army suffer constantly from signs and symptoms of parasitic worm infestation without feeling ill enough to report sick. The Egyptian soldier is notoriously lacking in resistance to the adversities of military service in a bad climate. There is every reason to believe that this is the direct result of his constitution having been undermined by chronic infestation with parasitic worms. Ninety-one per cent. of a batch of 292 recruits for the Police School, Abassia, Egypt, were found to be infested with parasitic worms, some harbouring as many as four kinds. 73 per cent. had ankylostomiasis, 52 per cent. schistosomiasis, 7 per cent. ascariasis, and 3 per cent. other infestations. The 212 ankylostomiasis cases were treated with a single dose of five cubic centimetres of carbon tetrachloride. Three months later 79 per cent. were found to have been completely cured. For efficacy, ease of administration, mildness of after-effects, safety and cheapness, carbon tetrachloride is incomparably the best anthelmintic yet discovered for the treatment of ankylostomiasis amongst Egyptians. The 152 schistosomiasis cases were treated with 21 grains of antimony sodium tartrate divided into twelve doses and given on alternate days by intravenous injections. Of the 132 who were available for re-examination three months later, 95 per cent. were found to have been completely cured. By amplifying the dose on the lines indicated, it is probable that 100 per cent. of cures could be obtained in these comparatively lightly-infested healthy-looking recruits. Cure depends upon finding the limit of saturation the patient can tolerate and maintaining it till all the worms are dead. Antimony sodium tartrate merely kills the worms; it cannot be expected to repair hopelessly-damaged tissues. The derangement of the heart found in 16 per cent. of apparently fit recruits is probably the outcome of chronic toxæmia, due to long-standing infestation with parasitic worms. The necessity for subjecting all recruits for the Egyptian Army to a simple test for cardiac efficiency was clearly demonstrated.

Trichomonas vaginalis Donné (R. W. Hegner, *American Journal of Hygiene*, May 1925).—Vaginal mucous obtained from twenty women in the United Fruit Company Hospital at Tela, Honduras, and from twelve women in the United Fruit Company Hospital at Port Limon, Costa Rica, was positive for *Trichomonas vaginalis* in 50 per cent. of the cases at each hospital. Measurements of 100 specimens gave a range of from 7 microns to 21 microns in length, with a mean length of 16 microns and a range of from 6 microns to 18 microns in breadth with a mean breadth of 11 microns. Morphological studies of smears prepared by the Schaudinn-iron-hæmatoxylin method reveal (1) four anterior flagella, which arise from blepharoplastic granules usually in groups of two; (2) three, four or five blepharoplastic granules; (3) a large spindle-shaped nucleus containing many scattered chromatin granules and sometimes a

karyosome; (4) a small, undulating membrane which extends back about half the length of the body; (5) a flagellum which runs along the outer edge of the undulating membrane, but does not become free at its posterior end; (6) a chromatic basal rod accompanied by chromatic granules; (7) an axostyle extending from the blepharoplastic granules along one side of the nucleus and thence to the posterior end of the body, from which it often protrudes, and surrounded by several rows of chromatic granules; and (8) a fibril which arises from a blepharoplastic granule, extends along the side of the nucleus opposite the undulating membrane, is separated from the nucleus by a clear space, and probably represents a cystomal fibril within the lip of the cytosome.

Some Observations and Experiments on the Irritating Properties of the Larva of Parsa hilarata Staudinger (R. G. Mills, *American Journal of Hygiene*, May, 1925).—*Parsa hilarata* Staudinger has been found in North China (Peking and its environs) and has been shown to possess intense irritating properties. Injury is due to the mechanical introduction of a toxic substance by contact with any of the sharp-pointed spines widely distributed over its body. It is apparently not necessary for a portion of the spine to remain in the skin. The so-called "nettling hairs" are of very little importance. The toxic substance is contained within the spines, probably closely connected with the protoplasm, and has not been separated therefrom. It was destroyed or activated by almost every procedure employed, the chief exceptions being water, formalin 5 per cent. and sodium hydrate 1 per cent. Living larvæ are more irritating than the dead ones, regardless of the manner in which they are killed. Rigidity of the body is not a necessary factor in the production of lesions with killed larvæ. Spines, just severed from the body, retain their irritating properties, but preparations and extracts from various portions, and produced in many ways, failed to induce more than a slight mechanical injury in a few instances. The hypothetical toxic principle has not been definitely isolated, and very little is known as to its nature. Observations bearing on the habits and life-history of the species are described.

The Toxic Action of Oil Films upon Mosquito Larvæ with particular reference to Pine Oil Films (M. E. Barnes, *American Journal of Hygiene*, May, 1925).—Pine oil has a powerful soporific or paralysing effect upon mosquito larvæ and pupæ, and in effective doses results in their death either directly or, apparently, by drowning while under the effects of the drug. Anopheline and culicine larvæ, in many cases, may be resuscitated after prolonged submersion, even after being in contact with oil films. A method of resuscitating supposedly drowned larvæ is described. Crude oil is an efficient and economical vehicle for carrying pine oil to larvæ by means of film dosage. A mixture of crude oil and pine oil in the proportions of nine parts of the former to one of the latter produces a better film than either ingredient and one which is highly effective in destroying all stages of anopheline and culicine larvæ and pupæ. The ova of *Anopheles quadrimaculatus* Say are partially resistant to pine oil acting through films.

The Vitamin Content of the Banana (Eva Sopp, *Norsk Magazin f. Laegevidenskaben*, Kristiania, September, 1924).—Researches have proved that the banana is an excellent food for children. It contains 19-20 per cent. sugar and starch, 4-5 per cent. protein, and one-half to one per cent. of fat. Authors do not agree, however, on the essential point as to whether it contains sufficient vitamins, especially vitamin A, which is of such vital importance in the case of children. Experiments have been carried out on rats with very interesting results. The rats were put on a basic diet free from A vitamin until they began to lose weight and show signs of A-deficiency. The majority had very advanced xerophthalmia. They were divided into three groups: Group I received bananas *ad libitum* in addition to the basic diet; Group II received 1 grm. banana daily in the basic diet: Group III received 2 grm. banana daily in the basic diet. All the groups began to improve after a fortnight on the banana diet, especially with regard to the eye lesion. After three weeks there was an improvement in the general condition and the weight began to increase. The rats grew steadily until the end of the experiment, when they were fully developed. Group I increased most quickly and eventually attained the greatest weight, and Group III had a similar advantage over Group II. Two control series were made; in one the young rats received banana *ad libitum* with their basic diet from the first, while in the second they received their basic diet without banana. The second group soon fell sick and were all dead in seven weeks, but the first group thrived well.

The experiments show that the disease-preventing or healing component of the A vitamin in the banana is very active, while the growth-promoting component acts rather more slowly, but is present in sufficient quantity. If these results can be applied to man the banana may be regarded as an ideal food.

The Effects of "Castela nicholsoni" in the Treatment of Chronic Amœbic Dysentery (G. R. W. French and A. W. Sellards, *U.S. Nav. Med. Bull.*, August, 1924).—During 1923 seventeen cases of long-standing amœbic dysentery were treated in a naval hospital—all veterans of the Great War, who had been infected for periods varying from three to six years. Treatment was difficult; it consisted in the injection of emetine. *Castela nicholsoni*, however, proved of value; it can be easily and pleasantly administered by mouth, and when properly used is more effective than emetine. It is necessary to use potent extracts and to administer practically the maximum tolerated dose. The response in individual cases varies greatly, symptomatic relief being obtained in the majority. In eleven the stools became temporarily free from amœbæ, in five the infection persisted, and in six the effects of the drug appeared magical.

Observations on Bilharziosis in Iraq (A. Hislop Hall, *Journal of the Roy. Army Med. Corps*, February, 1925).—Bilharziosis is endemic in Iraq. It is widespread throughout the country and is not confined to the areas unaffected by the tide of the Persian Gulf. In Iraq it is always due to infection by *Schistosoma hæmatobium*. Its effect on the population both rural and urban is so marked that the disease must be considered an important factor in the economic development of the country. It is liable to spread to other countries. Anti-bilharzia measures hold out reasonable prospect of success and should be put into operation. For the success of such measures close co-operation is required between the departments of health, irrigation and education.

Malaria among Chinese University Students (K. H. Li, *China Medical Journal*, September, 1924).—Of 460 students of the Soochow University, 395 claimed to be, or to have been, malarious; 124 had clinical symptoms and were found to harbour subtertian parasites in twenty, tertian in ten, quartan in six, and undifferentiated forms in twenty-five cases. A students' strike confused conclusions, but malaria is held to be the most potent cause of loss of class attendance. Large mononuclears averaged 17·75 per cent.

Report on an Investigation into the Epidemiology of Sleeping Sickness in Central Kavirondo, Kenya Colony (G. D. Hale Carpenter).—The epidemic of sleeping sickness in Central Kavirondo was introduced about 1903 from Usoga across a chain of islands, and finally from Mageta Island to the coast of Kadimu close by. Mageta was evacuated, and subsequent return of the population brought back the disease, leading to a second evacuation, second return, and renewal of the disease about 1920-21, leading to a final evacuation for two years. *Glossina palpalis* occurs plentifully along the 100 miles of coast examined. Ample evidence was obtained that non-mammalian blood is much preferred to that of the hippopotamus, which was the only source of mammalian blood, except man and cattle at some localities. No trypanosomes were found in 238 *palpalis* examined. An interesting account is given of the history of the great epidemic in Central Kavirondo, Sigulu and Mageta Islands. During the recent investigations no cases of sleeping sickness were seen so advanced as to be obvious to the eye alone, and the majority of the several cases diagnosed seemed in their own opinion in good health. Only two of the emigrants from Mageta Island showed tremors of the tongue and some degree of wasting. So far as could be ascertained by inquiry, the disease is quiescent at the present time, the only deaths reported being among the Mageta people who had come away two years ago.

The presence of these infected people in a settlement on the mainland in close contact with Jaluo natives, of whom none have acquired the disease, is strong evidence that agents other than *Glossina* are not of material importance in the epidemiology of the disease. It was thought possible at one locality, where *Glossina* was reported to be unknown, that sleeping sickness must have been carried by some other agent, but close attention to local conditions and their history in the past showed that there was ample evidence that at the time of the epidemic *palpalis* was probably there in adequate numbers, although barely able to exist at the present day. Attention is drawn to the fact that broad contact between a population of density over forty per square mile and *palpalis* at the rate of more than fifteen males per boy per hour conduces to infection by *Trypanosoma gambiense*.

Complaints of Patients under Anti-leprosy Treatment, I. Nature and Frequency in Cases Receiving Chaulmoogra Ethyl Esters Preparations (W. H. Wade, C. B. Lara and C. Nicolas, *The Philippine Journal of Science*, December, 1924).—Few conclusions are to be drawn from this paper, both because of its general nature and the influences affecting the data, though several points of interest are seen. The importance of complaints of patients in modifying the methods of treatment is emphasized. Their kinds and classification are discussed and so far as possible their relative frequencies as met with in the Culion Leper Colony. The sex of patients has no apparent influence on the number of patients complaining. Age has little relation to the total number of complaints, but local irritation is apparently most frequent in the youngest and most of the other conditions least frequent. Coughing and choking and lepra reactions are most frequent in the aged. Wide variations in the reports of the individual physicians prevent the drawing of conclusions as to the effect of different tendencies in administering medication. It is found that on the average the amount of medication given during the period involved was decidedly not intensive. Analysis of the general relation of treatment methods to complaints shows little of the natural relationship between dosage, &c., and frequency of the various complaints, indicating clearly that the treatment staff as a whole has been careful to modify the administration of the drug to the side-effects produced, particular attention having evidently been paid to the dangerous respiratory tract symptoms and to lepra reactions.

Complaints of Patients under Anti-leprosy Treatment, II. Comparison of Plain Chaulmoogra Ethyl Esters and Two Iodized Preparations (H. W. Wade, *The Philippine Journal of Science*, December, 1924).—The plain chaulmoogra ethyl esters are irritating, particularly to the tissues at the point of injection and to the respiratory tract, so much so as seriously to limit the intensiveness of treatment with it in a leper population such as that of the Culion colony. Iodized preparations of the ethyl esters are much less irritating locally, which permits their more intensive use, and they also cause fewer complaints of general symptoms. The 2 per cent. iodized ethyl preparation,

heretofore generally used, has, according to the data examined, certain minor but not insignificant disadvantages over the plain drug. The 0·5 per cent. iodized preparation is in several respects distinctly superior to the 2 per cent. and, unlike this, in no important way compares disadvantageously with the plain drug. It is, therefore, the best of the three for routine anti-leprosy treatment.

Height, Weight and Chest Measurements of Mongolian Peoples, with Especial Reference to Southern Chinese (Wm. W. Cadbury, *The Philippine Journal of Science*, December, 1924).—The Chinese people average 165 centimetres in height. The people living south of the Yangtze River, in general, are shorter in stature than those north of this river. For Cantonese students of twenty years or over, the average height is 163·6 centimetres. The weight of the Chinese averages 56·9 kilograms in the north and 52·6 kilograms in the south. For Cantonese students of twenty years and over, the average is 51·9 kilograms. Taking the weight-for-height index as a criterion the index is found to vary from about 313 in the south to 384 in the soldiers of the north. For Cantonese students it averages 317. These figures are much smaller than the averages for Americans and Europeans. The chest circumference of Chinese is relatively small, varying from 77·4 to 86·9 cm. For the students in South China, the average circumference of the chest during rest is 78·9 cm. and they have a play of chest of about 6 centimetres. The Southern Chinese are therefore inferior to their northern brothers in height, weight, and chest measurements. The Mongolian tribes of the far North and the peoples of Indo-China to the south are inferior in size to the Southern Chinese. Because of the great tendency of the Cantonese people to travel and their intermarriage with the Malay peoples it can be assumed that this admixture has had much to do with producing a smaller race of Chinese. On the other hand, the author has observed that they are capable of developing almost the same degree of muscular energy and physical endurance as are the larger races of mankind.

Studies in Addison's Disease (L. Browning, *Journal of American Medical Association*, January 31, 1925).—In this report emphasis has been placed on the improvement accruing under forced organotherapy. The results have exceeded expectations in several instances. On the other hand, in spite of thoughtful and continuous efforts, five of the twelve patients died under treatment. The prognosis in Addison's disease is very grave. Only in a certain proportion of the cases can marked or lasting improvement be expected or obtained. At best, the treatment can only combat functional insufficiency of the suprarenal glands. If this is the outstanding factor in the disease, a form of substitution or complementary treatment may prove of decided value. The treatment probably exerts no influence on the fundamental pathologic processes underlying the Addisonian manifestations. Since nothing better is available, the Muirhead treatment should be given a fair trial in every case of Addison's disease, care being exercised, however, to see that the patient's individual tolerance is determined and given due consideration, and that simultaneously every measure is utilized in combatting the associated symptoms and the underlying pathologic process.

The Skin Capillaries in Raynaud's Disease (G. E. Brown, *Archives of Internal Medicine*, January, 1925).—The skin capillaries in eight cases of Raynaud's disease were studied during the different colour phases exhibited by this disease. In the normal compensated periods, many of these vessels disclose evidence of disturbed capillary tone, abnormal flow or complete stasis. The degree in which these abnormalities exist determines in a large degree the colour of the skin. The stage of syncope reveals many empty or partially filled contracted loops with stasis. The period of asphyxia is due to refilling of the capillary loops from segments of arterial or venous blood, or both, and dilatation of the loops with varying periods of stasis which determine the degree of cyanosis. The longer the cessation of capillary flow, the more pronounced is the capillary dilatation, and the greater the carbon dioxide content of the capillary blood. The recovery or rubor phase is due to resumption of capillary flow, more complete opening up of capillaries, pressure of oxyhæmoglobin, and partial recovery of capillary tone. Additional evidence is presented to prove the existence of independent behaviour of the skin capillaries.

The Treatment of General Paralysis by Malaria (T. Wishart Davidson, *British Medical Journal*, March 7, 1925).—The conclusions of this article are that the malaria treatment of general paralysis is justifiable and hopeful, provided the patients are in fair physical health. The earlier the case the better the prognosis. The treatment is contra-indicated where the patient is likely to have a fatty heart or where there is poor physical health. It may be added that the administration of strychnine, with digitalin or strophanthin to steady the heart, is advisable and helpful, especially during the later pyrexial attacks. Relapses of malaria do occur, but practically only in mosquito infected cases. Compared with infection by the inoculation of trophozoites, it would appear that infection by the sporozoites from the mosquito produces a parasite which readily becomes resistant to the immune body, and thus relapses frequently occur. A previous attack of malaria would appear to induce partial immunity; although scanty parasites appear in the peripheral blood there is no rise of temperature.

Primary Carcinoma of the Lungs (B. M. Fried, *Archives of Internal Medicine*, January, 1925).—Primary carcinoma of the lungs is apparently much more frequent than is commonly believed. Because of the similarity, from the clinical point of view, of

primary lung cancer and a great many chronic lung infections, and particularly chronic pulmonary tuberculosis, primary malignancy of the lungs is often mistaken for phthisis or other lung disease. Primary carcinoma of the lungs possesses a vigorous metastatic power. From the cases here reported, it seems that the tumour metastasizes very early, and the bones and brain are apparently much more frequently involved than is generally recognized. The bones may be infiltrated with tumour without producing any change in the outward structure. Because of this property (early metastasis) the chief symptom of the patient, as well as the attention of the clinician, is concerned with the secondary involvement, while the primary lesion is often overlooked. In any case of chronic lung affection with an atypical course and persistence of symptoms, especially if tuberculosis is excluded, malignancy should always be considered. The presence of pulmonary tuberculosis does not exclude the coexistence of malignancy in the same organ.

Focal Infection in Peptic Ulcer (R. L. Haden and P. T. Bohan, *Journal of the American Medical Association*, February 7, 1925).—In the case reported, experimental proof of a causal relationship of chronic foci of infection to an existent peptic ulcer was obtained by the injection into animals of bacteria recovered from the focus. In twelve patients, dental infection was probably the primary cause. Forty-five rabbits were injected with cultures from dental foci in three patients; 53 per cent. of the animals showed peptic lesions at necropsy. Only seven per cent. of 535 control animals similarly injected had such lesions. Eleven rabbits were injected with the cultures from the tonsils of five patients. Ten showed at necropsy lesions of the stomach or duodenum. The duodenal lesions that are observed experimentally are limited to the duodenal bulb, just as they are in man. The gastric lesions have a similar anatomic distribution. The evidence presented is good proof of the infectious theory of peptic ulcer. Patients with peptic ulcer should be thoroughly studied from the standpoint of chronic infection, and all possible foci removed. Gastroduodenal malfunction without demonstrable focal lesions may likewise be a manifestation of focal infection.

Mycotic Paronychia and Dermatitis (L. B. Kingery and C. H. Thienes, *Arch. of Dermatology and Syphilology*, February, 1925).—This condition has not been hitherto described, and is apparently peculiar to fruit canners. It is commonly known as "fruit poisoning," and has existed in certain sections of North-west America for a number of years. Cultures from several patients have uniformly revealed pure cultures of a yeast-like organism. Animal and human inoculations with organisms thus obtained result in a clinical picture practically identical with known mycelial infections of the skin, and exactly corresponding to the symptoms of patients suffering from the disease.

Painful Nodular Growth of the Ear (O. H. Foerster, *Arch. of Dermatology and Syphilology*, February, 1925).—The remarkable uniformity in the clinical symptomatology, as well as in the histologic features of the cases of painful nodule of the ear recorded thus far by Winkler and Foerster, indicates that the condition is an entity. It is readily differentiated from epithelioma, keratosis and other conditions which may resemble it, on the basis of both clinical and histological characteristics. The ætiology is unknown, although the anatomic peculiarities of the part of the ear almost exclusively affected are suggestive of the pathogenesis of the condition, and lend support to the foreign-body theory advanced by Winkler.

Melanosis after Arsenobenzol (W. J. O'Donovan, *Brit. Journ. of Dermatology and Syphilis*, February, 1925).—The long-continued oral administration of arsenic is admitted to cause in rare instances a melanosis of the skin. This melanosis has special features of widespread distribution and circular white spots. Acute oral intoxication by arsenic may produce exfoliation and pigmentation. Minute doses of arsenic are sometimes sufficient for the production of melanodermia, although as a rule prolonged absorption, medicinal, occupational or accidental is responsible. A case is reported of grave and persistent melanosis after eleven doses of neo-salvarsan that is closely similar to the described cases of arsenical melanosis of the pre-salvarsan period.

Epidemiological Studies on Respiratory Infections of the Rabbit. VI. Ætiology of Otitis Media (D. T. Smith and L. T. Webster, *The Journal of Experimental Medicine*, February 1, 1925). — A common form of otitis media occurring in rabbits is described. The condition in the great majority of instances is associated with the inflammation of the upper respiratory tract known as snuffles and with the presence of *Bacterium lepisepticum*. This organism, when introduced into the external nares of rabbits hitherto protected from infection with it, is capable of inducing a purulent otitis media indistinguishable from the natural one. In the rabbit the connection between the nasal passages and the middle ear is such that a pathogenic agent introduced into the nose may readily invade the entire group of cavities connected with the upper respiratory tract.

The Influence of the "Diaplyte" Antigen of Dreyer on Tuberculosis of the Guinea-pig (J. J. Bronfenbrenner and E. L. Straub, *The Journal of Experimental Medicine*, February 1, 1925).—The writers have prepared "diaplyte" antigen according to Dreyer's procedure, and have studied its therapeutic and prophylactic value in experimental tuberculosis of guinea-pigs. In their hands it has failed to yield beneficial effects. The animals treated with the antigen tended in general to develop lesions more quickly and to die earlier than the controls.

Contributions to the Pathology of Experimental Virus Encephalitis. (2) "Herpetic Strains of Encephalitogenic Virus" (S. Flexner and H. L. Amos, *The Jour. of Exper. Med.*, February 1, 1925).—In this paper it is shown that unequivocal strains of herpes virus exist in man, which in the rabbit exhibit a degree of encephalitogenic power not exceeded, and perhaps rarely equalled, by any strain of the so-called encephalitis virus. The fact that such highly encephalitogenic strains of the herpes virus exist in nature has, at the moment, theoretical and practical importance. Until recently the view has been accepted by certain workers in the field that two biologically distinct viruses of this class occur—one including epidemic encephalitis and the other febrile herpes in man.

Abstract.

AGGLUTININ FORMATION FOLLOWING THE USE OF CASTELLANI'S GLYCERO-VACCINE.[1]

By CRISTOBAL MANALANG,
Of the Philippine Health Service, Zamboanga, P.I.

ONE of the difficulties encountered by the Philippine Health Service in its work is the complete administration of the three standard injections for immunization against cholera or typhoid in campaigns, particularly provincial campaigns. This is due to lack of trained personnel, long distances between houses, and, most important of all, the tendency of the people to avoid succeeding injections after having received the first one. Preliminary experiments were made to note the presence or absence of agglutinins following one injection of the usual vaccine (1 c.c. = cholera, 1,000 million; *B. typhosus*, 500 million; *paratyphoid* A, 250 million; *paratyphoid* B, 250 million). Ten prisoners from the municipal jail at Zamboanga were injected with 1 c.c. of saline anticholera typhoid vaccine. Only one showed agglutination with cholera vibrio in 1 to 10 dilution after one month of observation.

Failing to obtain satisfactory anticholera agglutinin formation by the use of this vaccine, we were tempted to investigate agglutinin formation by the use of a single dose of Castellani's vaccine. Although agglutinins are by no means the only indication of immunity, still, the study of this phase was the best we could do with our facilities. The vaccine used was prepared as follows:—

Seed.—Two strains of cholera vibrio from the Manila epidemic of 1919; two strains of *B. typhosus* from the University of the Philippines, 1920; *paratyphoid* A and B from the Army Medical School, 1918.

Culture.—Plain nutrient agar using meat extract, reaction to phenophthalein about 0·5 per cent. to 1 per cent. acid. Put up in litre flat pharmacy small-necked bottles containing about 150 c.c. of agar; when slanted a maximum agar surface of about 170 cm.[2] is presented.

Inoculation.—Standard twenty-four-hour agar slant of the seed was emulsified in ·15 c.c. of saline and each bottle inoculated with 5 c.c. of the emulsion, the agar surface covered by tilting, and the bottles incubated at room temperature (30° C.); 4 bottles were inoculated with cholera vibrio, 2 bottles with *B. typhosus*, and 1 bottle with *B. paratyphoid* A, and 1 bottle with *B. paratyphoid* B.

After twenty-four hours at room temperature the growth in each bottle was emulsified in 125 c.c. sterile saline, mixed in a sterile litre bottle and well shaken.

Standardization.—Wright's method and opacity method; 1 c.c. of the mixture to contain 8,000 million (cholera 4,000 million; *B. typhosus*, 2,000 million; *paratyphoid* A, 1,000 million; *paratyphoid* B, 1,000 million) approximately; preservation, 0·5 per cent. phenol, 2 per cent. glycerine.

Water Bath.—Fifteen to twenty minutes at 60° to 65° C. Tested for sterility by culture and animal inoculation.

Bottling.—Passed through sterile bottling set with sterile gauze filter into sterile bottles and stoppered with sterile corks.

Dose.—One c.c. for adults. Children, according to age and development (under 5 years, 0·5 c.c.; 11 to 15 years, 0·75 c.c.).

TECHNIQUE OF THE TEST.

At least one capillary drop of serum was obtained by the usual method and mixed with nine capillary drops of normal saline solution. From this other dilutions of 1 to 20, 1 to 40, &c., were made. Fresh eight to twenty-four-hour old cholera slant was used for the test by making a slightly turbid suspension of this in normal saline solution. One loop of this added to one loop of the 1 to 10 serum dilution gave a final dilution of 1 to 20, &c. The test was observed under the microscope and controlled with or without normal serum in a separate hanging drop. Observations were made at room temperature (about 28° to 30° C.) after one hour.

The sera of 43 student nurses and attendants of the Zamboanga General Hospital were first examined for anticholera agglutinin and all were found negative in 1 to 20 dilution at room temperature, after one hour. They were then injected subcutaneously with 1 c.c. of the above-mentioned vaccine. The reactions in all of them were swelling of the arm with heat, pain and redness. Headache and indisposition were present in about one-third of the cases. Slight fever (37·5° to 38° C. per axilla), lasting from one to five hours in five cases. One chlorotic girl had to be admitted to the hospital for two days due to fever (37·5° to 39° C. per axilla) and weakness. With the exception of this one person, all continued at work.

The sera was tested against cholera vibrio every day during the first ten days, every two days during the following ten days, and once a week thereafter, using 1 to 20, 1 to 40, and 1 to 80 dilutions. These observations were continued for 160 days and the following results were noted. In 6 of the 43 cases no agglutination in 1 to 20 dilution was found. Thirty-seven cases showed positive agglutination at

SUMMARY.

A single dose of 1 c.c. of Castellani's glycero-vaccine (cholera, 4,000 million; *B. typhosus*, 2,000 million; *paratyphoid* A, 1,000 million; *paratyphoid* B, 1,000 million) produced anticholera agglutinin in 37 of 43 vaccinated persons.

Of the 37 positive cases, agglutinins appeared in 24 cases between the ninth and fourteenth days after the single injection.

Six cases remained negative for 160 days of observation.

Of the 37 positives, in 20 cases agglutination became negative in dilutions of 1 to 20 within 160 days after vaccination.

In more than 50 per cent. of these cases agglutinins were present in the blood of vaccinated persons for a period of three to four months.

The formations of agglutinin observed in the blood of persons vaccinated with Castellani's glycero-vaccine were more satisfactory than those obtained with the usual saline vaccine when used in single 1-c.c. doses (cholera, 1,000 million; B. *typhosus* 500 million; *paratyphoid* A, 250 million; *paratyphoid* B, 250 million).

The reactions, both local and general, were practically the same as those from saline vaccine, considering the number of bacteria given.

This vaccine was given to at least 40,000 people and not a single mishap was reported.

Current Literature.

BULLETIN DE LA SOCIÉTÉ DE PATHOLOGIE EXOTIQUE, March 11, 1925.

Experiments of Antiplague Vaccination by the Mouth in Man (G. Raynal).—These experiments of vaccination *per os* were carried out during an epidemic of bubonic plague at Diego-Suarez during the months of July, August, September, 1924. Although the epidemic was a small one, the mortality was very high. The vaccine used was "Pestedo" and the results were very good. There were no intestinal or general reactions in any of the cases. The number of tablets taken by each patient was seven per day. These results call for further experiments on a larger scale.

Experiments of Antimeningococcal Infection in the Belgian Congo (F. Van den Branden).—Experiments carried out during the war with antimeningococcal vaccine did not give very satisfactory results. In 1923, however, Calbraic obtained excellent results in an Annamite contingent. In 1924, at the beginning of the dry season, an epidemic broke out at Stanley Pool of cerebro-spinal meningitis; thirteen cases due to meningococcus and ten cases to pneumococcus. All the natives of both sexes were given prophylactic injections of antimeningococcal vaccine according to age. The injections were administered either subcutaneously or intramuscularly; there were no appreciable local or general reactions. Nearly two months later thirteen more cases were detected; three due to meningococcus and ten to pneumococcus; of the first three one had not received injections, and the other two who had, quickly recovered. These results undoubtedly prove the value of antimeningococcal vaccine.

A Case of Dercum's Disease affecting the whole body except the Face, Hands, and Feet in a Native Woman of Morocco (Mme. E. Delanoe).—The patient was aged 40 to 45. She was an enormous size, and could hardly walk without balancing herself with her arms. She complained of pains all over her body which were almost insupportable at night; very often she could not sleep. The joints were the parts most painful, especially the small ones; headaches were continuous, and were also worse at night time. The patient believed the condition to be of syphilitic origin, and asked for intravenous injections. About twenty-five years ago she had contracted syphilis of a very severe type; there was a generalized eruption fever, and headaches. The eruption left a slight swelling all over the body, which had gradually increased, and had never ceased. Under iodide treatment the eruption disappeared and the pain ceased. When the pain returned the patient had recourse to iodide. She is now improving rapidly under injections of neoarsenobillon.

"Clou de Biskra," observed in the Neighbourhood of Algiers (J. Montpellier).—Report of three further cases of oriental sore near Algiers proves that the malady is more widespread than is generally believed. Attention is drawn to the likeness of oriental sore to cutaneous tuberculosis, which is the cause sometimes of diagnostic errors. In these cases a peculiar crust was observed, which is described, and to which the author thinks more attention should be given, as it is a very useful factor in diagnosis.

Secondary Infection of the Uterus post partum by Chilomastix mesnili (R. Pons).—*Chilomastix mesnili* is a parasite frequently found at Saigon in the stools at laboratory examination. In this case, however, the infection had made its way to the genital tract, vagina and uterus, after a confinement. The patient was of robust constitution and the mother of two healthy children. She had been suffering from dysentery about three years before giving birth to another child, but during this interval had regular attacks of serous diarrhœa. Two days after the child was born, fever set in and diarrhœa. Examination showed the presence of numerous flagella in the stools and lochia, identified as *Chilomastix mesnili.*

On the Culture of the Intestinal Protozoa (W. L. Yakimoff, Mlle. W. J. Wassilewsky, and Mlle. N. A. Zwietkoff).—Cultures of several protozoa of the intestine of man and laboratory animals have been obtained on Frosch-Schardinger gelose medium. With this medium cultures can also be obtained of protozoa of the earth, water, hay, straw and grain, but it is preferable to make the first culture on ordinary diluted broth. There are some protozoa, however, which are not cultivable on Frosch-Schardinger gelose: *Lamblia, Chilomastix, Trichomonas, Octomitus, Trichomastix.*

On the Existence of Ankylostomiasis in Turkey (Akil Moukhtar and Sedad).—A second case is reported of ankylostomiasis at Constantinople; the first was described by Vassif Bey. Both patients were peasants working in the fields and had never followed any other occupation.

THE INDIAN MEDICAL GAZETTE, April, 1925.

Clinical Studies on Digitalis in Bengal (S. C. Bose).—Over 150 cases of heart failure have been clinically studied, of which a large number were in imminent danger. Of these only 6 per cent. of cases had auricular fibrillation, while 94 per cent. had normal rhythm starting at the sino-auricular node. On the contrary, over 66 per cent. of all cases of heart failure in Europe and America have auricular fibrillation. Standardized tinctures obtained direct from Parke, Davis and Co. were used in almost all the cases, in preference to other preparations of digitalis. The average quantity of tincture necessary to induce toxic effects varies in cold countries from 4 to 7 fluid drachms. In Calcutta the smallest dose required was 9 drachms, the highest was 29 drachms, and the average dose was well over 14 drachms. This result is partly due to loss of potency of tincture and partly to increased decomposition in the alimentary tract and liver. To obtain prompt results in grave cases, the tincture has been used, and ought to be used in doses of 2 to 3 drachms per day for five days. Cases of failure with normal rhythm require nearly the same dosage as cases with auricular fibrillation. Cases of failure, with free aortic regurgitation, syphilitic myocarditis and a strongly positive Wassermann reaction, do not benefit permanently from digitalis. Senile hearts, cases of marked hypertension and cases of grave anæmia with fatty degeneration of the myocardium respond remarkably well to digitalis.

The stage of optimum benefit from digitalis usually merges into the stage of minor intoxication from cumulation of the drug. With the tincture as obtained in this country it is extremely rare to get toxic effects from the use of tincture of digitalis in B.P. doses of 15 minims thrice daily.

The toxic effects such as slowing of the heart rate, nausea, vomiting and diminished diuresis often come on almost simultaneously, and after massive doses of 2 drachms a day have been taken for more than seven days. Apart from slowing digitalis may rarely provoke a sudden paroxysmal tachycardia of 180 p.m., termed "digitalis tachycardia."

Combined Carbon Tetrachloride and Oil of Chenopodium in the Treatment of Hookworm Disease. A Report of the Treatment of Seventy Cases (Asa C. Chandler and A. K. Mukerji).—From results obtained by these experiments the authors do not think that the addition of chenopodium to carbon tetrachloride is of any value in pure Necator infections, but the evidence, so far as it can be judged from a small number of cases, is strong that the combined drugs have a considerably more powerful effect on ankylostoma than has either drug alone. In places where ankylostoma and ascaris infections are common, therefore, a combination of carbon tetrachloride and oil of chenopodium is the best anthelmintic to use. This has also been proved by various other authors. The dosage employed of 60 minims of carbon tetrachloride in milk and 15 minims of oil of chenopodium in a capsule is considered safe for controlled patients; for field work on a large scale a smaller dose of these drugs in the same proportions is recommended. It is significant, however, that the fatal cases of carbon tetrachloride poisoning have always followed small doses, indicating that the condition and diet of the patient are more important factors than the size of the dose.

The Treatment of Cholera by Cresol and Acid (F. J. Palmer).—The author has found that cresol in association with acid in the treatment of cholera is superior to cresol alone. So far only nine cases have been treated but the results have been quite promising. The dose of acid is a small one, and graduated in view of the greater liability of children to acidiosis. It is essential that the doses should be freshly made to obtain good results.

Is Trichomonas hominis Pathogenic? (P. Ganguli).—Opinions have varied as to the pathogenicity of *Trichomonas hominis* ever since its discovery in 1854 by Davaine. Dobell, O'Connor, Knowles and other protozoologists believe that this protozoon is not pathogenic. Ganguli, for the following reasons, is of the opinion that *T. hominis* is pathogenic:

(*a*) Out of forty-three cases in which trichomonas was found in human stools in Eastern Bengal, no less than thirty-six were suffering from either diarrhœa or dysentery. Stools of three such dysentery cases were "plated" but no colony of dysentery bacilli was discovered. Seven cases with normal-formed stools showed motile trichomonas. These cases are considered *carriers* in analogy with *Entamœba histolytica* carriers. Just as some persons may harbour *E. histolytica* without showing any signs of dysentery, so trichomonas may be found in persons passing healthy stools. (*b*) Trichomonas has been found to contain red blood-cells. No other non-pathogenic intestinal flagellate has been found to have ingested the red blood-cells. (*c*) Trichomonas infestation can easily be removed with large doses of oil of turpentine given with castor oil emulsion. Patients showing *E. histolytica* in their stools in addition to trichomonas require emetine as well. (*d*) In two cases passing dysenteric stools, both *E. histolytica* and trichomonas were found. The pH of both the stools was 6·8. In nearly all the cases the reaction of the stools showing trichomonas was distinctly alkaline; but in these two cases, although the reactions of the stools were acid, the flagellates were found to be as active as ever.

Trichomonas Infection in the Urine (S. K. Ghosh Dastidar).—*Trichomonas hominis* infection of the intestine and *Trichomonas vaginalis* infection have been described by several writers, but this is apparently the first description of trichomonas infection in the urine. In routine examination of some thousand specimens of urine of both sexes, the author recently encountered this parasite in four individuals—three males and one female. All the samples were collected in clean glass urinals, so that there can be no question of fæcal contamination. It would appear that trichomonas may cause a mild urethritis, attended with smarting and burning on micturition, or the discharge of pus *per urethram*, but that this urethritis is cured on the disappearance of the trichomonas.

On the Technique and Significance of the Rosindole Reaction, applied to Urine (A. Neave Kingsbury and K. Kanagarayer).—The authors describe a technique for the application of the Rosindole test to urine. A positive result does not indicate presence of indican in the urine. An interesting point is that the percentage of positive cases is decreased in nephritic cases and increased in liver and insufficiency cases.

Intravenous Injections of Sodium Iodide in the Treatment of Goitre (E. A. Davis and P. Bell).—Interesting results have been obtained by the administration of intravenous injections of sodium iodide in cases of goitre; 5-6 gr. intravenously is tolerated well without any reaction, in a solution of 1 gr. to 1 c.c. of distilled water. It remains to be seen whether, after the the goitre has been reduced to normal, it will remain so or whether it will recur. So long as the patient remains in his original surroundings it will probably recur, at least in the great majority of cases. After a cure the patient should be removed to a more suitable place with a varied diet. If sodium iodide could be issued in tablet form it would be more convenient for several reasons. A chemically pure supply of the drug is necessary for intravenous injections to ensure safety. Further observations on this subject will be published later.

Rodriques, I. G. Soliman.

Correspondence.

To the Editor of the JOURNAL OF TROPICAL MEDICINE AND HYGIENE.

SIR,—In regard to the common South African host for the *Bilharzia* parasites, although Professor Ferdinand Krauss originally described the species as *Physopsis africana* and is therefore entitled to have the brackets omitted from his name, the species is now being described as *Isidora* (*Physopsis*) *africana* (Krauss), as will be seen from Major M. Connolly's well-illustrated description of "The Non-Marine Mollusca of Portuguese East Africa," published in the *Transactions* of the Royal Society of South Africa, volume xii, part 3, 1925, where some interesting details are also given to enable us to differentiate the species from *Isidora* (*Physopsis*) *globosa* (Morelet) which I have found infested with two distinct schistosomes at Lourenço Marques, and which is believed to be the common host for the *Bilharzia* parasites right across the African Continent from Portuguese East Africa to the Gold Coast and Sierra Leone.

Yours faithfully,

F. G. CAWSTON, M.D.

June 22, 1925.

Original Communications.

STUDIES OF THE YELLOW FEVER EPIDEMIC IN SALVADOR, C.A., IN 1924.

By HENRY R. MULLER, M.D., and C. BYRON BLAISDELL, M.D.
Special Members, Field Staff, International Health Board, The Rockefeller Foundation.

DURING June, July, August, September, and October of 1924, an epidemic of yellow fever occurred in San Salvador, the capital of the Republic of Salvador, C. A. The diagnosis was made from the clinical symptoms and from the autopsy findings by the local physicians (Segovía, Lardé) and by members of the Rockefeller Commission (Molloy, Bailey, and Hanson). Altogether there were fifty-six recognized and recorded cases of yellow fever of which fifteen were fatal, but the total number of cases is difficult to ascertain exactly. At least five cases occurred in a barracks among soldiers and many in the Casa Presidential, in the hotels and houses within a radius of one or two blocks from the barracks. Although the first recognized case was in a man of German birth who became sick on June 5 and died on June 9, subsequently about fifty cases occurred in natives of Salvador or other central American countries. It is estimated that about 1,500 foreigners (British, French, Germans, Americans, Syrians and Chinese) live in San Salvador. That so many natives were affected is partly explained by the fact that many of them were non-immunes from the interior of the republic who had recently come to live in the capital, San Salvador, after having previously resided in the rural districts where yellow fever had not existed.

During the latter part of the epidemic, cases of yellow fever were reported in other parts of the republic, but these outbreaks were relatively small and all occurred in the western part of the country. For instance, in the city of Ahuachapan (eighty miles west of the capital), twenty cases, eight of them fatal, were reported as suspicious of being yellow fever between August 1 and October 16. Also in Chalchuapa (twenty miles from Ahuachapan) between September 17 and October 5, six suspicious cases, with three deaths, were reported.

Unfortunately, we arrived in Salvador a month after the last case of yellow fever was recorded in the country (November 13, 1924), hence we had to content ourselves with a study of such materials as could be gathered from the cases which had occurred earlier. Dr. Juan Segovía, the Director of the Public Health Department of Salvador, Dr. Lardé, the chief of the Anti-Larval Division of the Public Health Department, and Dr. Parada, Chief of the Laboratory of the Public Health Department very kindly turned over to us what could be obtained in the way of histories, autopsy protocols, autopsy tissues, and sera from convalescents and normal individuals. The facilities of the laboratories of the Dirección Géneral de Sanidad also were placed at our disposal. To Dr. M. E. Connor, of the Rockefeller Commission for Yellow Fever Control in Central America, too, we are thankful for constant help and attention.

We directed our attention, first, to a study of the Pfeiffer phenomenon with sera from convalescents. Supplementary to the Pfeiffer reaction in convalescents we carried out similar tests with the sera from groups of normal adults, normal children and individuals vaccinated against yellow fever. Next we studied the histopathology of yellow fever as it occurred in Salvador.

(I) PFEIFFER REACTIONS WITH THE SERA OF YELLOW FEVER CONVALESCENTS AND OF NORMAL INDIVIDUALS.

Through the kind efforts of Drs. Segovía, Lardé, and Parada, blood was obtained from individuals who had recovered from clinically well defined or clinically suspicious yellow fever during the epidemic of 1924. The sera from these cases were tested against virulent, living cultures of *Leptospira icteroides* in the following manner:—

A mixture consisting of 0·5 c.c. serum, 0·5 c.c. pure culture (taken from the surface of a growth on the usual "Noguchi leptospira medium," and 1·5 c.c. of 0·9 per cent. saline was immediately injected into the peritoneal cavity of normal, medium sized guinea-pigs (200 to 300 grm.). At intervals of twenty or thirty minutes, for a period of two hours, samples of the injected liquid were withdrawn from the peritoneal cavity with capillary pipettes and examined by means of a dark-field microscope. Control tests with the saline solution used and with sera from normal individuals, never exposed to yellow fever, were performed. Since it has been shown [1] that the various strains of *L. icteroides* obtained from Ecuador, Peru, Mexico and Brazil, are equivalent for this test, they were used indiscriminately. Most of the individual tests were repeated. It has also been repeatedly shown that the lytic substances present in the blood after an attack of yellow fever are specific against *L. icteroides* [1].

As indicated in Table A, of twenty clinically suspected or definite cases of yellow fever occurring in the city of San Salvador during 1924, sixteen gave definite positive Pfeiffer reactions, i.e., lysis of the leptospira within a period of two hours. Usually lysis took place in half an hour. One doubtful result was obtained in Case 10 which was clinically a positive case of yellow fever. Of the three negative cases, Case 24 was either not yellow fever or was aborted on the first day by the use of serum. Excluding this case we obtained 84 per cent. positive Pfeiffers in nineteen clinically positive cases of yellow fever.

It has been extremely difficult to get reliable histories from the cases of Chalchuapa and Ahuachapan, and as the specimens of blood were exposed to the rather warm ambient temperature for three days before they reached the laboratory it is possible that the sera may have been altered in their activity. Sera were obtained from five cases and only two gave positive results (Table B). These tests were repeated, with the same result each time. It is quite likely that many of the suspicious cases in these two towns were not yellow fever; for instance, in Case 27 the patient herself gave us a history which was not very

suggestive of yellow fever (see Remarks, Table B). In Case 30 also the history states that malaria organisms were found in the patient's blood during her illness, hence this case may have been a severe form of malaria. The sera from these cases gave negative Pfeiffer reactions.

With a view to determining whether certain individuals who had apparently remained well during the epidemic had nevertheless passed through a mild form of the disease without recognizing it, sera were obtained from a group of normal soldiers living in the barracks, where several cases occurred. Of the fifteen individuals (Table C), fourteen gave clear-cut negative results, and one a mild positive result. In this last case (Case 25), however, a vaccination, carried out either in August or September, 1924, may have been responsible for the mild positive reactions. However, negative results were obtained with the sera of three individuals of this same group who had been vaccinated 130 to 160 days previously (exact date is not available). The tests in this group were all performed between January 12 and 19, 1925, i.e., not more than six or seven months after the first recorded case of the epidemic of 1924. From past experience [2 and 3], we would expect the serum still to give a positive reaction if the individual had had the disease within this period, even though in a mild or unrecognized form. As already stated, among fifteen soldiers that were examined, no such clinically unrecognized types of the disease were detected by means of the Pfeiffer reaction.

It has been suggested that between epidemic periods the virus of yellow fever may be maintained in children who have the disease in an atypical form, so mild that it has hitherto not been recognized. It has been thought possible that such cases also

(Suspicious and definite cases.)

Case number	Name	Date of onset	Date of Pfeiffer test	Number of days between illness and test	Result of Pfeiffer	Remarks
7	E. de G.	2/5/24	12/12/24	224	+	Black vomitus; jaundice; albuminuria.
8	E. G.	9/6/24	12/12/24	186	+	Had much black vomitus; albuminuria late.
9	I. V.	15/6/24	14/1/25	213	−	Mild chills and fever, headache, backache, pains in legs, bilious vomiting; sick for 5 days; became jaundiced in last days of illness. Rapid recovery.
10	J. C.	18/6/24	11/12/24	176	±	Is father of Case 8. Less severe than Case 8.
11	M. C.	18/6/24	11/12/24	176	+	Typical case.
12	A. E.	29/7/24	4/12/24	128	+	Typical case with black vomitus; melæna, icterus, albuminuria and cylindruria; fever 7 days.
13	P. D.	31/7/24	8/12/24	130	+	Icterus; albuminuria.
14	S. M.	12/8/24	2/12/24	112	+	Fever 8 days; oliguria; albuminuria; bradycardia; epistaxis; bleeding from gums
15	K.	18/8/24	23/12/24	127	+	Diagnosed by Dr. Hanson as a "mild case of yellow fever."
16	S. M.	20/8/24	12/12/24	114	+	No history available; diagnosed as "yellow fever."
17	E. A.	25/8/24	24/1/25	152	−	Icterus; oliguria; albuminuria and cylindruria; vomitus spotted with blood; bleeding from gums; menorrhagia.
18	V. G.	28/8/24	2/12/24	96	+	Melæna, icterus; epistaxis; oliguria; albuminuria and cylindruria.
19	J. A. M.	31/8/24	2/12/24	93	+	No history available; diagnosed yellow fever.
20	S.	31/8/24	15/12/24	106	+	Mild case (Dr. Hanson), fever 5 days.
21	A. F.	?/8/24	8/12/24	130?	+	Mild case (Dr. Parada).
22	R. R.	?/8/24	31/12/24	150?	+	No history available, but his physician called it a typical case.
23	C.	4/9/24	15/12/24	102	+	Diagnosed mild case (Dr. Hanson); rapid recovery.
24	S.	4/9/24	26/11/24	82	−	Regarded by Dr. Hanson as atypical and questionable; given anti-icteroides serum on first day; improvement in few hours.
25	A. E.	8/9/24	2/12/24	115	+	Mild case, characterized chiefly by albuminuria; oliguria; cylindruria and bradycardia.
26	J. B.	?	8/12/24	?	+	No history available.

TABLE B.—PFEIFFER TESTS WITH SERA OF SUSPICIOUS YELLOW FEVER CONVALESCENTS FROM AHUACHAPAN AND CHALCHUAPA (SALVADOR), 1924.

Case number	Name	Date of onset	Date of Pfeiffer test	Number of days between illness and test	Result of Pfeiffer	Remarks
27	R. L.	2/9/24	22/12/24	111	−	Suspicious case in Ahuachapan; but no vomiting; no jaundice and no congestion of eyes, according to patient.
28	F. C.	3/10/24	22/12/24	80	+	Suspicious case in Ahuachapan.
29	G. A.	13/10/24	22/12/24	70	+	Suspicious, mild case in Ahuachapan.
30	M. G.	7/9/24	23/12/24	107	−	Suspicious case in Chalchuapa; *Plasmodium vivax* and *falciparum* found in blood during illness.
31	C. F.	1/10/24	23/12/24	83	−	Suspicious case in Chalchuapa.

occur during epidemics. With the hope that these cases might also be detected by the Pfeiffer reaction, sera were obtained from twenty-two children from 6 to 9 years of age (Table D), who had lived in San Salvador during the epidemic of 1924. All the sera gave absolutely negative results, hence no evidence was obtained in favour of the assumption just mentioned.

Pfeiffer tests were made also on another group of sixteen men (Table E), most of them young adults, natives of Salvador, employed as inspectors for the Anti-Larval Campaign in Salvador. With one exception all the results were negative, and the serum which gave a positive result was from a man (Case 76) who had had yellow fever in Peru in 1920 (diagnosis by Dr. Hanson).

In Table F are listed nine individuals who were vaccinated about three to five months previous to the Pfeiffer test. In no instance was there anything in the history suggestive of yellow fever either before or after vaccination. Of these, three sera gave strongly positive, three weakly positive, and three negative Pfeiffer reactions. These results show that in some vaccinated individuals, even after a period

* Had yellow fever in Peru, 1920. Diagnosed by Dr. Hanson.

there was no serum left with which to repeat the test. In Case 87, however, we obtained the following information from the individual himself:—

Aged 24. In May, 1924, he was taken sick with severe backache, headache, and fever lasting four days. His eyes were congested, but he recalls no vomiting, nor any black or bloody stools. At the end of the attack he thinks he was jaundiced. He was not seen by a doctor. He further stated that an aunt living in the same house had a similar attack at least half a month before he was taken sick.

This history might be interpreted as that of a mild, atypical case of yellow fever, having occurred in San Salvador about one month before the first case that was definitely recognized as yellow fever. In both this case as well as in Case 91 the positive reaction of the serum may have been the result of a yellow-fever infection in either this or in a previous epidemic. With the exception of these two cases we were able to get evidence by means of the Pfeiffer reaction that yellow fever occurs in such a mild form that it is clinically not recognized.

TABLE G.—PFEIFFER TESTS WITH SERA FROM A GROUP OF NON-VACCINATED, SUPPOSEDLY NORMAL INDIVIDUALS.

Case number	Name	Result of test	Remarks
85	La C.	−	Had malaria when blood was taken for test.
86	S. E.	−	Had yellow fever in Santa Elena, Salvador, 1900.
87	J. M.	+	History suspicious of yellow fever in May, 1924, obtained from individual after the test.
88	M.	−	Born in U.S.A. Has been in Peru several years.
89	J. O.	−	Infant, aged 17 months. No history.
90	C. Q.	−	Malaria in August, 1924.
91	I. G.	+	Born in Chalatenango, Salvador. No history of illness.

Among the cases listed in Table G is that of a woman (Case 86) who had yellow fever during an epidemic in Santa Elena, Salvador, in 1900. After an interval of twenty-four years, her serum gave a negative Pfeiffer test. The serum from Case 76 (Table E) still gave a positive reaction after a lapse of four years. That the duration of the property producing the Pfeiffer phenomenon is variable in different individuals is known, and there are two instances recorded [4] where positive reactions were obtained after four and four and a half years respectively.

Cases 85 to 91 inclusive (in Table G) were individuals of whose past history nothing was known before the test. They were negative with the exception of Cases 87 and 91 which gave positive Pfeiffer reactions. Case 91 could not be located after the test, hence the history could not be obtained, and

(II).—PATHOLOGY OF YELLOW FEVER IN SAN SALVADOR, 1924.

In view of the fact that autopsy material fro recent cases of yellow fever appears destined become increasingly more difficult to obtain, it seem justifiable to present here, in abstract form, histori and autopsy protocols in addition to the descriptio of the histopathology of the newly acquired materi even though the latter is rather scant.

Case 1.—O. F. C. H., aged 29, merchant, Germa Onset June 7, 1924. Temperature (buccal) 40° C., mark cephalalgia, rachialgia, discomfort in epigastrium, agitatio bilious vomiting; urine dark, without albumin. June 8: A. temperature 39° C., symptoms more pronounced. June temperature 37·5° C. "Black vomitus" severe. Jaundi which had appeared after the first twenty-four hours, st present. Almost complete anuria. Delirium in the night. Sto black (melæna). Malaria parasites absent. June 10: Comple anuria (*see* autopsy); black vomitus abundant; convulsio fever dropping, pulse almost imperceptible. Coma, death.

Autopsy.—Performed one hour after death by Dr. Zuniga Idiáquez. Skin and scleræ pronouncedly icteric. *Stomach:* Contains large quantity of "coffee-ground" liquid. The mucosa has hæmorrhagic spots, and numerous small erosions. *Small intestine:* Contains black material, and both small and large intestine are congested. Some mesenteric lymph nodes are enlarged. *Liver:* Normal in size, yellow (like straw) and friable. *Gall-bladder:* Contains normal bile, but no calculi. *Spleen:* Slightly enlarged, passive congestion. *Kidneys:* Turgid, increased in size, with parts stained yellow. Capsule not adherent. *Bladder:* Contains 30 c.c. markedly albuminous urine. *Pancreas and adrenals:* Normal. *Lungs:* Calcified node in apex of left lung and calcified nodes in hilum of same side. *Heart:* Firm, normal size.

Histological examination (hæmatoxylin and eosin sections).—The material received by us from this case consisted of pieces of liver and kidney embedded in paraffin. Since no other tissue was available, stains for fat could not be made. *Liver:* Necrosis of cells extends nearly throughout the entire lobule; only small groups of intact cells are on the periphery of lobules and around central veins. The necrotic material is coarsely granular and stains deep red. The other cells, as well as those only slightly necrotic, are vacuolated. A moderate degree of round-cell infiltration exists in the parenchyma and a lymphocytic infiltration in the periportal connective tissue. Mitotic figures were not found, but some nuclei of liver-cells are hyperchromatic and increased in size.

Kidney.—There is no necrosis but there are many hyalin- and blood-casts in the tubules. There is a large amount of granular material in the lumen. A number of small hæmorrhages are present. In the capsule of the glomeruli there is an exudate of serum.

Case 2.—J. R. A., aged 17, musician, born in Guadalupe, Department of San Vicente. Became ill on July 13, 1924, and died July 20, in the hospital.

Case 2 was diagnosed as yellow fever, but no history could be obtained. However, an autopsy protocol and pieces of liver and kidney embedded in paraffin were received.

Autopsy.—Autopsy performed by Dr. Lardé, fourteen hours after death. Skin and scleræ markedly icteric. Peritoneum yellow. *Stomach:* Dilated and contains liquid of a dark colour. Mucosa, markedly congested, has ecchymoses and small erosions. These lesions more marked near the cardiac end. *Small intestine:* Contains liquid of same colour as the stomach, and the first portion of the duodenum has lesions similar to those in the stomach. *Spleen:* Weight 210 grm. Firm in consistence and normal in colour. *Adrenals and Pancreas:* Normal. *Liver:* Weight 1,602 grm. Yellowish in colour. *Gall-bladder:* Contains 15 c.c. bile, no stones. *Kidneys:* The right weighs 164 grm. and the left 167 grm. Signs of nephritis. *Urinary bladder:* Contains 150 c.c. albuminous urine. *Pericardial sac:* Contains 30 c.c. yellow liquid. *Heart:* Weighs 415 grm. *Lungs:* Congested.

Histological examination (Hæmatoxylin and eosin sections).—*Liver:* Necrosis of the intermediary zone is very extensive, and only very narrow rings of intact cells exist around the central veins and periphery of lobules. Vacuolization (probably fat) is marked in the preserved cells and those undergoing necrosis in the intermediary zone, but it is much less marked in the cells and the periphery of the lobules and around the central vein. Mitotic figures are numerous among the preserved liver-cells. The necrotic masses of cells stain deep red. An infiltration of round-cells with some polynuclears exists throughout the liver. In the connective tissue around the portal canals is an infiltration of lymphocytes.

Kidney.—The nuclei of the tubules are small and pyknotic, and mitoses are present. Cell outlines are not visible and many nuclei are absent, indicating necrosis. The tubules contain hyalin- and red-cell casts. Small areas of hæmorrhage are present. There are some lumina that contain large globules, approximately the size of epithelial cells. These globules are either discrete or conglomerate (some mulberry-shaped) and they stain various shades of blue, generally very dark blue suggesting calcification. Some are stratified and have concentric rings, and sometimes these blue bodies exist as large granules (figs. 1 and 2).

Case 3.—R. M., aged 21, mechanic, German. Became sick on July 14 and died on July 20. No clinical history is available, but an autopsy protocol and pieces of tissue from liver and kidney fixed in Bouin's picroformal and embedded in paraffin were received.

Autopsy.—Performed by Dr. Lardé fourteen hours after death. Marked icterus of skin and scleræ. Peritoneum shiny and yellow. *Stomach:* Dilated, contains a black liquid. Mucosa is the site of some ecchymoses and numerous small erosions. *Small intestine:* Contains black liquid. Duodenum has ecchymoses and erosions. *Large intestine:* Black fæcal contents. *Spleen:* Weighs 300 grm. Dark red. *Liver:* Weighs 1,110 grm. Yellowish. *Gall-bladder:* Contains 15 c.c. bile, but no stones. *Kidneys:* The right weighs 162 grm. and the left 154 grm. Colour is dark red. *Adrenals and pancreas:* Normal. *Urinary bladder:* Contains 200 c.c. albuminous urine. *Pericardial sac:* Contains 30 c.c. yellow liquid. Some small ecchymoses in the parietal serosa. *Heart:* Weighs 450 grm. *Lungs:* Congested and œdematous.

Histological examination (Hæmatoxylin and eosin sections).—*Liver:* Extensive necrosis and vacuolization of almost the entire lobule. Among the necrotic cells are some cells with preserved nuclei and especially on the periphery of the lobules are these cells more numerous. Vacuolization is very marked. There exists a moderate infiltration of round-cells and polynuclears throughout the lobule, and there is a lymphocytic infiltration of the periportal tissue. Lobules and trabeculæ are not readily made out. Only small foci of less extensively damaged cells are located on the periphery of lobules and around central veins. A few mitoses are present.

Kidney.—Cloudy swelling of the epithelium of the convoluted tubles exists, and there are nuclei in various stages of karyolysis and karyorrhexis.

Case 4.—V. S., aged 27, born in San Salvador. Became sick on August 10 with fever, headache, and backache. Vomitus at first bloody, but later became black. Seen by physician for first time August 13. On that day had temperature 38° C., pulse weak, bleeding gums, bloody stools, epistaxis, generalized jaundice, greenish-yellow papules on lower extremities and on back. Urine scanty. Arrived in hospital August 15, delirious and dyspnœic. Face pale, lips cyanotic; conjunctivæ injected; scleræ reddish-yellow with some spots of extravasated blood; gums bleeding; extremities cold; stools bloody; no urine obtainable on catheterization; temperature 37·5° C., pulse 52; died at 9 a.m.

Autopsy (time and operator not stated).—Generalized jaundice; ecchymotic spots on cornea (?) of right eye, ecchymotic spots on gums, marked on inferior maxilla; a thin layer of coagulated blood on the labia majora. Peritoneum, strongly icteric; no excess liquid. *Liver:* Weighs 1,260 grm. Consistency is soft, somewhat friable and has externally an orange colour, with red ecchymoses. On the cut surface lobules cannot be distinguished, and the surface is smooth, yellow, and dotted with hæmorrhages. Gall-bladder and bile-passages are normal. *Stomach:* External surface yellow and hyperæmic. Contains 200 c.c. black liquid with bloody detritus in suspension. Many punctate hæmorrhages in the mucosa. *Duodenum:* Contains black material, similar to that in stomach. *Small intestine:* Contains dark, lead-coloured pasty material. The mucosa presents hæmorrhagic suffusions and the serosa numerous ecchymoses. *Large intestine:* Contains melanotic fæcal material. *Spleen:* Weighs 189 grm., and presents a normal appearance. *Kidneys:* The right weighs 147 grm. and the left 152 grm. Consistency is soft and the external surface is red. The cut surface of cortex is studded with punctate hæmorrhages. The medulla is red-wine colour. *Urinary bladder:* Distended with urinous ochre-coloured liquid. The mucosa is hyperæmic. *Adrenals and pancreas:* Normal. *Uterus:* The cervix is ecchymotic and the uterine cavity contains yellow mucus. The tubes are notably congested. *Pleura:* Ecchymotic spots on the visceral layer. *Lungs:* Congested and œdematous. *Heart:* Weighs 295 grm. Myocardium is flaccid and there is hypertrophy of left ventricle. Tricuspid and mitral valves have marginal endocarditic lesions.

Histological examination.—The material obtained (liver, kidney, heart, and spleen) were in formalin. *Liver:* In the hæmatoxylin and eosin sections the lobules can be made out, but the cords are distinguishable with some difficulty. Liver-cells are preserved only in small groups on the periphery of lobules and around the central vein. The cells between contain numerous fine vacuoles, but actually necrotic cells with lost nuclei are scarce and only occur scattered individually or in minute groups. The cytoplasm stains deep-red with eosin. The cells are swollen and the sinuses nearly obliterated. Among the liver-cells are lymphocytes and polynuclears. Red cells seem to be absent. The fibrous tissue is increased around

the portal canals but does not extend completely around the lobules. This connective tissue is markedly infiltrated, chiefly with lymphocytes, but also with a few large mononuclears.

In the scarlet R. sections the liver cords appear to be better preserved. Fatty degeneration is uniformly distributed throughout all the cells of the lobules. The fat is abundant and exists

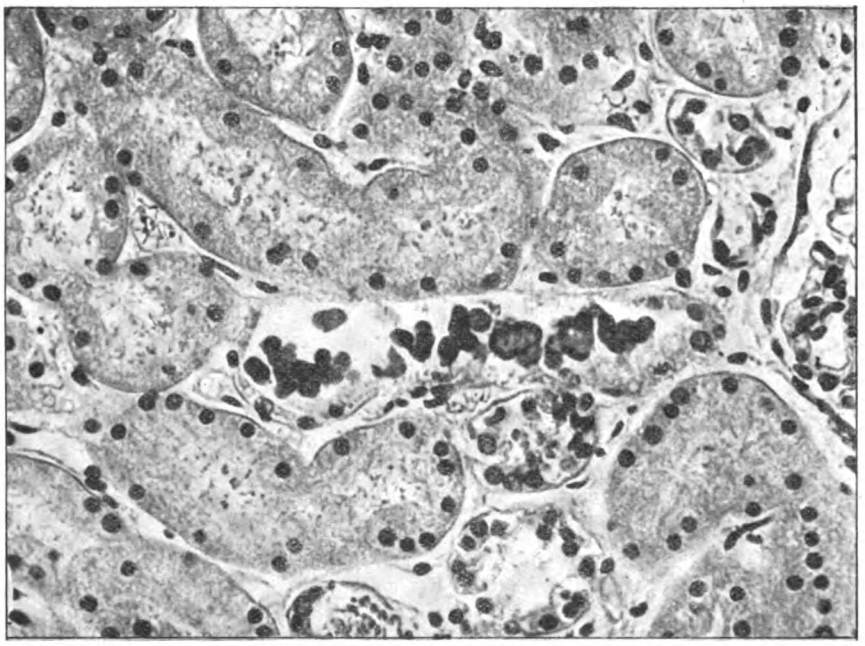

FIG. 1.

Case 2.—"Lime-casts" in Kidney. Calcified globules resembling calcified desquamated epithelial cells in tubule. Magnification × 370. H. and E. stain.

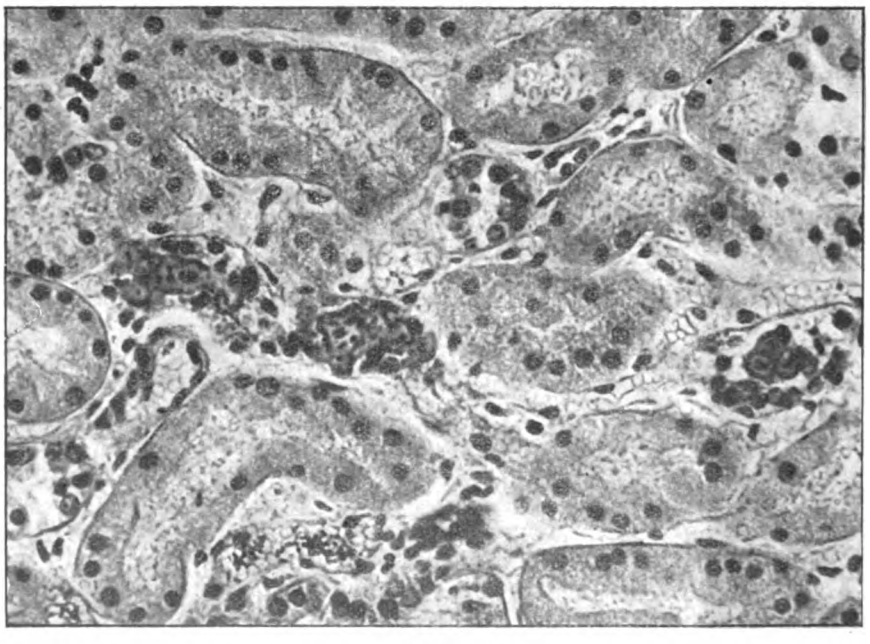

FIG. 2.

Case 2.—"Lime-casts" in Kidney. Calcified globules tending to be fused and forming solid masses. Magnification × 370. H. and E. stain.

Many cells contain very finely granular yellow pigment (bile ?). As a rule the nuclei are well preserved, but some are small and pyknotic. Mitotic figures are not found.

in the form of minute droplets. The epithelial cells of the bile-ducts also contain a moderate number of very fine fat droplets around the nucleus of each cell.

Kidney.—In the hæmatoxylin and eosin sections the cells of the convoluted cells are flattened and very granular. The lumen of the tubules is wide and contains abundant loose granular material. The nuclei are generally small and deeply stained, but in many tubes the nuclei are faint or absent. Some tubules contain red blood-cell casts. Many cells of convoluted and collecting tubules contain fine round vacuoles. The capsule of the glomeruli is slightly thickened and there is a mild infiltration of polynuclear and round cells in the glomeruli. The so-called "lime-casts" are not encountered.

In the scarlet R. sections a fairly marked fatty degeneration of the convoluted and collecting tubules exists, the fat being in the form of minute drops.

Heart.—There is fragmentation of the muscle fibres. Small patches of fibres present, fatty degeneration in the scarlet R. sections.

Spleen.—Follicles are small and sinuses somewhat dilated.

Sections of all these tissues impregnated with silver according to the Levaditi method failed to show any leptospira.

Case 5.—J.E.C., aged 39, born in San Martin, came to the capital two months ago. On August 12 he had prolonged chills and high fever, frontal headache, backache, pain in eyes, pains in muscles, joints and epigastrium. Vomiting was alimentary. Face and conjunctivæ congested. No jaundice or albumin in the urine. August 14: Headache, marked weakness, tiredness. Conjunctivæ slightly congested, scleræ faintly yellow. Vomitus watery and alimentary; stools semi-liquid and yellow. Urine scanty, contained 1·6 grm. albumin per litre. Blood examination showed absence of malaria parasites August 15: Temperature 38·5°C., pulse 100. Urine (250 c.c. passed in twenty-four hours) contains granular and cellular casts. Persistent "bilious" vomiting. August 16: Temperature dropped to 36°C. Anuria. August 18: Frank icteric tinge of scleræ Vomitus is "watery." Urine 30 c.c. passed in twenty-four hours. Temperature 36°C., pulse 80. Blood examination: Red blood-cells = 6,000,260; white blood-cells = 7,000; hæmoglobin 95 per cent.; polymorphonuclears 69 per cent; lymphocytes 25 per cent.; large mononuclears 0 per cent; medium mononuclears 2 per cent; eosinophils 3 per cent; transitionals 1 per cent. August 21: Restless, face slightly congested. Temperature 36°C., pulse 104. Urine 100 c.c. in twenty-four hours. August 22: Shows great anxiety; dyspnœic. Vomitus is watery with some spots of blood Urine 15 c.c. in twenty-four hours. Temperature 36·6°C., pulse filiform, impossible to count. Skin and scleræ jaundiced. Convulsions, death.

Autopsy (time of autopsy and by whom performed not ascertainable).—Jaundice of skin most pronounced on face and front of chest. Peritoneum yellow; no excess amount of liquid. Mesenteric lymph nodes not enlarged. *Stomach:* Dilated and filled with liquid. External surface is orange-coloured, with zones of hyperæmia, and some ecchymoses and blood suffusions. Abundant adherent mucus. *Small intestine:* Contains yellow, semi liquid material. Few spots of bloody suffusions in mucosa. *Liver:* Weighs 1,500 grm. and is of normal size. Colour pale yellow, many ecchymoses. Consistency pasty. The cut surfaces are pale red, studded with many yellow islands. *Gall-bladder* and its ducts are normal. *Spleen:* Weighs 109 grm. Normal in colour, but friable in consistency. *Kidneys:* Right weighs 182 grm. and left 159 grm., notably increased in size. The capsules are adherent. Small hæmorrhages present in cortex. *Urinary bladder:* Contains small amount of urine. *Adrenals and Pancreas:* Normal. *Heart:* Weighs 343 grm. Musculature hypertrophied, flaccid and pale. On the edge of the mitral valve are soft, œdematous nodules. *Lungs:* Bilaterally congested.

Histological examination (pieces of liver, kidney and spleen received in formalin).—*Liver:* The lobules are somewhat less distinctly demarcated than normal, and contain large, fairly well preserved cells around the central vein and on the periphery. The cells between these zones present necrosis and vacuolization corresponding to fat in the scarlet R. sections. This distribution of altered cells, however, is not uniform in all parts of the section, but there may be irregularly scattered patches of necrotic and vacuolated cells, i.e., "focal" necrosis instead of zonal necrosis. In all these zones of necrosis and fatty degeneration the infiltration of cells, consisting of lymphocytes, large mononuclears, and a few polynuclears, is particularly abundant. Around the portal canals there is an increase of connective tissue and a lymphocytic infiltration.

Kidney: There is moderate dilatation of the convoluted tubules which are filled with granular debris. Some tubules without epithelial cell lining contain deeply blue-staining large globules which may be the desquamated epithelial cells. These clumps, lying in the lumen, resemble the so-called "lime-casts." The globules are either conglomerate and form nearly a solid mass or they are more discrete. Necrosis and mitotic figures are absent Fatty degeneration, according to the scarlet R. sections, is relatively slight, being most marked in the collecting tubules. Hæmorrhages are present in both medulla and cortex.

Spleen: The follicles are small No pathological changes to be observed. Levaditi sections of these tissues are negative.

Case 6.—H. R., aged 36, farmer, born in San Vicente, has been in San Salvador for past nine months. October 10, at midnight, had severe chill, followed by fever, nausea and "bilious" vomiting. Had headache, backache and pains over whole body. He was admitted to hospital October 15. Temperature 39° C., pulse 83 (relative bradycardia). Sub-icteric tinge of skin; scleræ reddish yellow. Conjunctivæ very congested. Abdomen tender to palpation; backache marked: hiccoughs. No malaria parasites found in the blood. Urine contains 1·75 grm albumin per litre (Esbach) and many granular casts. October 16: Patient is delirious, and general condition is worse. Temperature 36·5° C., pulse weak, 80 beats per minute. Vomitus is watery with black streaks. 100 c.c. urine passed in eighteen hours. October 17: Temperature 36° C., pulse 82. Delirious; persistent hiccoughs. Scleræ frankly yellow. No vomiting; no stools. In afternoon was catheterized and 30 c.c. urine obtained, which contained 12 grm. albumin per litre (Esbach). October 18: Died at 2 a.m.

Autopsy (time and operator not stated).—Skin, conjunctivæ and scleræ icteric. *Stomach:* Greatly dilated, contains 500 c.c. of black liquid. The smooth mucosa has bloody suffusions and punctate hæmorrhages on the lesser curvature and at cardiac and pyloric orifices. *Liver:* Weighs 1,372 grm Consistency soft and fluctuant, of bright yellow colour and few ecchymoses. On the smooth, yellow, cut surface the lobules cannot be distinguished. *Spleen:* Weighs 140 grm.; appears normal. *Kidneys:* Right weights 120 grm. and left 140 grm. On the cut surface glomeruli appear swollen. Cortex and medulla present small hæmorrhagic spots and streaks. *Heart:* Weighs 304 grm. Consistence is firm and red. *Lungs:* Considerable congestion and œdema, bilateral.

Histological examination (material received in formalin).—*Liver:* Necrosis and vacuolization of cells of almost the entire lobule and only small groups of cells on periphery of lobule and around central vein are spared. Lobules and trabeculæ can be distinguished with difficulty. The vacuoles, which are fine and numerous in each cell, correspond to the fat stained in the scarlet R sections. The groups of necrotic cells correspond in distribution quite closely with the areas of most intense fatty degeneration. The necrotic cells are numerous, and their nuclei are in various stages of degeneration. Polynuclears and mononuclears are found among the necrotic cells. Mitoses are not found.

Kidney: There is marked cloudy swelling with much finely granular material in lumen Necrosis and mitotic figures are absent. Hyalin and blood-casts are numerous. Hæmorrhages, too, are frequent.

Spleen: There is dilatation of the blood filled sinuses. Follicles are small. There is much brown pigment, chiefly in macrophages.

Levaditi sections of liver, kidney, and spleen are negative.

The chief centre of interest in the pathology of yellow fever has, for a long time, been the liver. Chiari [5] has again pointed out recently that the two chief lesions of this organ are fatty degeneration and necrosis. The common feature in all the cases he studied was the existence of necrotic cells in the form of disseminated foci. When these are present in large numbers, the intermediate zone is most affected; the presence of necrotic cells most commonly in the intermediate zone is of secondary importance. Constantly among the necrotic cells can be found cells with marked fatty degeneration. The intermediary zonal necrosis is, however, found in numerous septic

diseases and cannot be regarded as pathognomonic for yellow fever.

With these statements we fully agree, and the aspect of the livers of our six cases confirms Chiari's findings. Case 5, for instance, presents "focal necrosis" as well as a "zonal necrosis."

With regard to the pathology of the kidney it seems that all grades of acute nephritis are found, ranging from severe necrosis of the epithelium of the convoluted tubules to various grades of "cloudy swelling." Hyalin and blood-casts are quite frequently found in the tubules. In two cases (Nos. 2, 5) so-called "lime-casts" are present. Their formation and presence are perhaps dependent on the type of nephritis existing in any individual case. Since in some instances they resemble calcified desquamated epithelial cells (fig. 1) and are present in tubules where epithelium is absent, or where only a few cells still remain in place, it is possible that they are formed only in those cases of yellow fever in which the type of nephritis is "desquamative"; in bichloride poisoning, for example, "lime-cast" formation is frequent. To the "lime-casts," therefore, we cannot assign any pathognomonic significance. It is possible that in certain epidemics of yellow fever the type of nephritis was such as to favour the formation of lime-casts, but in our present series, unfortunately small, they were not constantly present and were found only twice in six cases. Hoffmann [6], on the other hand, found them in twenty-four out of twenty-eight cases.

Fatty degeneration of the kidney is variable in its intensity and in our series was relatively less pronounced than fatty degeneration of the liver. It is most intense and most constantly present in the collecting tubules, but the convoluted tubules are nearly always affected also.

The spleen in our series presents no lesions. This observation is in agreement with the findings of others.

The negative findings in the Levaditi sections were not surprising when it is noted that the material came from cases 4, 5 and 6, in which death occurred five, ten and eight days respectively after the onset of disease, i.e., at a stage when the infectious agent, *L. icteroides*, is known to have disappeared from the body.

SUMMARY.

Among nineteen persons who had recovered from clinically positive cases of yellow fever in San Salvador, in 1924, in sixteen (84 per cent.) the serum gave a positive Pfeiffer test.

Of five persons from the western part of the republic, who had passed through a disease which was clinically suspicious of yellow fever, the sera of two gave positive reactions. The tentative diagnosis of yellow fever in these two cases was thus confirmed by the Pfeiffer tests.

The sera of fifteen soldiers who had lived in San Salvador and in the same barracks where yellow fever had occurred gave negative reactions.

Fifteen normal sanitary inspectors who had no history of yellow fever gave negative Pfeiffer reactions, while the test was positive in the case of one inspector who had had yellow fever in Peru four years previously.

Twenty-two children, from six to eight years of age, who had lived in San Salvador during the epidemic, all gave negative Pfeiffer reactions.

Pfeiffer tests of the sera of vaccinated but otherwise normal individuals showed that in some instances the lytic substances induced by vaccination may still be active against *L. icteroides* after a lapse of five months.

The pathological findings in six cases of yellow fever are presented. In the liver zonal necrosis was present and, more rarely, focal necrosis, together with marked fatty degeneration. Associated with these changes was a round-cell infiltration and a milder polynuclear infiltration. Mitosis and hemorrhages were frequently found. In the kidney there was evidence of acute tubular nephritis of varying intensity. Lime casts were present in two of the six cases. Their appearance suggested that they originated from desquamated epithelial cells which had become calcified. The suggestion is offered that lime casts are formed in some but not all types of nephritis associated with yellow fever, occurring especially when desquamation is a feature.

OBSERVATIONS ON THE EXPERIMENTAL USE OF FISH INDIGENOUS TO BRITISH GUIANA FOR THE CONTROL OF MOSQUITOES BREEDING IN VATS, TANKS, BARRELS AND OTHER WATER CONTAINERS.

By J. F. C. HASLAM, M.C., M.D., D.P.H., M.R.C.P.E.
Government Medical Officer of Health, British Guiana.

SINCE my arrival in the Colony, in 1921, I have known of certain water receptacles in which the owners were accustomed to keep one fish or more. In nearly every case the fish was a "hassa" (*Hoplosternum littorale*). In some cases the avowed object was to control mosquito breeding, while in others the intention seems to have been to have early warning in case a malicious neighbour should poison the water supply. In a few cases the belief was held that the presence of the fish ensured purity of the water. A handful of mud is sometimes placed in a barrel as it is thought that the fish thrive better if this is done.

Definite observations were commenced in February 1924, and as initial success was obtained, a large-scale experiment all over the coastlands was begun in August 1924. Every sanitary inspector carried out trials and made reports. Much of this work was not done with any intelligence, and large numbers of reports were

valueless. Laboratory experiments under close observation were then commenced, and also closely observed trials under ordinary conditions at the quarantine station and elsewhere.

The water containers to be dealt with are of innumerable variety. Large specially built vats and tanks are comparatively scarce, and the 40-gallon cask is perhaps the commonest receptacle, while old boiler casings, petrol cans, pans from derelict sugar mills, Dutch stoneware jars and a host of other almost unscreenable makeshifts form the balance.

The mosquitoes to be controlled, and which in this colony choose such receptacles as breeding places, are mainly *Aëdes argenteus* (*Stegomyia fasciata*) and *Culex quinquefasciatus* (*Culex fatigans*), but occasionally along with these *Anopheles tursimaculata* has been taken in an open water vessel.

Some experiments have been made with imported Barbados millions (*Lebistes reticulatus*), but the purpose of the inquiry was to find a suitable indigenous fish which could be easily obtained in quantity and, if possible, a fish well known to all village people, so that they can themselves stock their water vessels.

The following well-known fish have all been given a trial, and some notes are given of the results in every case, but as soon as any fish was found unsuitable for one reason or another its trials were stopped. Full particulars of experiments are only given in the cases of those fish which, as the experiments proceeded, showed a likelihood of being suitable for practical use:—

Local name	Provisional identification
Hassa	*Hoplosternum littorale.*
Patwa	*Cichlasoma bimaculatum.*
Congo Patwa	*Polycentris schomburghi.*
Kakabelly	*Peecilia vivipara.*
Hoorie	*Hoplias malabaricus.*
Sunfish	*Crenicichla saxatilis.*
Silverbait, also called Cellebe	*Tetragonopterus chalceus.* *Charax gibbosus.* *Hemigramms unilineatus.* *Hemigramms rodwayi,* and one not identified.
Millions (a very small fish locally so-called).	*Acanthophacelus melançonus.* *Acanthophacelus reticulatus.*

The small *Acanthophacelus*, locally called millions, are extremely plentiful in many ponds, trenches and concrete gutters, but proved to have no appetite for mosquito larvæ.

Much was hoped for, and expected, from the kakabelly as this fish (*Peecilia vivipara*) has proved of value elsewhere and has been said to possess most of the good qualities of the very effective *Gombusia affinis*. In this colony *Peecilia vivipara* is nearly always found in dirty water, most commonly in the small concrete drains of Georgetown, and the fish has nearly always died soon after transference to clean rain-water.

Never in my experience has this fish come near eating the average of fifty larvæ a day claimed for it in "The Use of Fish for Mosquito Control," published by the International Health Board.

Even had it reached this average it would still be of greatly inferior appetite to some others experimented with.

These experiments were made entirely with larvæ of *Stegomyia* and *Culex*, so it may be that *Peecilia* will redeem its reputation in the experiments with anopheles larvæ now going on.

Congo patwa (*Polycentris schomberghi*). This fish proved to be a hardy and a voracious feeder both in laboratory experiments and under the required conditions, but could not be obtained in sufficient quantity. Details are given of two closely observed barrels containing this fish, as the experiment illustrates a common observation both as regards this fish and the hassa, namely, that sometimes mosquito eggs are not devoured, nor yet larvæ, until these grow to a fair size. No pupæ appeared in the presence of the *Congo patwa*.

Barrels No. 4 and 5 *at Quarantine Station.*

January 3, 1925; Larvæ plentiful in both barrels. One polycentris (about 2½ in.) placed in each barrel.

January 10, 1925: Larvæ present in No. 4. None in No. 5. Fish alive in both.

January 17, 1925: No larvæ in either barrel. Eggs seen in both. Both fish alive.

January 24, 1925: Fine larvæ seen in both barrels. Both fish alive.

January 29, 1925: Eggs and fine larvæ seen in both barrels. Fish alive.

The barrels were regularly observed up to February 25, 1925, and on every occasion eggs and fine larvæ were observed, but never were pupæ or fully-developed larvæ seen. The fish thrived throughout. A control barrel alongside without fish bred mosquitoes to maturity as usual.

The hoorie (*Hoplias malabaricus*) was quite effectively larvivorous, but could not easily be obtained in quantity. This is a fish with a reputation for attacking with great courage and ferocity. It is said to bite the web from ducks' feet; and the white cat familiar to members of the Demerara Golf Club is stated to have had its nose bitten by this fish. I can vouch for the severity of the injuries, but not for the mode of infliction.

The sunfish (*Crenicichla saxatilis*) proved neither satisfactory nor readily obtainable.

The patwa (*Cichlasoma bimaculatum*) is a hardy and voracious feeder, very similar in appearance and habits to its near relation *Cichlasoma cetofasciatum*, the "crana" of British Honduras, which has established itself as a means of mosquito control in that colony. The fish is common, but cannot be obtained in quantity with the same certainty as some others, and does not stand such handling well. It is, however, a very satisfactory controller of mosquito breeding in large containers. The patwa grows to a length of about five inches and a breadth of not much less, and is quite highly esteemed for use as food. In laboratory experiments this fish made a record, one specimen having disposed of as many as 400 larvæ in twenty-four hours. Increasing feeds of larvæ were given each day, beginning with small numbers, and the limit of the fish's appetite was not reached until over 400 larvæ and pupæ were supplied. Like other fish reported on, *Cichlasoma bimaculatum* does not appear to eat mosquito eggs or very small larvæ.

The hassa (*Hoplesternum littorale*) is a tough, hardy fish, varying from about 3 in. to 7 in. in length, very plentiful in roadside trenches, inundated pastures and intentionally flooded canefields, but not

easy to obtain until the dry season sets in, when it is captured in nets and baskets. Unfortunately this fish is much sought after as food, a circumstance likely to limit its applicability to small household water-containers. Like the patwa, this fish seems to feed at night and, whether or no it feeds at the bottom, both in laboratory glass vessels and in tanks and barrels the fish are seen to remain almost motionless at the bottom during daylight.

PRELIMINARY OBSERVATIONS IN MANY DISTRICTS AND IN ALL SORTS OF VESSELS TO DETERMINE GENERALLY THE POWER OF HASSAS TO LIVE UNDER THE REQUIRED CONDITIONS AND CONTROL MOSQUITO BREEDING.

Hassa (*Hoplosternum littorale.*)

Serial number	Kind of vessel	Number of fish	Larvæ	Date of starting experiment	Next observation and remarks
1	Barrel (40 gals.)	1	Many culex and stegomyia	10/7/24	17/7/24. No larvæ.
2	Barrel (40 gals.)	1	,, ,,	4/7/24	7/7/24. No larvæ.
3	Barrel (40 gals.)	1	,, ,,	7/7/24	9/7/24. No larvæ.
4	Barrel (40 gals.)	1	,, ,,	12/7/24	19/7/24. No larvæ.
5	Barrel (40 gals.)	1	,, ,,	30/6/24	25/7/24. No larvæ.
6	Iron pan (100 gals.)	2	Many stegomyia	30/6/24	25/7/24. No larvæ.
7	Barrel (40 gals.)	1	,,	18/7/24	31/7/24. No larvæ.
8	Iron bowl (Tache) 150 gals.	3	Moderate number stegomyia	21/7/24	25/7/24. No larvæ.
9	Tub (20 gals.)	1	Many culex and stegomyia	2/7/24	5/7/24. No larvæ.
10	Barrel (40 gals.)	1	Moderate number stegomyia	17/7/24	20/7/24. No larvæ.
11	Barrel (40 gals.)	1	Many culex and stegomyia	8/7/24	11/7/24. Only very small larvæ present. This condition prevailed for a month. No larvæ pupated.
12	Tank (100 gals.)	1	Moderate number stegomyia	8/7/24	Ditto.
13	Barrel (40 gals.)	1	Moderate number culex	8/7/24	11/7/24. Few larvæ; fish dead.
14	Iron tank (300 gals.)	3	Many culex	5/8/24	16/8/24. No larvæ.
15	Tache (120 gals.)	1	Moderate number culex and stegomyia	10/8/24	15/8/24. No larvæ.
16	Vat (1,000 gals.)	2	Moderate number stegomyia	1/8/24	15/8/24. No larvæ.
17	Vat (2,000 gals.)	4	Moderate number culex	7/8/24	15/8/24. Larvæ reduced but present.
18	Barrel (40 gals.)	1	Few culex and stegomyia	7/8/24	13/8/24. No larvæ.
19	Barrel (40 gals.)	1	Many culex and stegomyia	7/8/24	15/8/24. No larvæ.
20	Barrel (40 gals.)	1	,, ,,	1/9/24	15/9/24. No larvæ.
21	Concrete tank (1,500 gals.)	2	Moderate number stegomyia	9/9/24	23/9/24. No larvæ.
22	Vat (1,000 gals.)	1	Few stegomyia	23/9/24	30/9/24. No larvæ.
23	Tank (80 gals.)	2	Many culex and stegomyia	9/10/24	10/10/24. No decrease. Fish dead.
24	Tank (12 gals.)	1	,, ,,	9/10/24	14/10/24. No larvæ.
25	Tank (80 gals.)	2	,, ,,	9/10/24	16/10/24. No larvæ. One fish dead.
26	Jar (5 gals.)	1	Moderate number culex and stegomyia	9/10/24	16/10/24. No larvæ. Fish stolen, 30/10/24, when no larvæ were found.
27	Barrel (40 gals.)	4	,, ,,	6/10/24	11/10/24. No larvæ. One fish dead.
28	Barrel (40 gals.)	2	Many culex and stegomyia	11/10/24	27/10/24. No larvæ.
29	Barrel (40 gals.)	10	Many culex	10/10/24	14/10/24. No larvæ.
30	Barrel (40 gals.)	1	Moderate number culex and stegomyia	13/10/24	30/10/24. No larvæ.

As illustrating the methods employed at this inquiry, a large number of the observations upon the hassa are given *in extenso*.

CLOSELY OBSERVED EXPERIMENTS IN VESSELS SUCH AS ARE IN COMMON USE, AND WHICH ACTUAL VESSELS ARE KNOWN TO BE FAVOURITE BREEDING PLACES AND WITH A CONTROL VESSEL WITHOUT FISH ALONGSIDE.

Iron tank (400 *gals.*) *No.* 1 *at Quarantine Station.*

October 8, 1924: *Culex* larvæ plentiful. Two hassas placed in tank.

October 14, 1924: All larvæ gone. No pupæ cases or other evidence of hatching. Fish alive.

October 21, 1924: All larvæ gone. No pupæ cases or other evidence of hatching. Fish alive.

Observations continued at intervals never greater than a week up to March 25, 1925, but larvæ were never observed.

The control barrel bred freely all the time.

Iron tank (400 *gals.*) *No.* 2

October 8, 1924: *Culex* larvæ plentiful. Three hassas placed in tank.

October 14, 1924: No larvæ. Three fish alive.

October 21, 1924: No larvæ. Three fish alive.

October 27, 1924: No larvæ. One fish dead and floating. Dead fish removed.

November 3, 1924: No larvæ. Two fish alive.

November 10, 1924: No larvæ. Both fish dead and floating. Dead fish removed.

Larvæ had reappeared in quantity by November 30, 1924.

On many occasions there has been reason to think that, as the hassa is of fair size, he starves once the existing larvæ have been eaten, unless very frequent deposits of eggs are made to keep up the food supply, as indicated by the continued presence of newly-hatched larvæ.

Iron Tank (700 *gals.*) *at County Inspector's House.*

February 5, 1924: *Culex* and *Stegomyia* larvæ plentiful Four hassas placed in tank.

There was steady diminution in the number of larvæ, but a few well-grown ones could be found up to April 25, 1924 when only minute larvæ could be found, none of which reached maturity, but young larvæ were observed throughout August. During August, 1924, one fish disappeared and may well have jumped out. The hassa is given to leaping.

September 8, 1924: No larvæ whatever could be found and all remaining fish were alive

Up to October 30, 1924, no larvæ were found, but during October one fish died and was removed.

On November 21, 1924, another fish was found dead, but no larvæ were found.

At present date, April, 1925, the remaining fish is alive and no larvæ can be found. Throughout the observations on this tank no pupæ were observed.

It seems not unreasonable to suggest that in this case the observed facts accord with the view that while three fish got a good living at first, the rate of deposition of mosquito eggs was insufficient to keep up a food supply for all. No fish died so long as tiny larvæ were to be found, but soon after these disappeared first one died, and then a month later another, while the sole remaining fish apparently continues to get enough to live upon.

Silverbait is a term locally applied to a number of small, bright silvery fish which abound in most clean trenches on the coastlands. Five different fish of this sort have been tried and have been provisionally identified as follows :—

Tetragonopterus chalceus, similar in general habits and appearance to its nearest relative.

Tetragonopterus æneus, which has established its usefulness in anti-mosquito measures in British Honduras. About two inches in average length, this is one of the larger members of the silverbait group.

Charax gibbosus, though never previously used to combat mosquitoes, so far as I can ascertain, belongs to the family of Characidæ, as does *Tetragonopterus*. This also is one of the larger members of the silverbait group. The smaller members of the group are *Hemigrammus rodwayi* and *H. unilineatus*, while the fifth silverbait experimented with has not yet been identified. All five fish were found to be actively larvivorus, attacking larvæ on sight. They live well in water-containers provided they are carefully transported and are transferred to vessels by means of a ladle. They must never be actually handled.

One variety or another, or a mixture of these five fishes may be obtained almost throughout the coastlands, and as they are known to the people generically as silverbait the experiments in actual water-containers were made with mixed lots, such as villagers might obtain for themselves.

Experiments in Actual Water-Containers.

On December 18, 1924, Nos. 1, 2 and 3 iron tanks (each 400 gals.) at the quarantine station were all breeding mosquitoes and are well known to be favourite breeding sites. On that date two "silverbaits" were placed in each, and observations were made every few days up to the end of March, 1925. In each case larvæ and pupæ disappeared in two to three days, and neither eggs, larvæ or pupæ were observed up to the end of the experiment, when all the fish were alive and active.

On January 3, 1925, larvæ were plentiful in barrels Nos 6 and 7 (400 gals.) at the quarantine station, and one "silverbait," about 1½ in. in size, was placed in each. Rapid disappearance of all early stages of mosquitoes followed in each case and this condition was maintained, the fish thriving. On January 29, No. 6 barrel was emptied to within three inches of the bottom to test the capacity of these fish to live in small quantities of shallow water. On February 12 both barrels were free of larvæ and the fish were alive in both, though evaporation had reduced the depth of water in No. 6 to considerably less than three inches. Water was added to a depth of three inches. On February 26 the experiment was closed, the fish still thriving and no signs of mosquito breeding being observed.

Laboratory experiments with silverbait enabled some interesting experiments to be made. All varieties attack larvæ instantly, and when larvæ are scarce in a large vessel the fish pursue them in a determined manner. It has occasionally been observed that on a first transference to a storage vessel the fish sulk for a time before beginning to feed.

All varieties have a preference for pupæ, and if eggs, larvæ and pupæ are given together, pupæ are taken first, then larvæ, and finally the eggs, though any stage if given alone is readily devoured.

A medium-sized *H. rodwayi* was used in a glass jar to determine its maximum destructive power.

On the first day 70 larvæ were given. All were devoured.
On the second day 100 larvæ and 11 pupæ were all taken.
On the third day 29 *Culex* egg rafts were taken in 5 hours.
On the fourth day 150 larvæ and 10 pupæ were all taken.
On the fifth day 200 larvæ and 30 pupæ were all taken.
On the sixth day 250 larvæ and 7 pupæ were all taken.
On the seventh day 260 larvæ and 30 pupæ were disposed of.
On the eight day 300 larvæ and 30 pupæ were given. All pupæ were taken and 260 of the larvæ in 24 hours.

In no experiments with these fish, either in the laboratory or elsewhere, were newly-hatched larvæ ever seen. The fish are practically never still during daylight, and take larvæ equally readily at the surface or the bottom and feed both by day and by night.

An important practical point in favour of these silverbait is that if larvæ are withheld altogether for long periods and no other food provided, they find enough to live on even in a glass jar.

In large vessels the continued presence and activity of the fish can be ascertained by throwing a small stick or a leaf into the water, when the fish are attracted to the surface at once.

Of the fish experimented with those which appear to be most serviceable are the silverbait group, the hassa and the patwa.

For the smaller domestic water-containers it would be difficult to find a fish more generally suitable than the silverbait, whose good points may be summarized as follows :—

(*a*) Enormous appetite for all early mosquito forms.

(*b*) Preference for the forms most nearly hatched out.

(*c*) Ease of obtaining these fish in unlimited quantity.

(*d*) Ability of fish to live when only a minimum of water remains in barrels, &c.

(*e*) Ability of fish to find a living after the original supply of larvæ has been devoured.

A little care is required in the capture and transport of these fish, and a net will often damage them enough to cause early death. A can containing flour or bread crumbs should be lowered by a string into a clean trench and be quickly pulled up after a short interval. The captured fish should then be transferred by ladle into a large vessel. Every transference should be made by ladle.

Hassa and patwa are less suited to the small containers, but do well in large vats and tanks. Among advantages may be enumerated: —

Hassa.	*Patwa.*
(*a*) Good appetite for larvæ.	(*a*) Enormous appetite for larvæ.
(*b*) Fairly easily obtained.	(*b*) Fairly easily obtained.
(*c*) Stands rough handling very well.	(*c*) Survives well in large containers.

Disadvantages are as follows:—

Hassa.	*Patwa.*
(*a*) May be stolen for food.	(*a*) May be stolen for food.
(*b*) May jump out of vessel.	(*b*) Does not stand rough handling well.
(*c*) Does not seem to survive well unless large supply of larvæ is continued.	

Hassa and patwa can be used to advantage in such large vats and tanks as those of Government institutions, when the fish can be caught, handled and regularly observed by members of a trained staff.

Throughout the villages, however, silverbait are proving the most satisfactory, for it is simplicity itself for villagers to be instructed to keep always a few silverbait in the barrel or tank. No offence is caused if these small fish die, and there is no difficulty in replacing them, while there is no temptation to take the fish for food and little, if any, tendency for the fish to jump out or be washed through the overflow in heavy weather. Relief from continual re-screening of vessels is greatly appreciated by villagers.

Since many trenches in British Guiana, although containing numerous fish and apparently clean, are contaminated by sewage, it is well to keep for a period in a pailful of clean water any fish intended to be placed in a source of drinking water.

Mr. Rodway, Curator of the Museum of the Royal Agricultural and Commercial Society, was kind enough to identify the various fish for me, and throughout the inquiry invaluable assistance was rendered by Mr. H. A. Moonsawmy, Member of the Royal Sanitary Institute, Sanitary Inspector for the Port of Georgetown.

Cholera Vaccination; its Effectiveness as evidenced by the Presence of Antibodies in the Blood of Vaccinated Persons (Otto Schobl and Jose Andaya, *Philippine Journal of Science*, March, 1925).—The amount of antibodies found in the blood of cholera-vaccinated persons stands in direct proportion to the amount of vaccine injected and to the number of injections given. Both the titre of the serum and the persistence of antibodies depend on the number of injections to a higher degree than on the amount of the vaccine given.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which **is Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers **at the** earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these,** with remittance, **is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

THE JOURNAL OF

Tropical Medicine and Hygiene

AUGUST 1, 1925.

Editorial Notes.

BACILLUS ABORTUS INFECTIONS IN MAN.

IN 1911 Schroeder and Cotton found that Bang's bacillus of infectious abortion was present in the milk of infected cows, and suggested that human beings might become infected.

In 1918 Evans made a thorough investigation of the organism and came to the conclusion that it was very closely related to *Micrococcus melitensis*, the cause of Malta fever in men and goats. He proved that, by inoculating pregnant guinea-pigs with *Bacillus abortus* from bovine sources and with *M. melitensis* from human sources, abortion took place within a few days.

These observations were confirmed by several investigators, and the general opinion, at the present time, is that *B. abortus* and *M. melitensis* are so closely related as to be practically identical. They are identical as regards morphology, appearance of cultures and biochemical characteristics. They cannot be completely separated by agglutination tests. Their effect on animals, except monkeys, is the same. In monkeys *B. abortus* seems to be less virulent than *M. melitensis*. According to most authorities the only means to distinguish the two organisms is Castellani's absorption test. By means of this test not only may *B. abortus* be distinguished from *M. melitensis* but several varieties of each can be separated.

The first authentic case of human infection with the *B. abortus* was reported in January, 1924, by Keefer from Baltimore. The source of infection could not be determined. The fact that the strain was of the abortus type was ascertained by serologic tests. A little later Orpen made known his serologic results with four strains from human cases of Malta fever in South Africa. These agreed with strains of abortus isolated in South Africa, as well as with a strain of abortus from Europe, but not with true melitensis strains from Europe. It was stated by Keefer and Orpen that their cases were clinically typical Malta fever. Later, a case of human infection with the abortus variety of the organism was reported by Evans. The patient, who lived in Virginia, was in the habit of drinking raw cow's milk. Several cases have been reported during the last few years in America, and the Hygienic Laboratory at Washington have been asked to identify three strains of abortus isolated from human cases of Malta fever in South Dakota, Connecticut and New York. In these cases it was impossible for the infection to have come from goats.

It has never been possible to establish definitely the source of abortus infection in man. Suspicion naturally rests on infected cow's milk, but De Korte rightly calls attention to the fact that *B. abortus* is widely distributed in countries where Malta fever-like fevers are absent, and therefore probably is not pathogenic to man through milk.

A cause for abortus infections in man is perhaps the handling of infected animals or carcasses. Cesari points out that in France the majority of cases of so-called Malta fever which cannot be traced to goats have occurred in men employed in slaughterhouses. It is interesting to note that of the few cases of abortus infection recognized in America two of them were in men who handled hog carcasses in slaughterhouses. In a very interesting case reported from South Africa by W. E. De Korte, the patient, a farmer, became infected after handling the placenta of a cow which had aborted the previous day. The observations of Hadley and Beach indicate that infected hog carcasses may be of special danger, and that porcine strains of infectious abortion are more virulent than bovine strains.

VETERINARY EDUCATION IN INDIA.

Fairly up-to-date colleges for the training of students in veterinary science exist at Bombay, Madras, Calcutta and Lahore, and there are also schools at Insein and Taunggyi in Burma. The colleges at Bombay, Madras and Calcutta give a three-year diploma course in English, while that at Lahore gives a four-year course. The number of students passing the final examinations at Lahore dropped from 112 in 1922-23 to 82 in 1923-24. Some of the reasons for this decrease are the inadequacy of the pay of veterinary assistants, the reduction in the number of appointments and the fact that the Military Department no longer sends students to Lahore College.

Instruction in the vernacular is given in the veterinary schools at Insein and Taunggyi in Burma, in a three-year and a one-and-a-half-year course respectively. The final examination at Insein in 1924 was passed by fourteen students as against ten in the preceding year. The Government has partly adopted a scheme for the better equipment of this school.

The first six officers of the Provincial Service selected for a post-graduate course of two years qualifying for appointment to the imperial cadre completed their training at the Muktesar Laboratory during 1923-24. Systematic courses of training in laboratory methods, extending over four or five months, have also been instituted at this laboratory for members of the Indian Veterinary Service and the Royal Army Veterinary Corps, and five officers availed themselves of the facilities afforded during that year.

Seven students passed out during the year from the veterinary compounders' class attached to the Nagpur Hospital.

Good work is done by the United Provinces Veterinary Medical Society, which was founded in 1912. The Society is publishing a veterinary journal in Urdu.

Annotations.

The Sugar Content of the Cerebrospinal Fluid and its Relation to the Blood-sugar (G. M. Goodwin and H. J. Shelley, *Arch. of Internal Medicine*, February 15, 1925).—To be of value in determining whether or not a spinal fluid sugar is high or low, the fluid must be taken after a night's fasting and the sugar content compared to that of the blood taken at the same time. From this paper the following conclusions might be drawn: The sugar content of the cerebrospinal fluid is not constant in the same individual. There is no level, within reasonable limits, which might be considered normal for different individuals. There is a

definite relationship between the sugar content of the cerebrospinal fluid and of the blood, which may be expressed as the percental relation of the sugar content of the cerebrospinal fluid to the sugar content of the blood. This figure lies with fair constancy within the limits of 45 and 65 per cent. The ingestion of carbohydrate in sufficient quantities causes a definite and constant rise in the sugar content of the cerebrospinal fluid and disturbs the usual relationship between the sugar-content of the cerebrospinal fluid and that of the blood. Meningitis, whether tuberculous, staphylococcus or meningococcus, frequently gives a lower sugar content of the cerebrospinal fluid, both as to the actual milligrammes per hundred cubic centimetres and in relation to that of the blood. The literature shows a high sugar content of the cerebrospinal fluid in relation to the sugar content of the blood in cases of encephalitis. Untreated cases of early cerebrospinal syphilis give a low actual and relative sugar content of the cerebrospinal fluid. Under treatment, this figure returns to normal. When considering the fact that the sugar content of the spinal fluid is lowered with a fair degree of constancy in cases of tuberculous, meningococcus and staphylococcus meningitis, one must remember that a low figure after intraspinal administration of antimeningococcus serum is of no diagnostic value.

Notes on the Therapeutic Value of Pneumococcus Antibody Solution Subcutaneously Administered in Lobar Pneumonia (W. W. Oliver and E. A. Stoller, *Arch. of Internal Medicine*, February 15, 1925).—The subcutaneous administration of pneumococcus antibody solution is attended by a very low incidence of thermal reactions as compared with its intravenous use, as reported by Cecil and Larsen, and Conner. The subcutaneous injection of pneumococcus antibody solution invariably produces a painful tissue reaction, and this may persist for days. The subpectoral region seems to be the most favourable site for injection. In this series of twenty-three cases treated by antibody solution only four cases gave evidence of subjective and objective improvement, while the remaining nineteen cases did not appear to be benefited by it. Pneumococcus antibody solution administered subcutaneously did not, in the authors' limited experience, tend to sterilize the blood-stream. Subcutaneous antibody treatment does not appear to prevent extension of the pneumonic process from one lobe to another. The best results were obtained in Type IV pneumococcus, in which the subcutaneous antibody treatment registered a mortality of 21·42 per cent. in the control Type IV cases. If these results were due to antibody solution, it would seem probable that they were attributable to a nonspecific action of the solution.

Action of Acriflavine on the Blood and certain Tissues of Rabbits (F. L. Meleney and Zung-Dau Zau, *Journ. of the Amer. Med. Assoc.*, January 31, 1925).—The bacterial inhibition action of neutral acriflavine within the body is so slight against the hæmolytic streptococcus, even in lethal doses of the dye, that it is not a legitimate intravenous medicament in hæmolytic streptococcus infections. Acriflavine has a selective action on certain body tissues in the rabbit which causes it to be taken up by some of those tissues in such concentration as to injure or destroy them. The kidney and the liver are particularly affected. Chemical substances that are intended for intravenous use in the treatment of disease should be subjected to the most rigid tests on animals to determine their safety as well as their efficiency. The outlines of certain experiments presented by the writers may be used for other chemical substances in connection with hæmolytic streptococci or other organisms.

Latent Syphilis (G. C. Willcocks, *The Medical Journal of Australia*, January 24, 1925).—Routine examination of the blood by the Wassermann test was carried out on 325 consecutive patients. A positive result for syphilis was reported in thirty-one patients. Twenty-six of these gave no history and showed no signs of syphilis. They were suffering from latent syphilis. The symptons and signs observed were not those usually attributed to syphilis. Except in the definitely syphilitic (clinically) patients, no obvious improvement followed antisyphilitic treatment. The cerebrospinal fluid gave a positive result in two out of ten persons. In view of the apparent frequency of latent syphilis it may be that the beneficial effect of potassium iodide in some obscure cases in the past finds here its explanation.

The Possibility of Immunization of the Tissues of the Nose, Throat and Ear by the Use of Vaccines Applied Locally (H. Hays, *Medical Journal and Record*, February 18, 1925).—Reports of the local administration of vaccines for other conditions, such as typhoid fever, have conclusively proved that they will render an immunity. The preparation of the vaccine is extremely simple. The vaccine can be administered without any difficulty directly on the part of the nose, throat or ear which is infected. The broth in which the vaccine grows possibly develops a bacteriophage which augments the effects of the vaccine. Certain definite results have been seen in those infections which do not respond to ordinary antiseptics. The local vaccine can be used on many patients who will not submit to hypodermic injections of vaccines as usually given.

The Question of the Existence of Amyloid Casts (E. R. R. Saleby, *Journal of the American Medical Association*, January 31, 1925).—Histologic sections of amyloid kidneys were stained with methyl violet, and the relative distribution of the amyloid degeneration studied. Casts of various forms were found in forty-five cases; and only one of these, though doubtful whether it was a cast, gave a definite microchemical reaction for amyloid. This would throw doubt on the occurrence of amyloid casts in the urine of patients suffering with amyloid kidney and may show that the specifically staining amyloid plays no part in forming any of the casts.

The Utilization of Solar Light and Heat in the Treatment of Night Soil (M. E. Barnes, *The American Journal of Hygiene*, March, 1925).—Insulated boxes provided with tight-fitting, double layered glass covers, as described by de Saussure, are an effective means of concentrating heat derived from the sun, under conditions prevailing in Siam. The temperatures attained within the de Saussure boxes, under favourable conditions, greatly exceed the thermal death points of the ova and larvæ of hookworms, and the maximum temperatures which have been attained, exceed the thermal death points of all vegetative forms of ordinary bacteria. The utilization of solar light and heat, by means of an adaptation of the de Saussure boxes, in the treatment of night soil in selected regions is suggested (see Abstracts).

Multiple Hæmorrhagic Sarcoma of Kaposi (G. J. Dillard and F. D. Weidman, *Archives of Dermatology and Syphilology*, February, 1925).—This paper is a histological study of two cases, one disclosing intestinal lesions at necropsy. Case 1 was an advanced elephantiasic one with bullæ, which did not come to necropsy. Case 2, in addition to the usual cutaneous lesions, hundreds of small, blood-red tumours were found in the intestines, and a few in the stomach, urinary bladder and mesenteric lymph nodes. Fungous granulomas were found in the sections of the mesenteric and omental nodes within which mycelia and chlamydospores were demonstrable. Histologic studies led to these conclusions: The lesion had its beginnings in the uppermost levels of the corium. The primary change was an irregular hyperplasia of capillaries, speedily accompanied by lymphangiectasia, hæmorrhage and hæmosiderin pigmentation. Secondary changes consisted in an exaggeration of all the processes mentioned above (the angiectases becoming cavernous), to which were added large nodular accumulations of lymphocytes around capillaries, together with nests of embryonal endothelial cells. There was little fibrosis, but much œdema. Kaposi's sarcoma is primarily chronic inflammatory, but secondarily may become sarcomatous. While the sarcomatous changes are not of a highly malignant order, they are definitely within the sarcoma category as viewed in the gastro-intestinal lesions. Authors whose experience has been limited to cutaneous studies are excusable for holding to the chronic inflammatory theory; but this does not constitute the whole disease, and the sarcomatous phase must not be denied. It is an open question whether the fungus invasion by way of the intestines is one of the causes of Kaposi's sarcoma.

It is suggested that in future this disease be regarded in the broadest possible internal medical sense. Patients should be studied from the standpoint of hæmachromatosis of Opie, the question of diabetes mellitus in connection with a pigmentary cirrhosis of the liver should be covered, and in this same connection the newer liver functional tests may prove of value. Examination of the urine for urobilin and hæmatoporphyrin might also give results that fitted into the complex blood destructive processes. In respect to the development of visceral lesions, examination of the fæces and gastric contents for occult blood might give information. The state of the lymph nodes (biopsy), not forgetting the supraclavicular node, should be determined—the presence of the latter may mean the same that Troisier's ganglion does, namely, visceral malignancy. Search for fungus in the fæces and gastric contents is justified, even though the result should be negative in repeated cases, until it is demonstrated that the disease is an ætiological entity, and that fungus causation can be excluded.

Rat-bite Fever with special reference to its Ætiological Agent (M. J. Parmanand, M.B., B.S., *Indian Journal of Medical Research*, April, 1925).—The spirochætes found in the author's Bombay cases of rat-bite fever are morphologically identical with those of the Japanese. Unlike other spirochætes, they are difficult to detect by the dark-ground illumination method. It is more easy to demonstrate them by the staining methods than by the dark-ground illumination. The lesser bandicoot (*N. bengalensis*) is the chief reservoir of infection in Bombay. Spirochætes isolated from naturally infected rats were morphologically indistinguishable from those isolated from human cases of rat-bite fever.

Abstract.

THE UTILIZATION OF SOLAR LIGHT AND HEAT IN THE TREATMENT OF NIGHT SOIL.[1]

By M. E. Barnes, M.D.

THE disposal of the waste products of the human body in such a way as to avoid nuisance and prevent the spread of disease is a problem which confronts every individual in the world, no matter how savage or how refined he may be. It is a problem, moreover, the acuteness of which is increased in direct proportion to the development of man's gregarious tendencies. Isolated individuals may and often do deal with the problem by a process of mental negation, but with communities this is impossible and some positive method of disposal must be adopted. The methods most widely employed throughout the world have been either the removal of such material by water, where this has been possible, or the adoption of some form of disposal upon or beneath the surface of the ground.

The removal of this offensive matter by naturally flowing waters is the easiest method, and consequently, from time immemorial communities have polluted streams. Modern cities have adopted what is simply a more refined method of water pollution in that they pour their wastes into a closed controlled water

[1] Abstracted from the *American Journal of Hygiene*, vol. v, No. 2, March, 1925.

system, and then release such waters into natural channels of flow with or without previous attempts to remedy the pollution. Such refined methods, valuable as they have been demonstrated to be as public health measures, are too complicated and expensive to be universally practicable. For example, only in the larger cities of the Orient could they be installed and successfully operated. For the hundreds of millions of people living in the villages and small cities of the Orient, and, in fact, throughout the greater part of the tropical world, some other system must be found which will be at once efficient, inexpensive, and simple in operation.

The purpose of this paper is to call attention to the possibility of utilizing solar light and heat in the solution of one of the most fundamental problems in sanitation. Whether or not it can be depended upon to accomplish the certain destruction of pathogenic bacteria, this natural force undoubtedly deserves careful consideration as a possible means of freeing night soil of its protozoal and parasitic menace. The possibilities along this line may be better realized when it is pointed out that by the use of an exceedingly simple apparatus, air temperatures of 250° F. have been attained, and large volumes of water have been heated to temperatures of 150° F. (65·6° C.). In one of the writer's experiments the temperature of two litres of water was raised to 160° F. (71·1° C.) and was maintained at a temperature exceeding 140° F. (65·6° C.) for a period of more than four hours. Moreover, the attainment of such temperatures is not limited to days of clear sunlight, the experiments showing the raising of one litre of water to a temperature of 140° F. (60·0° C.) on a day when the sun shone only through a haze, and when heavy clouds passed across the sky.

The possible influence of solar light and heat upon the ova and larvæ of intestinal parasites was first brought to the writer's notice during an anti-hookworm campaign in northern Siam in 1917. The microscope was being used to demonstrate to the villagers the living larvæ of hookworms in the infected soil of their own villages. The material for such demonstrations was secured from scrapings of soil which had recently been polluted with human fæcal matter. It was soon observed, however, that if such fæcal deposits had been exposed to the unobstructed rays of the sun for any length of time, living larvæ were not to be found in such material, or were present in very small numbers. Dead larvæ could be found, evidently having been killed by the sun's light or heat. Occasional references to similar observations may be found in the writings of those engaged in the study of these parasites. Thus, Augustine (1923) states that "a rapid dying out of the larvæ occurred under direct sunlight; out of an original number of 645 larvæ only one survived a week."

Heat is generated from the sun's rays when interference is offered to their passage. Certain substances, such as air, glass, &c., are largely diathermous and offer little resistance to the passage of solar rays. Hence comparatively little heat is generated in such substances. Opaque objects, on the contrary, and especially black objects offer the maximum resistance to their passage, and the greatest amount of heat is generated on the surface of such substances. The heat thus generated is rapidly dissipated by conduction and convection, though substances differ very greatly in their ability to conduct heat. One of the first problems in utilizing the heat generated by the sun's rays is the devising of some means of confining it within certain limits by preventing its rapid dissipation. This can be done by constructing a chamber of the desired size and insulating it by surrounding it with substances of poor conductivity for heat. For experimental purposes sawdust can be used. Glass has the property of offering slight resistance to the passage of solar rays, but of offering relatively great resistance to the passage of heat. Therefore, by using a tight-fitting glass cover upon an insulated chamber, the sun's rays can be admitted to the chamber, there transformed into heat, and the dissipation of the heat delayed to a certain extent. The dissipation of heat from such a chamber can only be delayed, because even though the walls may be well insulated, there is a constant loss occurring by conduction of heat through the glass cover.

According to Ackermann (1915) the principle of using a tight-fitting diathermous cover upon an insulated chamber appears to have been first employed by H. B. de Saussure, who in 1766 invented a "hot box," which consisted of an insulated air-tight wooden box, black inside, and covered with two layers of plain glass with an air space between them. Sir John Herschel in 1837 experimented with a similar apparatus which is described as "a small mahogany box, blackened inside, covered with window glass fitted to size, but without putty, and simply exposed to the sun's rays."

The experiments recorded below were performed by the writer, partly in Chiengmai, Siam (1920) and partly in Bangkok (1922) to determine the temperatures registered by such an apparatus under conditions prevalent in Siam. The de Saussure box, used in the Chiengmai experiments, consisted of a pine wooden box 20 × 14 × 6 inches in length, width and depth respectively, the boards being approximately 1 inch in thickness. A shallow tin vessel, made by splitting a 5-gallon oil tin longitudinally, was placed in this box and a tight-fitting cover of window glass was provided. In the first experiment a control was run, using an identical apparatus except that no glass cover was provided. The tin vessels in both instances were blackened to increase the absorption of solar rays. A cooking thermometer was placed in the covered box, and an ordinary thermometer was used in the open box, both instruments being graduated in the Fahrenheit scale.

(1) The Difference in Temperature Produced in an Enclosed Area by the Interposition of a Tight-Fitting Glass Cover.

The two boxes described above were placed flat upon the ground in such a position as to receive the direct rays of the sun throughout the day, but without any change being made in their position to correspond with changes in the elevation of the sun. The maximum temperature observed within the covered

box was 200° F. (93·3° C.), and for a period of more than six hours the temperature exceeded 126° F. (52·2° C.). The maximum temperature observed in the control box was 124° F. (51·1° C.) which was maintained for only about fifteen minutes.

(2) Temperature with Water within a de Saussure Box, with a Single Glass Cover.

As a means of approximating the actual amount of heat produced in the box, 1 litre of water was introduced into the tin vessel in the de Saussure box, and the temperature of this amount of water observed from time to time. The maximum temperatures to which this amount of water was raised on the four days recorded below were 158°, 150°, 146° and 154° F. respectively (the calculated Centigrade equivalents being 70°, 65·6°, 63·3° and 67·8°). It will be observed also that the litre of water was held at a temperature above 122° F. (50° C.) for periods of from four to five hours on each of these days. These sustained temperatures are quite as important as the maximum temperatures in a consideration of the possible practical applications of the de Saussure principle.

(3) Temperature of Water within a de Saussure Box Provided with a Double Glass Cover.

At this time the sky began to be cloudy and rains threatened. It seemed desirable to attempt to further insulate the apparatus, as the amount of heat absorbed during such weather would be expected to be less than in clear weather. Accordingly, a second layer of glass was fitted to the cover, with an air space between the glass sheets of 1 inch. In spite of the fact that on only one of the days recorded below there was clear sunshine, the temperature of the water reached 140° F. (60° C.) or more on five out of the seven days. Two litres of water were used on the last day, when the highest temperature was recorded.

(4) Effect of Increasing the Depth of the de Saussure Box.

Since only a definite proportion of the solar energy falls on each square foot of the earth's surface, the deepening of the de Saussure box would tend to increase the loss of heat by conduction through its walls. It was of interest to determine, therefore, whether the box could be sufficiently deepened to admit vessels of a large size (e.g., the size of night-soil buckets), without too greatly decreasing its heating capacity. For this purpose a packing box (of 30 × 30 × 36 inches dimensions) was lined with asbestos, and provided with a tight fitting cover with two layers of glass separated by an air space of 1 inch. A small door was made at one side through which the thermometer could be reached. In making the readings there was a small loss of heat involved in the opening and closing of this door. A 5-gallon tin of crude oil was placed in the box, a Fahrenheit thermometer suspended in the oil, and readings were taken from time to time. The maximum temperature to which the 5 gallons of crude oil were raised in the two experiments recorded was 142° F. (61·1° C.). It will be noted that in the second experiment, which ran through the entire day, the oil was maintained at a temperature exceeding 122° F. (50° C.) for a period of over five hours. These experiments were performed in Bangkok, Siam, in 1922.

(5) Effect upon Hookworm Ova and Larvæ of Exposure in a de Saussure Box.

In the apparatus used on August 25, 1920 there were placed ten specimen tins (of ¼-oz. capacity), each containing fæcal matter known to contain hookworm ova and newly-hatched and active larvæ. The covers of the specimen tins were removed, thus bringing the contents into direct sunlight. They were exposed in the de Saussure box from 12 noon to 1 p.m., during which time the thermometer in the box registered 220° F. At 1 o'clock the tins were removed, smears were made and examined, and the contents of each specimen tin placed upon moist soil in small dishes, the soil having been previously heated upon a stove to destroy any larvæ which it might have contained. The larvæ found in the smears made after the exposure were apparently dead. The soil in the dishes was examined daily for a week, but no larvæ were found at any time. Opportunity to continue this line of investigation was lacking.

Discussion.

These experiments have been given in some detail in order to place on record the data they contain concerning the de Saussure box operating under conditions prevailing in Siam. At the same time, they may serve to interest those who may be unfamiliar with the apparatus. Their possible bearing upon the problem of the disposal of night soil is at once obvious when consideration is given to the effects of light and heat upon the various pathogenic organisms found in fæcal matter.

Light has been shown to be injurious to various bacteria. Thus, Buchner found that after exposure to sunlight for one hour, no growth took place in broth cultures of typhoid or colon bacilli or of the spirillum of Asiatic cholera. The effect of light upon protozoan or animal parasites has not been so fully studied.

Jordan (1921) states that "the vegetative forms of most bacteria are killed at 55° to 58° C. by ten minutes' exposure to moist heat." He places the thermal death-point of the typhoid bacillus and of the spirillum of Asiatic cholera at 58° to 60° C., and points out that "the thermal death-point of those bacteria that are at all likely to be present in polluted water is low (57° to 60° C.)." The usefulness of the method of fractional sterilization is dependent upon this vulnerability of vegetative forms of bacteria to temperatures of from 60° to 70° C. (140° to 158° F.).

Boeck (1921) gives the thermal death-points of protozoan cysts as follows, heavy mortality in all cases beginning at temperatures approximately 10 degrees below the maximum:—

E. histolytica	68° C.
E. coli	76° C.
E. nana	64° C.
Iodamœba butschlii	64° C.
Giardia intestinalis	64° C.
Chilomastix mesnili	72° C.

Intestinal helminths are even more vulnerable to heat. Asada (1923) states that *Ascaris* larvæ in the egg-shell are killed if heated for ten minutes at 50° C. Stiles (1921) has indicated the effects of various temperatures upon hookworm ova and larvæ as follows :—

"40° to 50° C. Eggs have been observed to hatch at 40° C., but, in general, constant temperatures above 37° C. are reported as unfavourable to fatal for eggs and larvæ. However, both eggs and larvæ can stand 40° to 50° C. for a few minutes and live.

"50° to 60° C. Fatal to eggs and larvæ in one to five minutes.

"Above 60° C. Fatal to eggs and larvæ almost instantly."

Tsutsui (1924) has shown that 55° C. is the highest temperature to which hookworm ova and larvæ can be exposed and live, and concludes that if fæcal matter could in some way be raised to a temperature of 57° C., all infectivity for hookworm would thereby be destroyed. On account of the coagulation of tissue fluids, which takes place at temperatures around 60° C., it is highly improbable that any of the animal parasites could survive more than momentary exposure to such temperatures.

There appears to be little doubt that, under laboratory conditions, if these various organisms are brought to the actual temperatures indicated, they are killed. The question is whether the constituents of night soil are such as to protect the organisms from actually reaching the fatal temperatures. The only experiment reported in this paper which bears directly upon this point indicates that in small quantities fæcal matter did not protect hookworm ova and larvæ from the fatal effects of heat. The depth of penetration of such heat into fæcal masses exposed in the boxes has not yet been determined. However, as collected in buckets, night soil usually contains a considerable proportion of fluids, and the experiments with the heating of water in the de Saussure boxes give some indication as to what might be expected. If sufficient water were added to permit the circulation of convection currents, fæcal matter exposed in shallow de Saussure boxes could be made to stew for hours on each day of clear sunshine, in tropical countries, in water exceeding 50° C., with maximum temperatures considerably exceeding 60° C. Moreover, this process could be repeated daily for any desired period. The parasitic ova and larvæ or the protozoan cysts which could survive such stewing for even one day would be relatively few, except, perhaps, in the centre of fæcal masses which failed to disintegrate during that time. Such temperatures, together with the sunlight, should make anything but a favourable medium for the vegetative bacteria which were present. The thermophilic reactions of hookworm larvæ should cause any larvæ which might have hatched out to move into the water, as it gradually heated, just as is the case in the Baermann apparatus for the removal of such larvæ from samples of soil. With a properly constructed apparatus, exposure for one day to tropical sunshine should be effective, but a margin of safety might require several days' exposure. Yet even a week's exposure in such an apparatus, if it ensured a night soil that would be immediately and safely available for fertilizing purposes, would offer distinct advantages over the six months' storage which is now estimated as the requisite time to ensure the destruction of the more dangerous elements in such matter.

The practicability of this method of treating night soil is dependent upon its efficiency in destroying the dangerous elements in such material, upon the regularity and intensity of sunshine in the region where its use is desired, and upon the devising of suitable means of exposing the night soil with a minimum amount of handling. These are all matters which can be determined only by extended experiment and observation on the part of those, especially in tropical regions, who have the facilities for making such studies. The method deserves careful investigation in spite of its obvious limitations. Although the interruption in days of sunshine would make it impracticable as the *sole* method of treatment, it may well prove to be a very valuable supplementary method of treatment in communities where the bucket system of collection is in operation. If, instead of burying or of storing such matter for prolonged periods the fæcal matter could be exposed, during favourable weather, in these heated chambers for a time experimentally determined to be adequate to make it innocuous, this would permit its early return to the soil at a time when, presumably, its manurial value would be at the minimum. All night soil thus treated could be made a source of revenue in most tropical countries. During prolonged periods of unfavourable weather the communities could do just what they now do, or they might use fuel for heating on such occasions.

It is hoped that investigators in widely separated regions will undertake experiments with this apparatus to determine the depth of penetration of the heat into night soil, the maximum depth at which the de Saussure boxes will develop effective temperatures (e.g., whether night soil buckets can be treated without emptying), and the length of time of exposure required to ensure the desired result. Even though the destruction of bacteria may not be possible, the rapid destruction of the ova and larvæ or corresponding stages of hookworms and similar parasites, tæniæ, schistosoma, &c., would be of inestimable value in Egypt, India, South China, and throughout the entire tropical and subtropical world.

The apparatus required for such experiments is very simple, consisting, as it does, of an insulated box, lined with sheet iron or other metal, and provided with a tight-fitting double glass cover. For practical use the enlargement of the boxes to a suitable size would be required, thus forming a series of shallow, metal-lined, insulated vats, provided with tight-fitting windows, much like the well-known hot beds so commonly used by gardeners in northern climates during late winter.

If it should prove feasible to utilize heat generated in this way to free night soil of its present dangerous elements, sanitarians would have an additional means of attacking the problem of its disposal in small

communities, especially in tropical countries where sunlight is abundant, intense, and inexpensive.

CONCLUSIONS.

(1) Insulated boxes provided with tight-fitting, double-layered glass covers, as described by de Saussure, are an effective means of concentrating heat derived from the sun under conditions prevailing in Siam.

(2) The temperatures attained within the de Saussure boxes, under favourable conditions, greatly exceed the thermal death-points of the ova and larvæ of hookworms, and the maximum temperatures which have been attained exceed the thermal death-points of all vegetative forms of ordinary bacteria.

(3) The utilization of solar light and heat, by means of an adaptation of the de Saussure boxes, in the treatment of night soil in selected regions is suggested.

Current Literature.

BULLETIN DE LA SOCIÉTÉ DE PATHOLOGIE EXOTIQUE, April 8, 1925.

Bacillus flagellatus and Spirochæta omeliansky n.sp. (W. L. Yakimoff).—In 1914 Professor W. L. Omeliansky found a new organism in a receptacle containing river water. Numerous colonies were isolated on petri dishes, some not stained, others stained in different shades of red. On stained smears a bacillus was seen, with a long flagella at one end, well stained, which was six times as long as the body of the bacillus. This organism was named *B. flagellatus*. The same bacillus has been isolated from water at Chicago by Mabel Jones. During researches on water protozoa at Petrograd this microbe has also been isolated by the author in association with spirochætes; it has also been isolated from the intestine of the frog *Rana temporaria* at Petrograd. The spirochætes which are found with the bacillus have not hitherto been found in water; they are more numerous than *B. flagellatus* and have been named *Spirochæta omeliansky* n.sp.

On the Subject of Vincent's Angina (W. L. Yakimoff, A. Ioukowsky and S. L. Schirwind).—Of the 55 cases of Vincent's angina observed in 1922-23 at the dispensary of the Nicolas Railway, Petrograd, there were 38 cases of the ulcerous type and 14 diphtheroid; and there was one case in which the examination of the suppurations of the ear revealed the presence of fusiform bacilli and Vincent's spirochætes. Thirty-three of the patients were men and 22 women (4 children). The cases occurred in every month of the year, the highest numbers being during July, August, September. All cases were completely cured by treatment with chloride of potassium and perhydrol.

The Protozoa of the Human Intestine. The Examination of the Intestine of Frogs of Petrograd (W. L. Yakimoff and G. A. Miller).—These investigations have been carried out for the purpose of studying the source of human infection by *Chilomastix mesnili*. This organism is frequently found at Petrograd, and ranks as third on the list of the intestinal protozoa of man. The examination of the intestines of thirty frogs (*Rana temporaria*) revealed several species of protozoa, but no *Chilomastix*. A description is given of three spirochætes isolated: *S. ranarum*, n.sp., *S. amphibæ*, n.sp. *S. temporariæ*, n.sp. Species of spirilla were also found. It has not yet been determined whether the spirilla and spirochætes of the frog are in any way connected with the intestinal organisms of man.

Noguchi's Fixator for Spirochætes used for Flagella. (R. Patay.) — Noguchi has described a method of staining by which *Spirochæta cuniculi* and *S. pallida* can be distinctly stained, not only by Giemsa solution but also with basic stainings such as gentian violet and fuchsin. The author having verified the value of this process for the two spirochætes mentioned, tried it on various flagella with very good results. The fixation can be effected on wet or dry smears (the latter is preferred); minimum duration five minutes. This fixative, besides being simple, quickly destroys the red blood-cells and is therefore of great value in the diagnosis of spirochætosis and trypanosomiasis. It clearly shows the parasite in thick blood-smears.

Oicomonas Granulata in the Intestine of White Mice (W. L. Yakimoff and Mlle. J. Wassilewsky).—This organism was first isolated from human stools in 1906. It was found in three cases of intestinal infection, and in 1919 and 1920, during the epidemics of dysentery and cholera in Petrograd, it was observed four times in association with *Entamœba coli*. The organism found in the intestine of white mice is believed to be the same as that found in man; the only difference being a number of granules less elevated. The parasite is easily cultivated on Frosch-Schardinger gelose.

Treatment of Sleeping Sickness (P. Walraven).—The action of 205 Bayer on human trypanosomiasis has varied greatly according to different experimenters. The author has tried it with atoxyl, emetic and neosalvarsan; the results have been more or less favourable. Antimony with Bayer, with or without arsenic, has the best action on the nervous symptoms in human trypanosomiasis.

Epidemiologic and Prophylactic Study of Malaria in Albania (R. Daudy).—The examination of 385 children of Tirana, capital of Albania, showed a splenic index of 28 per cent. and a plasmodic index of 8 per cent. *Plasmodium præcox* is the parasite most frequently found. *P. vivax* is very rare and *P. malariæ* is almost entirely absent. The sites where anopheles are to be found are numerous and cover nearly the whole territory. Preventive quininization does not exist in Tirana. Quinine is used as a curative, but the supplies of quinine to the hospitals and dispensaries are not sufficient. The mosquito net for beds is used in the well-to-do families and in hotels, but there is great need for general preventive quininization and other prophylactic measures in these parts.

The Parasitology and Epidemiology of Malaria in Abkhasie (N. Roukhadze).—Cases of malaria are observed all the year round at Abkhasie. There are three periods, viz., the epidemic period, the winter relapse period, and the spring relapse period. Each of these periods is characterized by the presence in the blood of determined species of parasites; during the winter relapse period *P. malariæ* is found; during the spring relapse period *P. vivax;* and during the epidemic period *P. vivax* and *præcox.*

THE INDIAN MEDICAL GAZETTE.

May, 1925.

Giant Urticaria (Hugh W. Acton).—Giant urticaria or Quincke's œdema is defined by the author as an urticaria produced under the deep fascia by certain bases derived from the food, which only show their effects in those individuals in whom the defence mechanism is low. This defect in the defence mechanism may be inherited or acquired. The disease in India is more common amongst Europeans than natives, but whether this is due to the fact that the cases amongst Indians are misdiagnosed as filarial lymphangitis remains to be further investigated. The disease is probably more common in Europeans owing to the depression of the endocrine functions by long residence in a climate like Calcutta. Both sexes are equally affected; the disease appears in very young children from 15 months to 2½ years and in adults between the ages of 30 to 45 years.

Observations on the Anti-Diabetic Properties of Cephalandra Indica (Telakucha) (R. N. Chopra).—The fresh juice extracted from *Cephalandra indica (telakucha)*, a perennial creeping herb belonging to the natural order Cucurbitacæ, has no sugar-reducing effects when administered to patients suffering from diabetes. The active principles of the plant, an amylolytic enzyme, a hormone, and a body of alkaloidal nature do not produce any reduction of blood-sugar when administered subcutaneously to rabbits.

Observations on the Treatment of Kala-Azar with Urea Stibamine in the Medical Out-Patient Department of the Medical College Hospital, Calcutta (N. C. Kapur).—The results of treatment of fifty cases are given in tabular form. The course of treatment with urea stibamine for bringing about cure in kala-azar is remarkably short. In some of the cases cure took place in only seven days. In cases of antimonyl tartrates the course of treatment frequently extends to more than three months. The average number of injections required for a course of treatment with urea stibamine is about seven to ten, whereas in the case of antimonyl tartrates it frequently amounts to thirty or more. The beneficial effects obtained with urea stibamine in cases resistant to the antimonyl tartrates are strikingly shown in the tables. Jaundice and albuminuria were no contra-indications to the treatment of kala-azar with urea stibamine. Such cases are best treated with small doses, slowly increased. No signs of intolerance were observed in any of the cases. Sometimes a reactionary fever took place after injection which subsided after a few hours. Cases in which signs of intolerance showed themselves after injection of sodium antimonyl tartrate bore urea stibamine very well. The most striking results with urea stibamine are: (*a*) rapid disappearance of the splenic enlargement; (*b*) rapid subsidence of the fever; (*c*) early disappearance of the leukopenia; and (*d*) the short treatment required for a complete cure.

Quinine plus alkalies in the Treatment of Malaria (K. V. Raju).—These observations were made on the in- and out-patients of the M. and S.M. Railway Hospital, Hubli. The conclusions are as follows: As the doses of the two mixtures have to be given according to a strict time-table, the method is more suitable for in-patients than for out-patients. In seventeen cases of proved malaria in the first series treated with the quinine and alkaline treatment alone, the patients became afebrile after 20 gr. of quinine in nine cases; after 40 gr. in two cases, and after 50 gr. in four cases. Crescents were still found in a patient who had taken 100 gr. In nine cases of clinical malaria in the second series, treated with the quinine and alkaline treatment alone, the patients became afebrile after 20 gr. in four instances; after 50 gr. in four instances; and after 60 gr. in one instance. In the majority of cases the mixtures are well tolerated, whilst there is the additional psychological effect of giving two mixtures instead of one to illiterate patients. Although all these patients were instructed to return to the hospital if fever recurred, the only one who did so was the patient who had received an intravenous injection—thirty-three days after the injection. He was now placed on treatment with quinine and alkalies and was discharged well on the tenth day. The combined quinine and alkali treatment is being tried side by side with the ordinary acid quinine sulphate mixture as a control. The scantiness of parasite findings is a feature of the series. If there is any drug which could be administered to drive parasites into the peripheral circulation, it would be of benefit to know of it; arecaline hydrobromide is said to possess this quality, but the author has been unable to procure it from any chemists.

Choroidal Hæmorrhage Following Cataract Extraction (M. M. Cruickshank).—This paper is based on thirty cases of choroidal hæmorrhage occurring throughout a series of 2,777 cases of cataract extraction at Shikarpur, Sind, where the incidence of glaucoma is very high. In the treatment of glaucomatous cataract the importance and the necessity of estimating the tension with the tonometer has been proved; but although tonometry is a valuable guide it is not the only guide as to the operative measures to be followed in the treatment of glaucomatous cataract, and in the prevention of choroidal hæmorrhage.

Original Communications.

BLOOD- AND TISSUE-CHANGES IN CANCER WITH REFERENCE TO DIAGNOSIS AND TREATMENT.

By J. A. Shaw-Mackenzie, M.D.Lond.

Introduction.

My attention was directed early to the examination of certain defensive processes that appeared to be at work in organisms invaded by cancer. The existence of such natural defences may be inferred from the fact that in the human body the disease may remain stationary for a considerable period, or even disappear altogether. The former fact was noted by Sigmond [1] in 1837, whose lectures I quoted from in 1906. The last-mentioned point is well authenticated by occasional cases of unexpected recovery at the present day. Moreover, in inoculated tumour mice, disappearance of the cancerous growth takes place in a large percentage of cases. Last, but not least, a certain number of mice are "negative" to tumour inoculation, a natural immunity that it is not unreasonable to suppose may be present more or less in human beings. On such grounds it seemed to me of the utmost importance that a preliminary investigation should be made of the blood, both in man and in lower animals, in order to ascertain if any differences existed between normal and cancerous blood, and if present, whether these differences could be controlled so as to benefit the invaded organism.

I have now long maintained that certain changes in the blood are present in cancer, in addition to the usual local manifestation. In 1905 [2] I drew attention to cases of cancer in different families in which one or other parent died of diabetes, or diabetes and cancer were observed in members of the same family, and that occasionally the two diseases are coincident in the same subject. Such facts led me to suggest that in cancer there might possibly be some underlying cause in functional defect in the liver or pancreas leading to cell proliferation, and local irritation determine the site of growth. In particular I referred to the ferment erepsin (which is different to trypsin and acts on proteoses and peptones) which Vernon described as universally present normally in all organs and tissues of the body and undoubtedly plays an important part in tissue metabolism. This intracellular enzyme was shown by him and others to be deficient in particular in the liver in certain cases of cancer, and on the other hand to be increased in other cases of cancer as well as in tuberculosis and septicæmia. This led me to suggest that natural and induced increase of the ereptic and proteolytic enzymes in the tissues might be a defensive response.

Lipase; the Lipolytic or Fat-Splitting Enzyme.

Since then my attention has been concerned mainly with another enzyme, namely lipase, the lipolytic or fat-splitting ferment of the pancreas. Changes in the blood in cancer have been found, associated in particular with this enzyme and its defective fat-splitting in the blood and tissues. When small amounts of serum are added to pancreatic extracts or to pancreatic juice itself the fat-splitting action is markedly *increased*. When carcinoma serum or sarcoma serum is added in the same way the action is *decreased*. The central fact in the blood of cancerous subjects is a deficiency of the fat-splitting activity present in normal blood-serum. On the other hand, coupled with improvement or recovery the serum regains its normal power or is increased. This lipolytic increase with corresponding increase in fatty acid products is an important factor in the protective processes of the body. It is particularly the case in malignant disease, although this lipolytic defensive increase or response is not specific to cancer but is common to tuberculosis and other bacterial invasions. It affords, as shown, an explanation in part of induced resistance and of natural and therapeutic immunization. It was found that this increased lipolytic accelerating power of the serum followed injections of certain normal mouse organ tissues known to render such animals immune to subsequent inoculation with mouse tumour. Furthermore, in favour of the view that the action is a protective one is the fact that such increased power of the serum is noticeable in mice which have proved "negative" to mouse tumour inoculation or have recovered spontaneously from large growths. The experiments which led to these conclusions, carried out in the Physiological Laboratory, Bacteriological and Public Health Departments, King's College, have been described in my previous papers [3].

Defective Tissue Lipolysis in Cancer.

The physiological mechanism by which the fats are normally split and utilized in the tissues carried to them by the blood-stream after digestion in the bowel, and the failure of this mechanism in cancer, have been described. Briefly it is that lipase, the fat-splitting enzyme or ferment in pancreatic extracts and in pancreatic juice, is separable into two parts, commonly spoken of as *coenzyme*, and *inactive lipase* or *prolipase*. Each is inactive by itself; but the power of splitting fats is raised to its original value by mixing them together. The inactive lipase is destroyed by heat but the coenzyme is not destroyed. The separation into these two parts in (*a*) extracts was effected by filtering a glycerol pancreatic extract through paper, or when diluted by the centrifuge, or by means of a Pukall clay filter, as shown by Rosenheim [4]; the clear filtrate or supernatant fluid after centrifuging contains the coenzyme, and its activating property has been concluded to be due to organic and inorganic phosphates; the residue of inactive lipase is obtained in the form of a greyish-white deposit; (*b*) I [5] showed a similar separation by heating diluted pancreatic juice; the lipase contained mainly in an inactive form in the juice is thus destroyed, and the thermostable coenzyme remains; but on adding the coenzyme to fresh juice the fat-splitting power is developed. Serum itself, when diluted and heated, as well as a great many organ press juices and tissue extracts, when substituted for the pancreatic coenzyme give similar fat-splitting power or activation,

in different degree. Carcinoma serum, and carcinoma extracts prepared in the same way as extracts of the pancreas, show a similar separation of a thermostable coenzyme which activates inactive lipase, but in less degree compared with normal serum and normal tissue extracts. The finding in this respect seems so similar to the separation of a "specific factor" from virus shown by Dr. W. E. Gye and Mr. J. E. Barnard [6], that I venture to draw attention to this aspect of the matter. In Dr. Gye's researches it would seem that the "specific factor" corresponds to the separable thermostable coenzyme of carcinoma serum and carcinoma extracts. The chemical nature of this substance or coenzyme has not been fully determined. But in carcinoma extracts [7] it has appeared to be in part the nature of a protein and in part a fatty acid digestive product or derivative of lipins (phosphatides) with cholesterol which are soluble in alcohol, ether, and chloroform, with reduced activating properties on lipase. Drew [8] showed that watery extracts of normal organs (kidney, liver, and spleen), and of tumour tissue, when incubated for a short time stimulate cell proliferation of adult tissues very greatly *in vitro* which is more marked in the case of sarcoma tissue. This stimulation seemed to me to be produced by products of partial or defective digestion, whether this is due, as stated in 1913 [9], to imperfect normal enzyme action in the tissues in areas of the body affected or to the presence of unusual enzymes in the cancer material. In this respect it has to be borne in mind that autolysis or self-digestion is synonymous with enzyme action in the cells and tissues; these intracellular and bacterial enzymes may not be identical with those in the alimentary canal, but their action on proteins, carbohydrates and fats and lipins is substantially the same. In this view we have thus a factor or stimulus to cell growth in enzyme action and imperfect products, whether due to prolonged irritation and interference with normal enzyme action, or due to ususual enzymes. In both cases a coenzyme action is concerned, one intrinsic, the other extrinsic, or both. The intrinsic cause underlying the altered metabolism in cancer is not known. But may it not be in addition, as in diabetes that an underlying factor is in faulty action of one or other of the larger organs. In order to make my position clearer I reproduce the following protocol of one of my experiments, referred to already, in 1915, illustrating the inability of either separated coenzyme or inactive lipase alone of pancreatic juice to split fats, but together produce the active normal fat-splitting enzyme; this was estimated, after incubation, by the amount of alkali required to neutralize the fatty acid products liberated, as in the case of similar separation and mixture of the two parts in pancreatic extracts.

Pancreatic juice (fresh)	Pancreatic juice (heated after dilution to 60° C. for 15 minutes)	Water	Olive oil emulsion	Time	N/10 KOH required
c.c.	c.c.	c.c.	c.c.	hours	c.c.
0·5 ..	— ..	2·5 ..	2·5 ..	18 ..	2·0
— ..	0·5 ..	2·0 ..	2·5 ..	18 ..	0·2
0·5 ..	0·5 ..	2·0 ..	2·5 ..	18 ..	10·5

It will be seen that both factors are intrinsic in th juice, but mainly held apart in some unknown way— the inactive lipase or prolipase contained being subse quently activated on the liberation of its natura coenzyme, or by other activators, in the duodenum o by serum. In the same paper it was shown in table that when carcinoma serum alone, or when dilute and heated is substituted for the natural pancreati coenzyme, the result is less than with normal serum The serum from certain specific infectious disease acted similarly, and I have pointed out elsewher that vaccines contain a thermostable coenzyme wit varying activating power. If as demonstrated b Dr. Gye two factors are requisite in tumour produc tion, and that "specific factor" and virus each whe rendered inactive together produce tumour growth, i is difficult to understand this tumour productio *in vivo* without a third responsible factor, namel unusual enzyme action, with consequent productio of abnormal fatty acids, not only in the living an treated virus but in the infected body cell. Dr. Gy himself alludes to a labile chemical substance con tained in the "sand filtrate" rendered innocuou with chloroform, which in some way unknown render the cells susceptible to infection by the virus. On can hardly doubt that the labile substance containe in virus is of a similar nature to inactive lipase, an that it is activated by the "specific factor" in chloro form extracts, in culture filtrates, and in the cell In this connection inactive lipase is insoluble i chloroform. While "specific factor" alone does no produce tumour, as shown by Dr. Gye, the effect o prolonged and continuous action, it would seem, i not excluded. In my experiments it was shown als that graduated additions of carcinoma serum, o serum from infectious disease to the inactive pan creatic fresh juice still further reduce the fat-splittin activation, compared with the progressive rise wit additions of normal serum. In immunization o treatment the treated or killed part or residue i probably an important factor.

Serum Reactions or Blood-Tests in Cance

In 1913 the defective lipolytic action of malignan serum compared at the same time with normal serun led me to utilize this reaction as a means of differen tiation between the two. This method frequentl warranted a positive diagnosis of cancer, confirme later. On the other hand, the absence of the reactio has been of service in excluding cancer in suspecte and post-operative cases. Recovery after operatio was shown by the gradual return of the reaction t normal in favourable cases within nine month These reactions, however, are not specific to cancer, a similar reactions have been found in tuberculosis an other infectious diseases. Later, my investigation have been directed to the serum itself and it behaviour on the addition of different extracts an substances. Serum itself does split fats unde ordinary circumstances.

But addition to normal serum of pancreatic coenzym of lipase after incubation does exert a lipolytic actio As well known normal serum is milky after a mea

When the pancreatic coenzyme is added to and mixed with normal milky serum after a meal, and incubated at 37° C. for two or three hours the serum becomes perfectly clear. It does not do so if incubated without the coenzyme. The addition of the coenzyme to carcinoma cloudy serum does not completely effect clearance. Sodium oleate in weak dilution exerts a similar lipolytic action with normal serum, but in less degree. Turbidity is produced when added to carcinoma serum, but here again similar results were found with tuberculous serum. I prepared therefore alcohol, ether, and chloroform mixed extracts,[1] or ether extract alone of carcinoma tissue, with or without saponification, in the hope that they contain a specific coenzyme or antigen. These extracts in suitable amount, when added respectively to carcinoma serum, after incubation at 37° C. for usually eighteen hours, give a cloud, or turbidity in varying degree, or sometimes a ring at the junction of the fluids with carcinoma serum, visible to the naked eye in good daylight. This turbidity does not appear with normal serum nor with non-cancerous serum with certain exceptions, including tuberculosis, which will be referred to later. In two cases of sarcoma serum the reaction has failed; this has suggested in a possible presence of sarcoma in any given case that sarcoma extracts need to be tried. The saponified mixed extract has an advantage of removing after incubation any slight initial turbidity in control normal serum. I have somewhat discarded the ether extract, owing to the uncertainty of obtaining ether free from alcohol, the presence of which in itself precipitates proteins. More recently I have been using cholin HCl (1 per cent. sol.), also adding it in the same way as the extracts to serum, with "positive" or "negative" results, after incubation. It occurred to me to try this decomposition product of lecithin, as very early in the course of this work it was found that cholin as well as cholesterol inhibited the action of lipase contained in pancreatic extracts, and lowered also the activating power of serum. It has proved satisfactory, and has the advantage also of simplicity and general availability.[2]

I use usually the saponified carcinoma mixed extracts and cholin, preferring not to rely on one method alone. Distilled water gives a turbidity also with carcinoma serum, but not so marked as with the extracts and cholin, although marked in the presence of fats in the cloudy serum. The turbidity does not appear with normal serum.

Directions in the Collection of the Blood.—It is of the greatest importance that care should be taken in the collection of the blood: (1) the blood should be taken while the patient is fasting, four to five hours after any solid or liquid, preferably before breakfast; as a rule 10 c.c. are taken from a vein in the usual way. (2) The needle; and all-glass syringe must be quite dry. Care must be taken that no water after sterilization remains in the needle or drawn up into the syringe after attachment of the needle; the piston of the syringe should be drawn up before the needle is attached and then the water expelled with a downward thrust of the piston; the needle should be detached from the syringe before slowly expelling the blood. Do not use a rubber attached needle for taking the blood, and do not use blood which may have run over from a punctured vein in failure to successfully insert the needle into the lumen of a vein. (3) The glass tube in which the blood is collected should be broad to readily permit separation of the serum; preferably the blood should be collected direct into a centrifuge tube; the serum should be clear and free from hæmoglobin; there should be as little manipulation of the blood and serum as possible; shaking of the blood clot and serum, for example, in transport must be avoided. (4) The serum should be centrifuged and examined within a few hours after separation; specimens kept in the ice-box for twenty-four hours are not satisfactory. (5) Pipettes should be free from all trace of alcohol or ether; if used more than once the pipette can be cleansed with distilled water which is then removed. (6) Note the colour of the blood-clot and serum. The blood in cancer is usually dark, sometimes almost black, and the serum opalescent and greenish. This is not pathognomonic, but is useful to note in conjunction with the serum reactions; similar coloration of the blood-clot and serum is witnessed in profound anæmia and anæmic conditions.

At first I was confronted with turbid serum. This not only made the test difficult but leads to inconsistent results. This difficulty of initial turbid serum due to incomplete digestion of fats after a meal is removed by the addition of 0·3 c.c. of glycerol coenzyme[3] first to 0·3 c.c. of the serum and after well mixing and incubation for two hours or so at 37° C., proceeding with the addition of each test solution. It is an additional precaution which I take if there is any suspicion of initial turbidity.

By means of these serum-reactions or blood-tests, it has been possible without any clinical knowledge of a case to differentiate cancer from non-cancerous cases in the majority of cases and, what is hardly less important, in obscure cases and after operation to exclude the presence of cancer. Up to the present in a total of 261[4] serums examined (including cancerous, non-cancerous, and normal) the method has proved correct in 248 or 95·3 per cent. The errors have been associated chiefly with tuberculous, sarcomatous, and febrile conditions. In one case (obscure abdominal) the reaction was "negative," but two months later, on post mortem and microscopic evidence, a primary carcinoma of the liver was found. So far

[1] The method of preparation of these extracts, procedure, and technique were more particularly described in my former papers; mammary carcinoma tissue (scirrhus), acetone dried in the usual way, has been mainly used, although I have used carcinoma and normal liver extracts as well. Usually 0·3 c.c. of the saponified extract in 1 in 3,000 and 1 in 5,000 dilution is added slowly to 0·3 c.c. of serum, so that the solution floats on the serum; accurate measurement is secured by the use of a micrometer screw pressure arrangement connected with a short stiff rubber tubing to a 1 c.c. pipette, graduated in tenths and hundredths. A normal serum is examined at the same time. (*Lancet*, October 7, 1922; *Medical Press and Circular*, January 3, 1923.)

[2] It can be obtained from Mr. W. Martindale, London. The crystals are hygroscopic and must be kept in stoppered glass bottles. A fresh solution should be made each time (0·1 gramme to 10 c.c. distilled water).

[3] *Preparation of Coenzyme Solution.*—Fresh pig's pancreas is freed from fat, minced and mixed with twice the amount of glycerol; after stirring and standing for twenty-four hours a turbid extract, strongly lipolytic in action (also tryptic) is obtained by straining through two layers of fine muslin. One part of this is added to four parts of water in a tall cylinder and the milky fluid allowed to settle; the fluid decanted from the precipitate when boiled and filtered and concentrated to a fifth of its volume contains the coenzyme of lipase, as shown by Rosenheim.

[4] I regret that illness for some months has prevented any material addition to my former list of cases and results. I am able now however to resume work as usual.

this is the only case of carcinoma, except one case of small superficial epithelioma in which the "positive" reaction has failed. In another case cirrhosis of the liver with ascites gave an erroneous "positive" reaction, in contrast to a "negative" reaction in more than one case of simple enlarged liver with jaundice, or gall-stones. The additional usefulness of the test has been demonstrated especially in obscure abdominal conditions and cancer of the stomach, as recorded in my original paper by Mr. Stanford Cade, of Westminster Hospital, to whom and other members of the Staff I am indebted for many blood specimens. So far as I have gone twelve cases of cancer of the stomach have been successfully differentiated from five cases of gastric ulcer, the diagnosis having been verified later.

Plate I illustrates the turbidity reaction in a case of cancer of the stomach, with the carcinoma extracts, and cholin, and cholin added after the previous addition of pancreatic coenzyme to the serum, after incubation, each result being compared with normal serum similarly treated. The patient was under the care of the late Mr. A. M. Crabtree in 1924, and under the observation of his brother and other practitioners. Clinically there was no question of the diagnosis, and the patient's very grave condition precluded any operative measure. Examination of the serum confirmed the clinical diagnosis. Intravenous injections of sodium oleate were commenced as a last resort. These were followed in a fortnight or so by amelioration of symptoms and mitigation of pain; the patient before long was able to leave his bed, to enjoy any kind of food and to take long walks; in fact for nine months he appeared to have recovered; treatment was left off, relapse and hæmorrhage occurred from which the patient shortly succumbed, without further treatment.

Plate II illustrates an absence of the turbidity reaction in a case of clinically suspected cancer of the stomach, reported by Sir W. J. Simpson [10]. It was that of a friend whose family history in regard to cancer was not a good one. He was suffering from gastric symptoms which suggested something more than simple ulcer. In the uncertainty of the diagnosis, exploratory operation was offered but this the patient was unwilling to undergo. In the still uncertainty, it was decided to examine the blood. The reactions to saponified mixed carcinoma extracts, ether extract alone, cholin, and water were absolutely "negative" to cancer. Two months later the reactions were found to be again normal; the patient had regained his former good health which has continued. The serum "negative" result with cholin is alone shown.

I am indebted to Mr. J. R. Ford for the accurate coloured drawings of the original test-tube reactions; to Messrs. Oliver and Boyd for the excellent and accurate blocks in reproduction; and to Messrs. Bale, Sons and Danielsson for the excellent printed illustrations of the same.

Another striking case is that of a friend who was at home from abroad. In this case also the family history in regard to cancer was not good. He was undoubtedly ill and unaccountably losing flesh rapidly. He desired especially to have his blood examined. The serum-reactions were entirely "negative" to cancer. The blood-clot was dark and the serum showed the greenish coloration of marked anæmia. He was advised to seek advice of a physician with experience in tropical disease, with the result that "amœbic cysts" were found, and under appropriate treatment he soon recovered.

In a more recent case among others the serum-reactions were found to be quite normal in a patient nine years after removal of her breast for scirrhus. On the other hand, it has been possible to decide as to the latency of the disease after operation. In two cases I found the "positive" reaction present twelve and eighteen months respectively after previous removal of the breast for scirrhus. The patients looked well and were apparently in good health, but within three months of that finding metastasis was only too evident in each case. In another case the reaction was present previous to a small local recurrence after operation for squamous epithelioma of ths skin, some twelve months before. These cases show that as long as the reaction persists the patient cannot be considered free of the disease.

It is not claimed that the reaction is specific and as I have already mentioned there is a 5 per cent. margin of error, but the practical utility of the reaction is not greatly affected and is evident in 95 per cent. proving correct. The reaction or test is in part associated with a marked cholesterol content in carcinoma serum as more recently shown by Mr. H. Gordon Reeves [11] in the Physiological Department, King's College. Further investigation on the chemical nature of the serum contents in carcinoma are in progress.

The defective tissue lipolytic action in cancer is witnessed in the case of other enzymes. As well known, antitryptic power of the serum is increased in cancer. This does not appear to be the same as the antitrypsin of normal serum, as the power of the former to resist heat is far greater. It has, moreover, long been known in the work of others that catalytic or oxidizing enzyme action of the blood and tissues is diminished in certain diseases such as tuberculosis, nephritis, and carcinoma.

In a former paper "On Cancer," by Professor E. Freund [12] (Vienna), it is stated that carcinoma extract with carcinoma serum and sarcoma extract with sarcoma serum respectively yield a specific turbidity or precipitation, whereas none occurs with non-carcinomatous serum and non-sarcomatous serum. Professor Freund has favoured me with his later published papers and details of his method with much useful information in correspondence. Briefly his test in carcinoma serum consists in extracting carcinoma tissue with sodium chloride and monobasic phosphate of sodium solution, and pressing the isolated cells through a fine cloth. The emulsion is heated with dilute acetic acid neutralized and filtered. It will thus be seen that his method though not the same as mine is partly dependent on a turbidity reaction. Kahn [13] has more recently described a turbidity test in which he uses sodium oleate in glycerol, which is not dissimilar to my test. It is of interest to note that he associates the reaction with inhibitory bodies in carcinoma serum against sodium oleate hæmolysis which is in line with the ascertained inhibitory action of cholesterol against sodium oleate, one of the substances which accelerate fat-splitting action, and with the marked presence of cholesterol in carcinoma serum.

Cancer Therapy.

We have thus arrived at the fact that there is a difference between normal and cancerous blood.

These changes are associated with defective normal enzyme action in the tissues, and in particular with defective tissue lipolysis. It has been shown furthermore that improvement and recovery are associated with increase of lipolytic activity in the blood and tissue.

In this direction, and restoration of physiological balance or control it seems evident that pancreatic

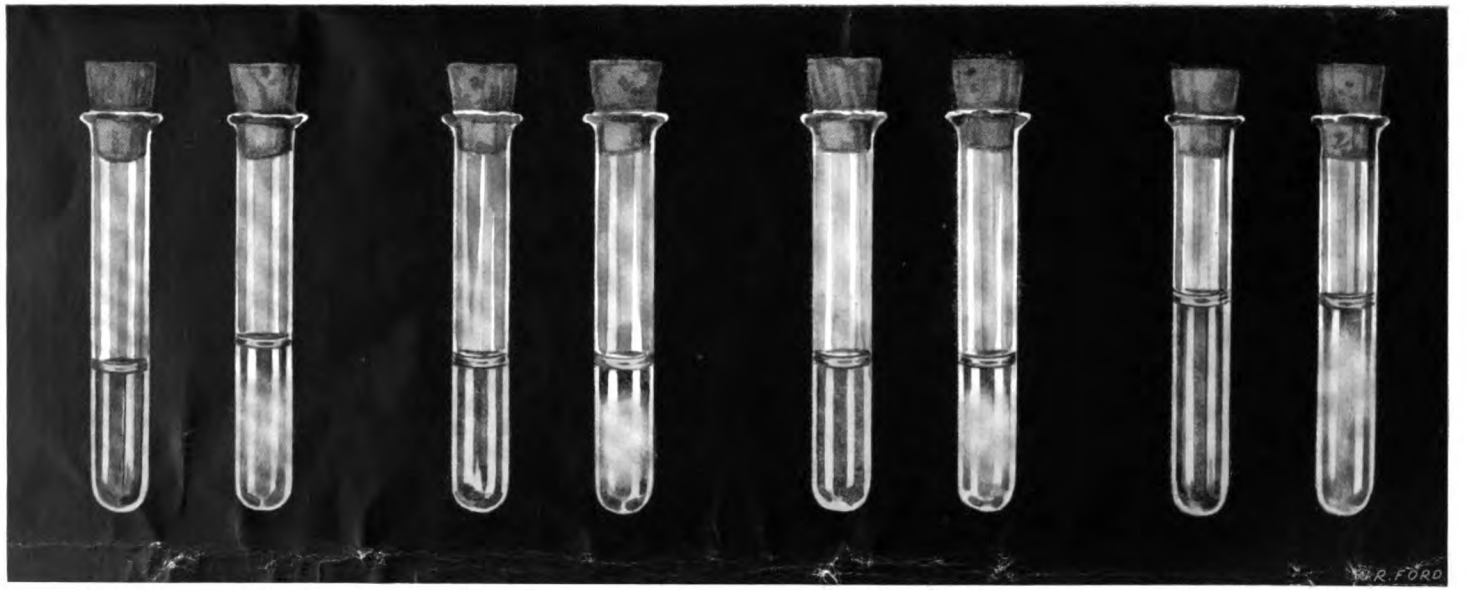

PLATE I.

SERUM TURBIDITY REACTION OR BLOOD-TEST IN CANCER.

The illustration shows a turbidity serum reaction from a case of cancer of the stomach.

The turbidity was produced by means of extracts of carcinoma tissue, with or without saponification (1) and (2), and cholin alone (3) and with coenzyme (4), added separately to the serum—after incubation, each result being compared with normal or non-cancerous serum, similarly treated.

Saponified alcohol, ether, and chloroform carcinoma mixed extracts, added.	Ether carcinoma extract, added.	Cholin, added.	Cholin, added after addition of glycerol coenzyme (lipase) first to the serum.

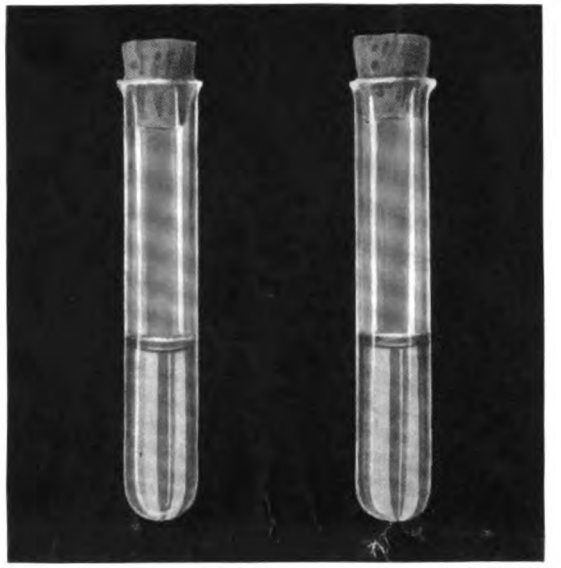
PLATE II.



SERUM TURBIDITY REACTION OR BLOOD-TEST IN CANCER.

The illustration shows an absence of the turbidity reaction from a case of clinically suspected cancer of the stomach.

The serum is left as clear after application of the test (see Plate I) as the normal serum similarly treated. The serum was found to be again normal two months later, with regain of the patient's former good health.

The absence of reaction with cholin is alone shown, but the saponified and ether carcinoma extracts in each case gave the same "negative" result.

Cholin, added.

coenzyme and other activators of lipase, with its normal fatty acid protective products, e.g., sodium oleate, extracts of normal organs and of carcinoma tissues and serum, are indicated in treatment.

Sodium Oleate.—I drew attention formerly, and on many occasions since, to the work of the late J. H. Webb [14] of Melbourne. He obtains good results by subcutaneous injection of sodium oleate in cases of inoperable cancer, and sent me notes of many cases to which, with details of treatment, I drew especial attention in 1906 [15]. The dosage recommended or worked out is 30 to 60 minims of a 0·8 per cent. sterile solution of sodium oleate; this is injected subcutaneously in sound tissue in the neighbourhood of the growth, preceded by a little eucaine; the injections are repeated every fourth day or so; in addition dried ox-gall which, like the well-known action of bile salts, is a powerful activator of lipase, is given by the mouth, in five-grain doses two or three times a day, in cachet, or in mixture of one-drachm dose of glycerol with cardamoms and peppermint water. The dosage is regulated so as to have a moderate action on the bowels. More recently favourable results have been recorded by Drs. S. Blakely and W. E. M. Armstrong [16], and by Dr. A. Wilson, in inoperable breast carcinoma. In addition to the notes of the carcinoma of the stomach, treated by intravenous injections of sodium oleate (Plate I), a practical proof of the value of this method has been forthcoming in a previous case of carcinoma of the stomach treated in this way with apparent recovery, which I have recorded. The patient at the time was under the care of Dr. A. L. Grant, of Burghead, Morayshire, in 1922, now in practice at S. Pasadena, California. Here there could be no question clinically of diagnosis, and from the point of view of therapeutics in control of reputed "cures," the reactions of the serum were precisely the same as in Plate I. When I examined the blood a year later in the Northern Infirmary, Inverness, these reactions were almost completely absent. The patient is in good health at the present time (three years).

The dosage of sodium oleate by intravenous injection employed in these cases is 1 to 3 c.c. of a one per cent. sterile solution of sodium oleate, weekly, to start with; 2 c.c. of a two or three per cent. strength appear to be well tolerated. There is no doubt sodium oleate has a favourable influence over some forms of cancer but a sufficient number of cases treated in this way would have to be forthcoming. Nakahara [17] has recently noted the fact that by means of oleic acid and of sodium oleate previously injected in small amounts the proportion of growths in inoculated tumour mice is lessened by almost one half and the course of established growths also is considerably modified. He shows that the immunization is associated with a general lymphoid tissue response and increased activity in the spleen and lymph glands. He refers also to the many views of others that the lymphoid cells are concerned in the digestion of fats and lipoids. In two cases I have recorded disappearance of ascitic or pleuritic fluid secondary to carcinoma of the breast with disappearance of the disease itself, in the former case involvement of the liver. After repeated ineffectual tapping the fluid seemed to "empty itself" by the kidneys. A similar disappearance of cancerous ascites has recently been mentioned to me. In two of the three cases, the patients were undergoing sodium oleate treatment. It is a point which suggests further attention to diuretics as aid in treatment, and the possible influence of the kidney in cancer metabolism. The assumption in Webb's recommendation of sodium oleate was a deficiency of the bile-salts and soaps with consequent separation of cholesterol as a determining factor in the cell proliferation of cancer; this took place either locally from injury or irritation or from some functional disturbance in the liver. Increase in cholesterol content in the cancer cell together with increase of lecithin which has long been pointed out is found also in the fatty deposits in the subcutaneous tissues and mesenteries of carcinoma cases (Brailsford Robertson and Burnett [18]) and in the neighbourhood of a growth, as well as noted already in carcinoma serum. It is not improbable that the liver is in some way responsible for this widespread distribution in association with unsaturation of the fatty acids with which the liver is intimately concerned. It is not impossible that this organ in the same way may be responsible for the separation or production of the fatty acid factor or coenzyme in cancer blood and cancer tumours. Adipose tissue is rich in catalases. Oxidation of unsaturated fats has been shown by Hopkins [19] to be readily catalysed by "glutathione" isolated by him from yeast and animal tissues, acting by virtue of its chemical structure as a means of hydrogen transport within the cell.

Normal, Carcinoma, and other Pathological Tissue Extracts.—In view of the above and that the phosphorized fats (lipins) and derivatives might be more important than ordinary fats, I prepared, with a view to treatment, extracts of the liver and extracts of carcinoma tissue, in the same way as for diagnosis. Protein derivatives, and acid-meta-proteins were made also. These have marked activating power on fat-splitting *in vitro* and *in vivo*, but no conclusions, clinically, can yet be drawn in this experimental stage. Similar extracts were prepared from tuberculous tissue.

Serum.—(1) Animal sera are more powerful in activating lipase than human serum. Dr. A. Wilson [20] has recorded some striking results with goat serum injected in cases of inoperable cancer, one of which results I witnessed. (2) Auto-serum, or the patient's own blood-serum, gave me, at one time, encouraging results. Two inoperable cases—uterus and breast—apparently recovered under this method and remained well. The breast case returned ten years later with recurrence and hopeless involvement of the pleura. Her history was that for nine years she had been in good health and free from any evidence of recurrence. (3) Anti-serum. In 1913 [21], I inoculated rats with mouse tumour, and goats and sheep repeatedly with human carcinoma material, as well as separately with carcinoma serum alone. After some six inoculations the serum power on lipase was reduced; this reaction was shown to run parallel with that of anti-diphtheritic serum as previously

ascertained; injections of anti-diphtheritic serum in cases of diphtheria are followed by a marked rise in lipolytic activity of the blood coincident with improvement. This method of obtaining serum by repeated inoculation of animals (sheep) with cancer material was originally introduced by the late G. Carrington Purvis, of Grahamstown. Lately, Dr. T. Lumsden [22] has shown that the serum of animals—rats and rabbits—repeatedly inoculated in the same way, with mouse tumour, is destructive to mouse tumour cells *in vitro*.

The clinical side has still to be investigated. One point needs consideration. The response to produce an effect was found in my experiments to vary in the different animals. The sheep was more responsive than the rat, goat, and, in a few experiments, rabbit. The question arises whether the horse or cow might be more suitable.

GRANULOMA VENEREUM.[1]

By A. VISWALINGAM, L.M.S. (Singapore).

Assistant Medical Officer, Federated Malay States Medical Service, Kuala Lumpur.

GRANULOMA VENEREUM, also described as granuloma pudenda, granuloma inguinale, ulcus molle serpiginosum, is thought to be rare in the Malay Peninsula. On the contrary, it is frequent enough to deserve more attention at the hands of the profession. Besides, we meet in this country other diseases such as syphilis and yaws that are often characterized by granulomatous lesions, and therefore it is necessary that confusion should be avoided.

Definition.—Granuloma venereum may be defined as a disease of the external genitals and adjacent parts, characterized by granulomatous tissue formation and going to ulceration and cicatrization, pursuing a very chronic course and invariably following impure sexual contact. It is therefore preferable to call it granuloma venereum, although it is not a venereal disease in the sense of gonorrhœa or syphilis.

Distribution.—The disease was at one time thought to be peculiar to the tropics, and hence called granuloma inguinale tropicum. Now, however, it has been described by so many observers in various parts of the world that it may be said to be almost universal.

Ætiology.—The true ætiology of the disease has not been definitely established. Some authors have described the disease as a tubercular ulceration, others have described what are called "inclusion bodies" in the mononuclear cells, and yet others consider it a syphilitic process. Judging from the character of the lesion in the cases that have come under my observation and the response to treatment with antimony, a drug allied to arsenic, it is likely the infecting agent is a spirochæte of the Treponema group.

Race, Age and Sex.—All my patients were Chinese and Tamils of lower classes—not very particular about their personal cleanliness. I do think that the habits of the individual and the nature of secretions such as sweat, &c., of the external genitals has more to do with susceptibility towards the disease than age or sex. All were adult males above 25 years of age, a factor in support of sexual contact in the ætiology of the disease.

Incubation Period.—This is very indefinite and varied from a few days to three or four months.

Mode of Spread.—The usual history is, that following an impure sexual contact the disease appeared in some part of the external genitals. But in some cases it appeared to me that it spreads also by auto-inoculation. In one case the patient developed a granuloma on the prepuce and a few weeks later developed a similar lesion on the lower third of his left thigh. It is likely the lesion in the thigh started as an ordinary ulcer which later got infected from the discharge of the original lesion.

Clinical Appearance.—The lesion generally starts as a papular eruption about the external genitals, groins or the perineum, and develops either into a granuloma, or it ulcerates and follows a serpiginous course with irregular and undermined edges. In either case, while the lesion extends along the periphery the central or distal portions are found to heal and cicatrize firmly. The cicatrix is often pale and leathery in consistence. What may appear to be a healthy scar one day may be seen to ulcerate the next. Lesions about the groins may extend to the pubis and the lower abdomen and the flanks, those about the root of the penis may ulcerate all round and

[1] Paper read before the Annual General Meeting of the Malaya Branch of the British Medical Association, held in Kuala Lumpur, on April 11, 1925.

isolate the penis from the rest of the external genitals; those that appear about the lateral aspect of the scrotum generally follow the genito-crural folds and extend towards the perineum and the anal region. In all cases there is profuse serous discharge. The disease pursues a chronic course for weeks, months and years, apparently responding to treatment but only to break out soon after. The general health gets gradually lowered. The chronicity of the disease, the profuse discharge, and the poor response to treatment begin to be felt and the patient becomes depressed, worried and apathetic and some cases develops a suicidal tendency. The patient goes from one practitioner to another and drags on a miserable existence. Some cases, for some unknown reason, take a turn for the better and heal spontaneously.

Diagnosis.—This may be done on the finding of the so-called "inclusion bodies," but one should be guided more by the clinical appearances, history and response to treatment than by microscopical findings which are as yet uncertain.

Granuloma venereum has to be differentiated from yaws, syphilis, epithelioma and tuberculosis. It can easily be differentiated from yaws by the history and the ready response to treatment by N.A.B., and by the fact that yaws is prevalent among the Malays and rarely in other races and attacks all ages and sexes; from syphilis by the absence of a positive Wassermann and the failure to respond to antiluetic treatment; from epithelioma by the absence of characteristic microscopical appearances of tissues excised from the lesion; from tuberculosis by the absence of tubercle bacillus, and by its being limited only to the external genitals.

Prognosis.—This is very unsatisfactory, but with the introduction of antimony there is better prospect of improvement and cure. However, the disease is very refractory to treatment, and patients are not usually intelligent enough to undergo prolonged treatment.

Treatment.—Until recently reliance was placed on local treatment by means of caustics and in the administration of drugs of antisyphilitic nature, with little or no success. The successful employment of tartar emetic in the treatment of trypanosomiasis has encouraged its use also in granuloma venereum. I have administered the drug both by the intravenous route and by the mouth, more frequently by the latter. The salt used was the tartrate. The dose employed to start with was ½ gr., gradually increased to 2 gr. once in three days intravenously. After a course of eight to ten injections the drug was stopped for at least a week and then repeated. The results were not as satisfactory as I was led to believe from the reports of other observers. Therefore I used the drug in combination with large doses of potassium iodide by the oral route, beginning with 1 gr. and 15 gr. and working up to 2 gr. and 1 drm. respectively. The results were more satisfactory and the healing more rapid.

My observations lead me to conclude:—

(*a*) That the dose of antimony tartrate by the intravenous route should not exceed 1 gr. at one time and must not be repeated oftener than once in three days.

(*b*) That it is best to administer the drug in combination with potassium iodide by the oral route along with the intravenous injections.

(*c*) That intravenous injections of antimony tartrate should not be undertaken lightly, and that individual susceptibility should be carefully watched for and the injections discontinued on the evidence of any adverse symptoms.

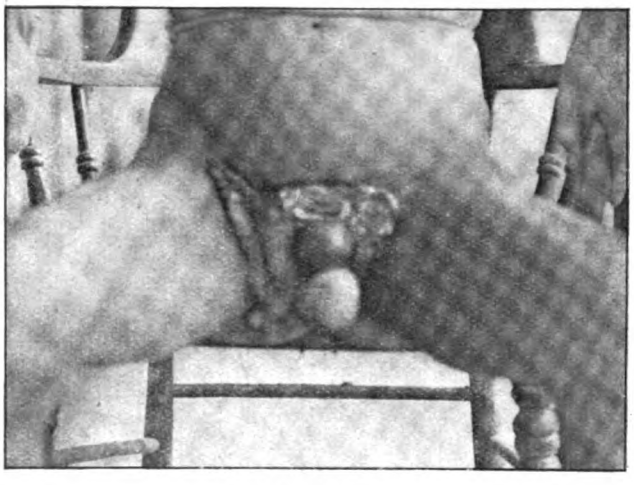

FIG. 1.

Local Treatment.—Scraping and cauterizing were useless. Excision of the lesion, keeping well out of the advancing area of ulceration, was done with doubtful result. Better results are likely to be had if every endeavour is made to keep the lesion and the adjacent parts dry. For cleaning the lesions it is best to employ mild astringent antiseptics in preference to strong lotions.

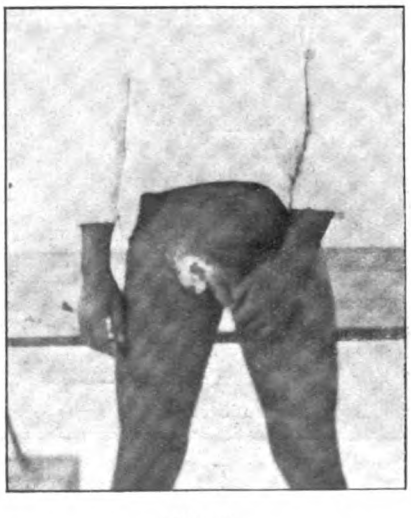

FIG. 2.

To summarize:—

(1) Granuloma venereum is not a rare disease in Malaya.

(2) It is certainly a sequelæ to impure sexual contact, and in that sense it may be classified as a venereal disease.

(3) In treating the disease early diagnosis is essential to success.

(4) Tartar emetic alone is not likely to give as satisfactory results as its combination with potassium iodide in large doses.

(5) Utmost care must be taken to keep the parts as dry and clean as possible.

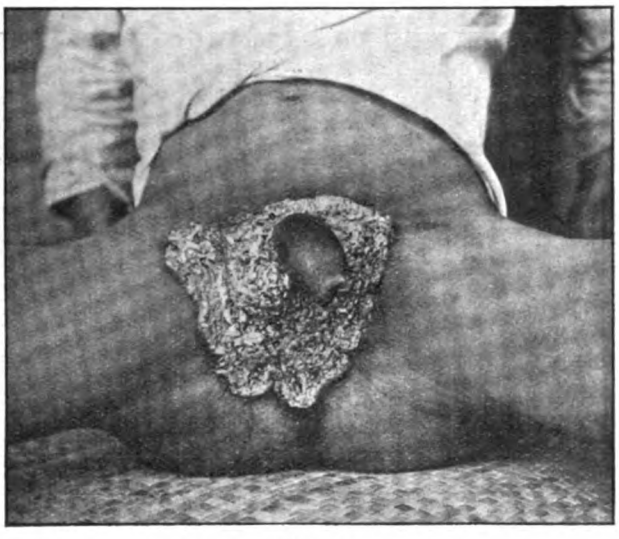

FIG. 3.

(6) Patients under antimony treatment, by whatever method the drug may be administered, must be closely watched for any adverse symptoms and the drug discontinued immediately they appear, as it is well known that prolonged administration of this drug leads to fatty degeneration of the liver, kidneys, &c., and patients not infrequently complain of severe pain in the hepatic region soon after injection.

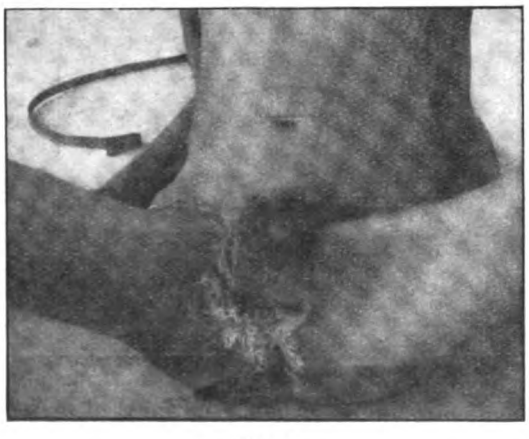

FIG. 4.

Fig. 1.—A Tamil, first seen in 1917, with a large granuloma inguinale in the right groin, said to have appeared as a pimple some weeks after an impure sexual contact.

Local applications of strong lotions and scraping and antiluetic treatment for three months with no benefit. Patient left hospital dissatisfied.

Seen later, in 1919, clinical picture same as before. Patient placed on the following mixture on October 27, 1919:—

℞ Pot. Iodide ...	...	Gr. 30
Antim. Tart.	...	,, ss
Aqua Chloroform ...		Oz. 1
Fit. Mist. Sig.	...	,, 1 T.I.D.

The ulcer was dressed with pulv. iodof. The pot. iod. was gradually increased to 60 gr. and the tartar emetic to 1 gr. t.i.d. Three intravenous injections of antim. tart. 1 gr. once in three days was given.

After the third injection patient was collapsed and doubled up with pain in the hepatic region within almost half an hour. The injections were discontinued from this date. On January 8, 1920, signs of healing appeared in the centre of the lesion, and on March 2, 1920, patient left hospital with a pale but healthy leucoderma-like scar of leathery consistence.

Fig. 2.—Chinese male, 35 years of age.

Admitted on May 8, 1920, for serpiginous ulceration of one year's duration, said to have started in the right groin twelve days after impure sexual contact, and to have extended along the genito-crural fold to the root of the scrotum, the perineum and anal regions. Left hospital on June 15, 1920. Treatment similar; but patient had 6 gr. of tartar emetic intravenously on twelve occasions.

Fig. 3.—Chinese (an opium smoker), admitted on January 13, 1921, with granulomatous ulcerations involving the pubic and genito-crural regions, the scrotum and perineum. Said to be of fifteen months' duration and to have developed as a small sore at the root of the penis four months after impure coitus. The growth presented a typical cauliflower appearance with indurated and elevated edges. Before patient came under my observation the lesion was diagnosed as epithelioma, and was treated by caustics and later by actual cautery on February 19, 1921.

Intravenous injections of tartar emetic, ½ gr. once in three days. was started and given on and off till June 12, 1921. Patient was also given pot. iodid., 20 gr. t.i.d.

On July 15, 1921, patient left hospital. Fig. 4 shows his condition on discharge.

A Typical Case of Splenomegaly (I. Treiger, M.D., *Archives of Internal Medicine*, May 15, 1925).—A woman, aged 60, who had had typhoid fever at the age of 10, and eclampsia at 31, nineteen years ago, received a diagnosis of enlarged spleen. The present findings were a greatly enlarged spleen and liver. The blood-findings were anæmia and leukopenia until a few months ago, when leukocytosis, with myeloid changes, appeared. The course of the disease was divided into the three stages, splenic, hepatic and myeloid; the first stage lasted over a period of twenty years, the second over a period of a few years and the last has been in evidence for nine months. The spleen, liver and bone marrow are interrelated in their function. This case represents a pathologic correlation of these three, while usually only involvement of the spleen and liver is seen.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings** per annum, may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these, with remittance, is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 ,, ,, ...	1	3	3
200 ,, ,, ...	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 ,, ,, ,,	2	6	0
200 ,, ,, ,,	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

THE JOURNAL OF

Tropical Medicine and Hygiene

AUGUST 15, 1925.

MASSAGE BY CHINESE METHODS, ANCIENT AND MODERN.

As long ago as 1891 and 1892 I attended two lectures on Chinese methods of massage by Dr. John C. Thomson, M.A., M.D., Edinburgh. Dr. Thomson recently taught as superintendent of the Alice Memorial Hospital of the London Missionary Hospital, Hong Kong. The "Alice" referred to was the late wife of Kai Hokai, who, after a course of instruction at the medical school of St. Thomas's Hospital, London, had graduated at the University of Aberdeen as M.B. and C.M., and later took the degree of M.D.Aberd. At the same time as Hokai ate his dinners at the Middle Temple in London he was called to the Bar and practised law before the High Court at Hong Kong. As a public man in many walks of life, Hokai was knighted and styled Sir Kai Hokai.

When Dr. J. C. Thomson began his lectures on early Chinese massage he dated the period from an epoch some 4,000 to 5,000 years before the Christian era and elaborated throughout the succeeding thousands of years to more modern times a chain of events which in its course showed the elaboration of massage in more modern times. In Europe these methods led to greater skill, and it was many hundreds of years of development before so-called modern methods of massage began to come to the front in Swedish and other systems of muscular development. Not that the ancient systems were neglected. Not so; every branch of surgery was maintained and new plans brought forward; for, as Dr. Thomson says, the Chinese themselves draw a very fine distinction between internal medicine and external medicine, as they term surgery. I have in my entrance hall in Harley Street "boards of testimony" presented to one of the Chinese heroes of surgery who, 4,000 years ago, performed abdominal surgery with delicate elaboration and success. One of these was presented to me as a fitting testimony for my having done removal of an ovarian tumour as skilfully as it was done 4,000 years ago by the great Chinese surgeon. Surgery was then far advanced. There was some knowledge of the circulation of the blood. The operation of castration had been successfully performed by the year 1100 B.C. Methods of cure by massage had been boldly and skilfully practised, and already syphilis was being cured by mercury.

In ancient medicine, as in everything else in China, specialization reached its acme. There were doctors for the eye, chest, bowels, skin, women, children, bone-setting.

The summary of these possibilities in China 4,000 years ago are to be met with to-day amongst American curers, oculists, dentists, neuropathists, bleeders, faith healers, and a host of such wise men and women, snake charmers, &c., &c.

The massage (say Swedish) of to-day, or amongst Japanese, was originally such as is dealt with in systems of to-day amongst Chinese and Japanese and Swedes, consist of muscular movements, and are of several kinds. The Chinese had originally twelve kinds.

CHINESE MOVEMENT CURE.

The sixth operation of surgery, which I have rendered "Shampooing," is worthy of more than passing notice, since in addition to the general idea

of massage it has developed into a science resembling in some respects, and rivalling in detail at least, the now famous Swedish Movement Cure. Massage in its simpler form, consisting of tapping, kneading, pinching, chafing, and pommelling the body all over, is widely used as a remedy for muscular fatigue, nervousness, headache, paralysis, pelvic disorders, labour, &c., and also as a simple luxury, the barbers being the operators and concluding their daily shaving and dressing operations with a sound pommelling to the back and limbs of such of their patrons as can afford to pay for it.

This, as well as the more complicated system of massage combined with air-swallowing and muscular exercises, is of great age, being traced not to the usual Hwang Ti (2697 B.C.), legendary though that emperor be, but some twelve centuries beyond him. Into the history of the system, however, I shall not here enter, referring for that and for a full description of its theory to a paper on the subject by D. J. Macgowan, M.D., Wênchow, in the Customs Medical Report, No. 29, 1884-85; and here passing directly to a brief account of the frictions and movements themselves, taken from that paper.

The period of air-swallowing and friction exercises is to be divided into three parts of one hundred days each. After certain preliminary carefully described inhalations of the sun's air on the first of the moon, and of the moon's air at the full moon, all is ready for a commencement being made. During the first month friction is to be made by two youths, each on alternate days, they rubbing the patient's abdomen with the right hand and from right to left, at first lightly, but gradually increasing the pressure, and this for an hour three times daily. By the end of the first month the services of the youths may be dispensed with, when a form of shampooing is to be practised by the patient himself, thumping his ribs with a bag filled with water-worn pebbles, weighing a pound, three times daily. During the third month a pestle about six inches long, or a round bat somewhat longer, is to be employed for pounding the abdomen three times a day; they are to be made of hard wood. Meanwhile friction and pounding the ribs is to be continued. During the fourth month the bat and pestle are to be alternately used along with friction, and this completes the first period of one hundred days.

From the fifth month of the exercises the bag of pebbles is to be used continually till the close of the eighth month, which closes the second period of a hundred days. During the third period the back is to be pounded in like manner. During the whole three hundred days it is directed that continence be maintained, except once between the hundred-day periods; and ever afterwards, except once in fifty days.

"I. Stand erect and firmly, retain the breath, bring the flexed hands together on the chest, knuckles meeting, keeping the mind at absolute rest.

II. Stand on the toes and extend the arms literally, with eyes fixed, mouth closed, and mind perfectly quiescent.

III. Maintaining the tiptoe posture, raise the arms above the head and bring the hands together with palms turned upward, joints closed, tongue pressing roof of mouth; clench the fists and bring the arms firmly and slowly down.

IV. Raise one arm above the head, palm hollowed, eyes directed towards it, inhaling through nostrils, and forcibly and slowly bring down the arm. Repeat with the other arm.

V. As if pulling the tails of nine bulls, stand on one foot bent and extended forwards, the other extended backward; cause the air of the pubic region to move forcibly, thrusting one arm forward, the other backward, eyes fixed on the clenched fist. Repeat, reversing the legs.

VI. Extend the arms forward, as if pushing out and drawing in, seven times.

VII. Head inclined, with a hand stretched behind the neck. Repeat with other hand. Maintain erect posture, with gentle breathing.

VIII. Sit with legs wide apart, pressing the hands on the floor, and forcibly raise them, eyes fixed, mouth closed; rise and bring the feet together.

IX. Turn the arms alternately across the chest, fixing eyes on the hands, the mind meantime settled.

X. Assume the posture of the "crouching tiger," one knee bent, the other stretched backward, head turned upward, palms resting on the ground.

XI. Bend forward, placing the hands at the back of the head, so as to cover the ears; close the teeth, press roof of mouth with tongue.

XII. Finally, keeping legs erect, bend forward, with fixed eyes and upturned head, the hands clasped on the ground; rise; stamp twenty-one times, and stretch the arms alternately seven times; then sit cross-legged, each leg in turn, with closed eyes.

The above exercises are to be performed three times daily for an indefinite period."

In the year 1895 I read a paper before the China Society, and gave a demonstration. The China system was read out of one paper, whilst I gave an exhibition of the British system and also the Chinese massage.

Beyond alteration in the terms applied to the movements of the limbs and body, but few changes are to be made. For instance, when the "command" is given, "Assume the *posture of the crouching tiger*," or "*as if pulling the tails of nine bulls*," &c., and such other orders.

J. CANTLIE.

(To be continued.)

Annotations.

The Fight against Malaria at Madagascar (Thiroux, *Bull. de l'Office Internationale d'Hygiène Publique*, January, 1925).—Malaria is one of the greatest causes of the decrease in the population of Madagascar. It appears to have always been prevalent on the coast and especially in regions of medium altitude. On the Plain of the Grande-Ile, however, malaria is of relatively recent origin, possibly between 1902 and 1904. In Antananarivo alone malaria has been the cause of 11,337 deaths since 1905. The average annual number of deaths from malaria during the last sixteen years is roughly 500 in a population of less than 60,000 people. Malaria is prevalent in active form during seven months of the year, affecting three-fourths of the population ; with the coming of the cold season it is not surprising that these enfeebled people do not resist the pneumonia and influenza which invariably set in. The largest number of patients suffering from pulmonary infections are found in malarial districts. Prophylactic measures already carried out have borne good results, but much yet remains to be done to rid the country of one of its worst scourges.

Plague Transmission through the Ectoparasites of the Tarabagan (W. Lien Teh, J. W. H. Chun and R. Pollitzer).—The authors have succeeded in infecting a healthy animal by means of tarabagan fleas, which shows that these parasites play an important part in the spread of the infection, not only from animal to animal, but also from animal to man. Observations on the lice and fleas from one and the same naturally infected tarabagan is certainly illustrative of their important link in the propagation of the disease from animal to animal. It is at present difficult to gauge how far the lice actually spread the disease to man. A few outbreaks, where the affected had contact with tarabagan skins only, seem somewhat suggestive of their rôle. Observations made both on the fleas and the lice thus show that any attempt to control the handling of tarabagans and the trade with their skins must include not only bactericidal, but also insecticidal measures.

The Effect of Fatigue upon the Susceptibility of Rabbits to Intratracheal Injections of Type I Pneumococcus (G. H. Bailey, *American Journal of Hygiene*, March, 1925).—Fatigue artificially induced in rabbits by forcing them to walk for periods of one, two or three successive periods in a motor-driven drum seems to decrease their resistance to intratracheal injections of Type I pneumococcus. This occurs whether fatigue precedes or follows the injections, but is more evident in the latter case. The increased susceptibility of rabbits fatigued in this manner is shown by a considerably higher mortality, as well as a shorter mean time of death. This is more evident when fatigue follows injection than when injection follows fatigue. Forcing rabbits to walk in a motor-driven drum from six to twelve periods on alternate days before injection, during which time they become well trained to such exercise, apparently increases the resistance of these animals to injections of Type I pneumococcus. The gross pathological lesions indicate that more extensive pulmonary lesions occur in fatigued rabbits injected intratracheally with Type I pneumococcus than occur in unfatigued controls.

Contributions to the Pathology of Experimental Virus Encephalatis. (1) "An Exotic Strain of Encephalitogenic Virus" (S. Flexner and H. L. Amos, *Journal of Exper. Med.*, February 1, 1925).—In this paper is given an account of an inoculable virus disease produced in the rabbit with cerebrospinal fluid taken from a case of vascular and neural syphilis. The study which yielded the results presented was undertaken in the course of an investigation into the ætiology of epidemic or lethargic encephalitis. Twenty-seven samples of cerebrospinal fluid, derived from cases of epidemic encephalitis, were tested upon rabbits without positive results. The one successful instance in which an inoculable disease was produced arose from the injection of one of three specimens of the cerebrospinal fluid taken from the case of syphilis. Following this success, two subsequent injections of the fluid, taken from the same patient were made unsuccessfully. The name virus encephalitis is proposed for the experimental disease produced in rabbits by the inoculation of the herpes and allied viruses.

Skin Infection of Rabbits with Hæmolytic Streptococci isolated from a Patient with Erysipelas (T. M. Rivers, *Jour. of Exper. Med.*, February 1, 1925). —Small areas of skin infiltrated with immune serum proved refractory to the injurious action of a filterable rabbit virus inoculated twenty-four to forty-eight hours later. Infiltrations of normal serum did not appreciably protect the skin against the virus. The local protection afforded by the infiltrations of immune serum appears to constitute an example of local passive immunity. Small areas of skin infiltrated with either normal or meat infusion broth proved more refractory than normal skin to infection with hæmolytic streptococci inoculated twenty-fours later. The refractory state induced in the tissues was not specific in character. A greater amount of local protection against hæmolytic streptococci was afforded by infiltrations with a hæmologous immune serum than by infiltrations with normal serum. The difference in the amount of protection afforded by immune serum over that induced by normal serum may be thought of as representative of the degree of local passive immunity conferred.

A Certified Milk-borne Paratyphoid Outbreak (Huntington Williams, *Jour. Amer. Med. Assoc.*, January 24, 1925). – During March, April and May, 1924, there occurred an outbreak of paratyphoid fever among a group of about sixty infants and young children in New Rochelle, N.Y., and nine neighbouring communities. There were no fatal cases. During

the preceding December there had occurred in the near-by city of Mount Vernon a small group of cases of similar clinical nature. The characteristic symptoms of the outbreak were: a green, mucoid, blood-tinged diarrhœa, with fever, abdominal pain, and occasionally vomiting. The clue to the correct ætiology of the outbreak was the isolation of *Bacillus paratyphosus* B from the stool of one of the children during convalescence. The diagnosis of the clue was followed by isolating the paratyphoid organism from three other convalescent children. In addition, there were two cases giving positive Widal reactions and four other cases giving partial Widal reactions with *B. paratyphosus* B. There was no common vehicle of infection other than the certified milk that had been consumed in all the cases. The outbreak was caused by an enteric carrier of *B. paratyphosus* B, who was a milker employed at the dairy farm producing the milk in question. The ætiologic organism was isolated from the stool of this carrier and also from the stool of his 4-year old child. Only one previous outbreak of infectious disease spread by certified milk is known: a diphtheria outbreak that occurred in Westchester County, N.Y., in 1920.

Observations on Inoculated Malaria (A. Pijper, M.D., and E. D. Russell, M.R.C.S., L.R.C.P., D.P.H., *South African Medical Record*, May 9, 1925).—In *early* cases of simple tertian malaria an injection of neosalvarsan is a *therapia magna sterilisans*. An injection of neosalvarsan has a provocative action on latent malignant tertian malaria, whilst curing a simple tertian infection. Daily red-cell counts in inoculated simple tertian malaria show a marked incubational increase in the number of red cells, and this was confirmed by daily determinations of the percentage volume of the red cells. Malignant malaria acts likewise. Not all cases of general paralysis show an increased sedimentation rate of the red cells. Korteweg's observations on the "initial fever" of simple tertian malaria are confirmed. The type of fever with which simple tertian malaria begins depends on the state of immunity of the subject. Simple tertian malaria paroxysms are the expression of a state of allergy, both in first attacks and in relapses, or later reinfections. Spontaneous cures occurred in a large percentage of these cases, and this is to be ascribed to acquired immunity. South African natives often show a marked immunity against inoculated tertian malaria. Inoculated simple tertian malaria causes a mild leukopænia, and the leukocyte curve on the whole runs parallel with the parasite curve. Certain deductions as regards immunity can be made from the relative height of the two curves. The incubation period is not dependent on the number of parasites inoculated. During the course of malarial infection enormous number of parasites are destroyed, but the number does not seem to stand in any fixed relation to the immunity reached. High rises of temperature are associated with large numbers of parasites in the blood.

Many of the author's observations suggest a particularly active participation of the bone-marrow in the pathogenesis of malaria.

A Group of Micro-organisms transmitted hereditarily in Ticks and apparently unassociated with Disease (E. V. Cowdry, *Journal of Experimental Medicine*, June 1, 1925).—Pleomorphic, bacterium-like, Gram-negative intracellular micro-organisms, which stained much less intensely with ordinary dyes than most bacteria, were found in sixteen species of ticks comprising examples of the Argasidæ and the Oxididæ. In six of these species studied intensely slight differences in the micro-organisms were detected, sufficient to permit identification of the vectors by microscopic examination of the micro-organism alone. No evidence was seen of injury to the tissues of the arachnid hosts of the micro-organisms other than that incident to mechanical distention of the cells containing them. The detection of the micro-organism in the eggs of ten species in the unfed larvæ of eight species, and at nearly related stages throughout the life cycle of three others, leads to the conclusion that they are transmitted hereditarily.

The Liver as a Source of Bacterial Agglutinin (F. S. Jones, V.M.D., *Journal of Experimental Medicine*, June 1, 1925).—Serum and tissues containing agglutinin for the hog cholera bacillus may be dried *in vacuo* over sulphuric acid without appreciably injuring the antibody. The desiccated material when extracted with appropriate amounts of distilled water offers a basis for accurate comparison of antibody content. The greatest concentration of agglutinin occurred in the liver, provided the animals injected with small amounts of antigen were killed within a short period. The serum of those more highly immunized contained the highest concentration of antibody. A single injection of antigen into a radicle of the mesenteric vein resulted in a considerable concentration of agglutinin in the liver. Other experiments indicated that the liver does not act as a reservoir for the antibody. It has also been shown that this concentration of agglutinin cannot be ascribed to the blood left within the liver, since the blood serum was relatively poor in antibody. The experiments indicate that the agglutinin was produced within the liver.

Skin Reactions to Simultaneous Treatments with Radiant Heat and Soft X-rays (James A. Hawkins, Ph.D., and Harry Clark, Ph.D., *Journal of Experimental Medicine*, June 1, 1925).—Guinea-pigs have been exposed to suberythema doses of soft X-rays, to radiant heat of intensity at about critical for producing slight burns, and to both radiations simultaneously. No erythema was produced in the skin of the animals exposed to X-rays alone and only slight burns resulted in 50 per cent. of the animals exposed to heat radiation alone. The

animals exposed to heat and X-radiation simultaneously developed well-marked burns which healed much more slowly than those produced by heat alone.

A comparative study of the environment associated with Kala-azar prevalence in Calcutta (L. Everard Napier, M.R.C.S., L.R.C.P., *Indian Journal of Medical Research*, April, 1925).—In order to summarize, it can be said that, as far as Calcutta is concerned, kala-azar seems definitely to be associated with: vegetation in close proximity to the dwellings, earth unprotected by cement or paving stones in and around the dwelling; ground floor residence, possibly with insanitary conditions, especially with reference to the presence of fowls and ducks in and around the dwelling, and within the endemic area, and with masonry houses (rather than bamboo and khola huts).

Studies on Lathyrism—I (L. A. P. Anderson, Albert Howard and J. L. Simonsen, *Indian Journal of Medical Research*, April, 1925).—The seeds of khesari (*Lathyrus sativus* L.) have been found, on chemical examination, to be free from substances of alkaloidal nature. Controlled experiments with this seed over long periods with ducks and monkeys have demonstrated that the grains are harmless and provide a nourishing diet for these animals. An examination of the weeds which contaminate khesari has proved that akta (*Vicia sativa* L. var *angustifolia*) contains bases showing alkaloidal properties. Two such bases, vicine and divicine, and a cyanogenetic glucoside vicianin, have been isolated, prepared in the pure state, and used in inoculation experiments on animals. Divicine which occurs in akta in combination with a sugar as the glucoside vicine, produces on inoculation in guinea-pigs a characteristic and fatal disease. Akta, when fed to ducks, causes death. In monkeys it produces a very characteristic train of symptoms affecting the nervous and muscular systems. Though certain of the symptoms occurring in monkeys fed on diets containing akta have been described in cases of human lathyrism, it has not yet been proved that akta is the cause of lathyrism in man.

The Blood in Purpuric Small-pox (Kano Ikeda, M.D., *Journal of the American Medical Association*, June 13, 1925).—The purpuric type of small-pox is a definite clinical entity which presents a series of characteristic clinical manifestations wholly or partly unlike those of pustular small-pox. Its occurrence is rare. An unusually large number of cases of this type of small-pox was recorded in Minneapolis during the recent epidemic. Ten per cent. of the cases admitted to the Minneapolis General Hospital within a year were diagnosed as purpuric. Clinical diagnosis of purpuric small-pox occurs comparatively early, and is sufficiently specific to make its prompt and definite recognition possible. An attempt was successful in differentiating this type of the disease during its initial period from other forms of small-pox and also from other doubtful exanthems and acute infectious and toxic diseases by means of blood examinations.

The Fate of an Intravenously-Injected Dye (Brilliant Vital Red) with Special Reference to its use in Blood Volume Determination (H. P. Smith, *Bulletin of the Johns Hopkins Hospital*, May, 1925).—A study is made of the behaviour of brilliant vital red when introduced into the blood-stream. The relations of these findings to the physiology of phagocytosis and to the theory of blood-volume determination are discussed. It is found that the dye is slowly eliminated by the liver but not by the kidneys. Before being eliminated from the body much of the dye is taken up and stored by phagocytes. The phagocytes do not completely remove the dye from the plasma, because the phagocytic reaction is a matter of equilibrium between phagocytes and the dye-coloured plasma. The question of loss of dye from circulation and the possibility of incomplete admixture of the dye and plasma are discussed in relation to blood-volume determination. It is shown that dye passes in considerable amounts into the lymph, and that therefore the blood-volume figures also include part of the lymph and tissue fluids. This phenomenon doubtless explains in part the fact that the dye method gives figures which are larger than the carbon-monoxide or direct method of Welcker. Other reasons for this difference are discussed.

Abstract.

OXYURIS VERMICULARIS AS A CAUSATIVE FACTOR IN APPENDICITIS.[1]

By WILLIAM H. HARRIS, M.D., and DONOVAN C. BROWNE, M.D.

THE occurrence of *Oxyuris vermicularis* in the vermiform appendix of the human species has been frequently described in the literature. The description of parasites in this structure dates back to Fabricius, in 1634, and Santorini, in 1724. Metchnikoff was the first to lay stress on the relationship of intestinal parasites to appendicitis. Even though many reports, chiefly of single instances, have appeared from various centres, especially abroad, over a considerable period of time and form in their aggregate quite a voluminous literature, nevertheless, the rôle of the oxyuris as a causative factor of appendicitis has received little consideration. The reasons for such a condition are probably twofold: (1) The failure of proper clinical and pathological observations as to the extent of their occurrence in appendical involvements; (2) the difference of opinion existing relative to the pathogenic rôle played by these nematodes in such lesions.

[1] Abstracted from the *Journal of the American Medical Association*, February 28, 1925.

Unless the pathologist directs specific attention to the frequency of the occurrence of *O. vermicularis* and makes a careful examination of series of appendices with such a purpose in mind, hundreds of such structures will pass through the usual routine of pathologic examination, and such worms or their ova will not be observed. When, however, an appendix appears presenting a large number of oxyurids, they must of necessity be noted, even though the gross inspection has been of only a casual character. Such an occurrence alone, or the repetition of this happening, will often stimulate a more detailed observation of such structures, which will usually result in the finding of milder types of infection; that is, when lesser numbers of such organisms exist.

As observed in the series of instances here reported and as generally described by others, the oxyuris invasion has occurred especially in appendicitis clinically and pathologically of a subacute and chronic character. Excluding, therefore, the acute lesions which frequently require obligatory surgery, the question arises, if the casual relationship of oxyuris to the subacute and chronic types is finally accepted, whether the determination of the presence of these casual excitants classifies these particular cases into a medical rather than a surgical category.

The object of the present report is to record our observations of twenty-two appendices containing *O. vermicularis* in a series of 121 appendices presented in routine hospital laboratory examinations, together with the special consideration of the histopathology of those appendices in which *O. vermicularis* infection has been found.

Ætiologic Relationship.

The evidence of actual intramural invasion of the parasites into the mucosa and even submucosa of the appendix, with the destruction of tissue structure in their passage, indicates the capacity of the *Oxyuris* worm to produce pathologic changes of a degenerative character in the appendix. Like *Endamæba histolytica* or *Balantidium coli*, the manner in which the lesion is produced appears somewhat uncertain. Whether there occurs a mechanical destruction of structure or the production of a lytic substance capable of dissolving the cellular elements has not been determined. In either event, the parasites traverse from the lumen into the inner coats, and either *per se* or through the secondary bacterial invasions thus permitted, or by both methods bring about degenerative, and at times exudative changes. The latter exudate is usually representative of a chronic involvement, and thus produces the clinical manifestations that naturally emanate from such tissue changes. The fact that oxyuris worms may at times be found in the normal appendix does not negative the fact that they do actually produce disease of this structure either directly or conjointly.

Comment.

There exists a broad divergence of views relative to the ætiologic relationship of *O. vermicularis* to appendical lesions. There is also some variance in the character of cases presented. Frazier reports an acute case with the appendix filled with oxyurids, and regards the parasite as a predisposing cause occasioning blockage and favouring the invasion of *B. coli*. Innes and Campbell tabulate seventeen positive cases. They believe that the parasite produces the lesion, and conclude that there is probably a classic type of oxyuris appendicitis. Wood reports seven cases occurring in fifty-seven operations designating the condition as appendicopathia oxyurica. He considers that the oxyuris produces typical catarrhal lesions and at times nervous symptoms out of all proportion to the lesion. Romain states that the oxyuris enters into the appendix and causes disease through the inoculation of pathogenic microorganisms into the mucosa. Still states that 19 per cent. of healthy appendices of children harbour oxyurids. Cecil and Bulkley report a series of 129 unselected appendices of children, from 2 to 15 years of age, in which oxyurids were found in nineteen instances, or about 15 per cent. It is noteworthy that these authors observed the parasites only in acute instances. In fourteen, the histopathologic diagnosis was acute catarrhal appendicitis, and in three, acute gangrenous. In no instance was the appendix chronically inflamed. The change in the acute catarrhal types consisted especially of swelling of the follicles, with greater or lesser amounts of epithelial cell destruction. In some instances, however, they report cellular elements, such as eosinophils and lymphoid cells, which seem representative of subacute and chronic inflammation. These authors have reviewed the literature up to the time of their publication. Among other conclusions, they state that, "when oxyuris occurs in a diseased appendix, they are in most cases the existing cause of the pathological changes found." Since they consider the pathological condition present in the appendical lesions of children as acute, and as the greater number of instances reported in adults, including our own demonstrates a cellular and connective tissue response of a subacute and chronic variety, it is not unlikely that these infections may exist over a period of years and thus eventually demonstrate a histopathologic picture of a chronic type in later life. Like Cecil and Bulkley, we have observed the parasites in the lymphoid follicles creating no exudative response to the area, but with degenerative changes in evidence. At times exudative elements may be present about the nematode, but in these instances the presence of bacteria having a different chemitactic influence seems likely.

That the oxyuris produces pathologic changes in the vermiform seems indisputable. Their attachments to the mucosa, the hæmorrhagic ulcerations occurring at times about these attachments, and actual intramural invasion down to the musculature, and even penetrating this portion, with the destruction of tissue in their route of transit, form definite evidence of disease production. These changes usually provoke a clinical and pathological picture representative of a chronic and subacute form, as presented in such cases irrelevant of oxyuris invasion. That they may occur in the lumen of a normal appendix is also

evident, but that they remain in such a structure indefinitely without provoking pathologic changes is open to question, although it is conceivable that certain of these structures may not be vulnerable to the parasite. It is also probable that even in the absence of actual production of pathologic change, the oxyuris may at times give rise to appendicular colic. These later features, however, do not vitiate the fact that the oxyuris present in the appendix usually demonstrates a pathogenic rôle.

Whether or not the recognition of infection by the oxyuris in certain of the clinical cases of chronic appendicitis would save the patient from surgical procedure and place him within the power of medical therapeusis to heal seems still an open question.

In this connection Harnett reports a case wherein obscure symptoms existed with an eosinophilia of 10 per cent. Oxyuris was suspected, but the stool examinations were negative, even though santonin was administered. After operation, oxyuris was found in an inflamed appendix. Frazier reports an acutely inflamed appendix filled with oxyurids, which were crawling out of the open end. No worms could be found in the stool after operation, even though a course of calomel and santonin was given. Orton likewise reports an appendix somewhat thickened and slightly reddened, containing seventy-four adult female oxyurids and a number of males, in which the examination of stools after operation and following a laxative was negative for worms and ova. Wood does not consider that an anthelmintic could reach the worms and ova in the appendix. He considers that the danger of a delayed operation is greater than that of the operation itself. Armstrong believes that treatment directed against oxyuris infection may save the patient from operation.

A consideration of this phase of the subject appears to us to necessitate two subdivisions: First, in acutely inflamed appendices, even if oxyuris infection was known to exist, treatment with anthelmintics and purgatives would very clearly be contra-indicated. The lesion should be handled in a manner similar to acute appendicitis, due to any other cause. Second, in the obscure, low grade lesions with recurrent attacks, wherein the appendix is usually removed as a probable causative factor, it seems desirable that oxyuris infection should be primarily considered. In that event careful and repeated stool examinations should be made, and if found negative, similar examinations following the administration of an anthelmintic should be carried previous to operating. If infection of oxyuris is found present, specific treatment along this line seems in order. It appears possible, however, in the light of reported examples, that oxyuris infection may exist in the appendix and such examinations at times be negative.

In regard to the latter divisions, it must be appreciated that it may be possible to exterminate the oxyurids in the appendix, and especially those which have invaded the mural structures. Again, even though the parasites may be destroyed with treatment, the appendical lesion may possibly continue as the result of the pathological condition already set in motion and maintained because of concomitant bacterial factors that have secondarily invaded.

It appears logical that a proper opinion concerning the handling of the chronic cases, wherein oxyuris invasion of the appendix is considered, can be reached only after a series, with this specific purpose in mind, has been dealt with.

It seems remarkable that these parasites occur in the extent which they apparently do in the intestinal tract of even adult life. The frequency of the parasite in appendical lesions is also very striking. In France, Railliet reports fifty-eight infections in 119 cases of appendicitis, or 48 per cent., while Brumpt, in the same country, found oxyuris present in 3 per cent. of normal appendices and in 40 per cent. of all cases of appendicitis. In Germany, Hoepfl reports their presence in 19 per cent. of all cases of appendicitis. In England, Innes and Campbell report that 17 per cent. of inflamed appendices examined showed oxyuris infection. In this country, Cecil and Bulkley found 15 per cent., and we found approximately 17 per cent.

It is evident that insufficient attention has been given to the rôle played by *Oxyuris vermicularis* in the causation of appendicitis. This factor has been neglected by clinicians, surgeons, and pathologists. The oversight is especially attributable to the pathologist, for if a series of 100 appendices removed at operation for appendicitis are carefully studied for oxyuris invasion, the worms will most likely be found present in a considerable percentage of cases. Appendices, like tonsils and adenoids, when received in the laboratory, are usually given only a cursory gross examination and then sectioned for microscopic study. In this manner a great number of positive instances are not brought to light. Such an occurrence demonstrates the fact that it is of considerable importance to study the causation of the pathological condition of all structures sent to the laboratory, as well as the tissue changes produced by the process of disease.

Summary and Conclusions.

Infestation with *Oxyuris vermicularis* occurred in twenty-two appendices out of an uninterrupted sequence of 121 cases of operative appendicitis.

The study of the gross and histologic pathologic condition of the appendices containing the oxyuris demonstrates conclusively that these nematodes possess a definite pathogenic rôle in the causation of the appendical lesion.

The failure of recognition of the oxyuris as a factor in the production of appendicitis is due in general to the lack of detailed gross and microscopic study of the vermiform appendix.

It is important in all cases of chronic recurrent appendicitis to consider the likelihood of *Oxyuris vermicularis* as a causative factor.

Aside from the frequency of occurrence of the oxyuris in appendicitis, the widespread presence of these worms in the intestinal tract of adult life is not generally realized.

The observations on record of the frequent relationship of the oxyuris to appendicitis justify a more general and thorough study of this subject.

Current Literature.

The Indian Medical Gazette.
June, 1925.

A Note on the Disinfestation of Houses by Fumigation with Cresol (R. B. Lal and C. D. Tiwari).—These studies on the efficacy of fumigation with cresol were undertaken in August, 1924; the results were very favourable. Cresol fumigation, as ordinarily carried out, has no action on rats, but has a definite toxic action on rat fleas in muslin bags, free in the room, or on the bodies of the rats, but more than two ounces (quantity recommended by Colonel Lane) is required for ordinary sized rooms of 1,000 to 1,500 cubic feet capacity. Household furniture and rat runs afford effective protection to the fleas against the action of the vapour, even when the drug is used in large quantities. Fumigation with cresol tends to cause the fleas to leave their host. The toxic action of cresol vapour is more manifest at higher levels as compared with the floor level. Slightly better results are obtained by vapourising cresol on two heaps of smouldering cow-dung cakes instead of on one. The recommendations given to make the disinfection by cresol effective are: Remove all the furniture and sundries before disinfestation, and thoroughly expose them to the sun. Use ten ounces of cresol in an ordinary room of 1,000 cubic feet capacity. Preferably distribute the drug over two iron pans containing smouldering cow-dung cakes placed in different parts of the room. Some mechanical means should be arranged for preventing the vapour from directly rising up. Room should be carefully sealed before fumigation, and kept closed for four hours afterwards. Floor should be washed with phenyl lotion after the disinfestation is over, and rat runs should be fumigated with *neem*-cartridges and then closed.

Abdominal Tuberculosis in Indian Practice (E. W. C. Bradfield).—Cases of abdominal tuberculosis are not rare in India, as is shown by the records of the General Hospital, Madras. Of 205 cases admitted to hospital in 1924 for surgical forms of tuberculosis 95 were abdominal cases; this is a higher percentage than is found in the European general hospitals. The author believes that absence of bovine tuberculosis in the Madras Presidency influences the incidence and character of the disease in South India. Tuberculous diseases of bones and joints, though not so commonly seen as in European hospitals, pursue a much more intractable course and are less amenable to non-operative forms of treatment. The various types of tuberculous disease as met with in India are described and results of operations are given.

Yaws (Framboesia) in the Chin Hills (P. Bell).—Until the arrival of the author in the Chin Hills, 1923, many cases of yaws were being treated as syphilis. He clearly compares the two diseases clinically, and finds that a microscopical examination is unnecessary. The typical case is described as follows: Onset usually a small pimple at the margin of the anus, which bursts, spreads, and eventually involves the groin or private parts, some cases starting in the groin and on the labia majora. Some cases start with an ulcer as already described at the angle of the mouth. Two women stated that their breasts were affected first. No history of primary sore; sometimes whole families are affected. Males, females and children appear to be affected equally, though females mostly apply for treatment.

Report on a Visit to the Leper Island of Culion and on the Anti-Leprosy Work in the Philippine Islands (E. Muir).—From this interesting report it will be seen what valuable work has been carried on during the last nineteen years in the Philippine Islands with regards to leprosy. It was determined by the Americans in 1906, on their occupation of the Philippine Islands, to deport all bacteriologically positive lepers to Culion, an island about 200 miles to the S.W. of Manila, and since that year there has been a very considerable reduction in the prevalence of the disease. The author, who has had large experience of anti-leprosy work in India, compares conditions connected with leprosy in that country with corresponding conditions in the Philippines, and gives the methods to be adopted in both countries to bring about the entire disappearance of the disease.

Diabetes and Insulin Treatment in Bengal (Lal Mohan Ghosal).—Although at the present day much benefit is being derived from insulin in the treatment of diabetes, both in Europe and in America, the results with this product in Bengal appear to be very poor. It was thought that this might be due to the diabetes in Bengal not being due to pancreatic defect, and investigations were therefore carried out. The results were as follows: (*a*) With very marked pancreatic defect, even with a big tumour at the head of the pancreas, sugar was never detected in the urine in some cases. (*b*) Even with marked diabetes, pancreatic defect could not be found in some cases. Such patients are long lived, keeping good health throughout. None of them responded satisfactorily to insulin. (*c*) With pancreatic defect and glycosuria, the patients were always in bad health and there was evidence of rapid emaciation from the beginning; these are the cases that respond to insulin treatment. To obtain beneficial results from the use of insulin, cases of diabetes due to pancreatic deficiency should be selected; this may be done by using the following points as a guide: *Clinically*, the disease is of short duration and within a very short time the patient becomes very emaciated; the anæmia is very marked; the body fat is markedly reduced, leaving a skeleton-like appearance; dyspepsia is very troublesome; sleep at night is disturbed, sometimes there is no sleep the whole night; weakness is very marked; irritability of the temper is very prominent and there is general lethargy and lassitude. *Pathologically*, the pancreatic deficiency as shown by Cammidge's test is very marked.

Original Communications.

GONGYLONEMA.

By Louis W. Sambon, M.D.

Lecturer in the London School of Hygiene and Tropical Medicine.

In my first cancer paper, read before the Royal Society of Medicine, May 23, 1924, I explained how the peculiar topographical distribution of cancer in Romagna, the prevalence of the disease in the œsophagus and in the cardiac portion of the stomach, the constant presence of cockroaches, meal-beetles and cellar-beetles—all fosterers of the larval stages of *Gongylonema neoplasticum*—in the houses where cancer cases had occurred, led me to inquire whether gongylonema might not be a factor in the causation of certain neoplasms affecting the upper portion of the alimentary tract of man, as is well known to be the case in rats infested by this spiruroid worm.

I pointed out that already, in 1864, Professor Carlo Pane, of Naples, had described, under the name of *Filaria labialis*, a nematode found in the upper lip of a Neapolitan medical student, which, from the drawing of the worm accompanying his paper, I recognized to be a *Gongylonema*. I gave a list of the species of *Gongylonema* described to date, together with a short history of the genus and all available information concerning the cases of gongylonema infestation in man recently observed in the United States of America by Ward, Stiles and Ransom.

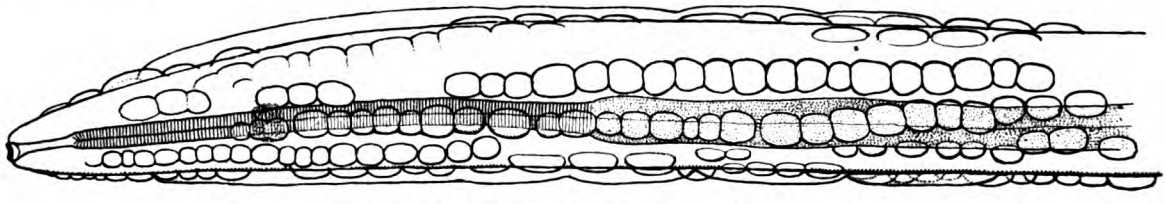
Since then considerable advance has been made in our knowledge of the genus *Gongylonema*. In the autumn of 1924, Dr. Baylis and I went to Northern Italy and we looked for *Gongylonema*, finding it in the cattle, sheep, goats and hogs of the Provinces of Trento, Bologna and Ravenna, where hitherto it had escaped notice. *Gongylonema* no doubt is distributed widely throughout Italy and neighbouring islands. It had been found by Professor Giulio Alessandrini, of Rome, in the sheep of the Roman Campagna and in cattle imported from the island of Sardinia.

A careful comparative study of the material brought back from Italy, and of other material kindly given or lent by Professor Henry, of the Ecole Nationale Vétérinaire d'Alfort, Mr. Frank Ware, of the Royal Veterinary College, Professor Johannes Fibiger, of Copenhagen, and Dr. Cesare Cappelli, of Bologna, enabled Dr. Baylis to invalidate certain names such as *G. scutatum* and *G. ransomi*, which, he considers, should be looked upon merely as synonyms of *G. pulchrum* Molin 1857. Already Professor A. Railliet, in 1892, had pointed out the great similarity between *G. scutatum* and *G. pulchrum*, but had cautiously reserved judgment until male specimens should be forthcoming. These were eventually found by Fayet at Tebessa in Algeria and sent to Professor Neumann, who, however, retained the two species, remarking that they were "*tout à fait voisines*," differing only slightly in size.

I am inclined to agree with Dr. Baylis as to the synonymy of *G. scutatum*, *G. ransomi* and *G. pulchrum*. The slight differences in body size, relative distance between certain parts of the body, acumination of posterior extremity, length of spicules, seem far too slender, far too variable to permit of specific distinction, but if constant in the same kind of host, they would indicate the establishment of "host-races." There can be no doubt that in parasites with wide zoological distribution, and especially in those whose life-cycle is spent in two alternating hosts—a vertebrate and an invertebrate brought into close association by peculiar biological conditions—the host environment may be more or less favourable and may determine certain adaptive modifications of size and shape in the parasite, just as variable œcological surroundings may cause colour and other variations in free-living species of wide geographical distribution.

In a paper on "The Hæmogregarines of Snakes," published in the *Transactions of the Pathological Society of London*, in 1907, I suggested for parasites the recognition of "host-varieties" or "host-races" corresponding to the so-called "geographical races" of free-living animals. When adaptation, to a new environment in the case of free-living animals, or to a new host in the case of parasites, becomes marked and constant then the differentiation acquires specific value, but the recognition of race has many advantages; it avoids a bewildering multiplicity of names and manifests the zoological distribution of the parasite, a matter of no little importance to the sanitarian in preventive work.

Often I had found considerable difficulty in writing up differential descriptions of certain hæmogregarines, leucocytozoa and other blood protozoa obtained from closely allied host-species, yet I was fully convinced of their specificness. My studies had taught me that hæmogregarines differ specifically in different host-species when the latter inhabit different zoological regions, and this specificness is supported by the far more easily determinable specific differences present in the several metazoan parasites simultaneously infesting these same host species. On the other hand, certain species of hæmogregarines, like certain species of metazoan parasites, may be found in a variety of hosts belonging not only to closely related species, but also to different genera or even families, provided the latter inhabit the same zoological region and are attacked by the same species of blood-sucking ecto-parasites.



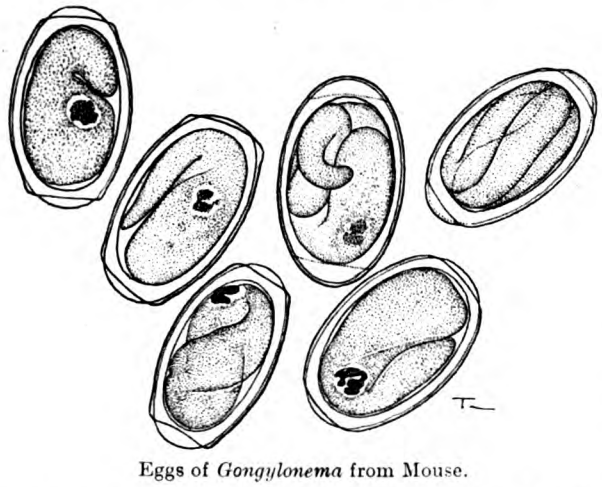
The specimens of *Gongylonema* with shorter spicule found in Algerian breeds of sheep and in the Indian buffalo can hardly be regarded as specifically different from those with longer spicule found in Italian breeds of sheep and in the Italian buffalo, originally imported from the East.

More difficult is the case of the rat gongylonema: *G. neoplasticum* of Fibiger and Ditlevsen, 1914. Here the difference of size is of little moment, but the difference in the length of the left spicule is so strikingly great that it seems to indicate specificness.

The first *Gongylonema* ever described—the type species of the genus—is *G. musculi*, a nematode found by Rudolph in the house mouse (*Mus mus-*

culus) " *circa ventriculum et in hepate*," and mentioned in his Synopsis (1819) without either description or figure.

Under the heading of " ? *Filaire de la Souris* " Dujardin (1845) states that a mature female specimen sent from Vienna to the Paris Museum, in 1816, measured 21·6 mm. in length by 0·154 mm. in thickness. It presented two lateral membranous alæ in the anterior portion and a tapering but blunt-ended posterior extremity. The elliptical ova measured 45 microns long by half that size in thickness. These characters, he thought, suggested a *Spiroptera*. Only two mice were found infested out of 1,274 examined.



Anterior extremity of female *Gongylonema* from Mouse.

It was the Italian helminthologist, Dr. Raffaele Molin, who first proposed, in 1857, the genus *Gongylonema* for this parasite, which he described under the name of *G. minimum*. His description was based on several specimens, male and female, some free, others embedded in a piece of liver, from which they were extricated with difficulty.

Molin's description is as follows:

" *Gongylonema minimum*— *Os* orbiculare, inerme; *Corpus* capillare, inerme, flexuosum, breve; extremitas anterior maris attenuata, apice nudo, obtuso, bulbillis parvis, coarctatis; *extremitas anterior feminæ* attenuata, apice obtuso, bulbillis, magnis, discretis; *extremitas caudalis maris* inflexa, sensim attenuata, subtus excavata, fovea elliptica, magna, utrique limbis amplis, singulus quatuordecim papillis elevatis, decem ante, quatuor infra aperturam genitalem, vagina penis dipetala; *extremitas caudalis feminæ* subito attenuata, inflexa; *apertura ani* propo apicem caudalem; *apertura genitalis feminæ* in posteriore corporis parte, ab apertura ani remota— Longit. mar. 4″ (8·8 mm.); Longit. fem. 8″ (17·5 mm.)."

Eggs of *Gongylonema* from Mouse.

Molin adds that examining the sheath of the penis, at first sight it appears to be a ligulate sheath, but lightly compressing the caudal extremity of the male between two slides the said organ spreads apart into two branches like a forceps and, being released, at once returns to its former shape. The female's long oviduct was full of embryonated eggs.

Speaking of Dujardin's brief description of this gongylonema, Maurice C. Hall (1916) says, " Dujardin notes a specimen from Vienna as having two cervical alæ. This would suggest that he was not dealing with gongylonema." But the presence of cervical alæ more or less developed and often festooned is characteristic of gongylonema. On the other hand, the presence of this parasite in the liver, noted in the Vienna Museum catalogue and also reported by Molin, to my mind suggests confusion between *Gongylonema and Hepaticola*.

While studying gongylonema infestation of rats in Holland with a view of determining their rôle in the ætiology of gastric carcinoma, Dr. Wassink found this nematode in mice from an Amsterdam sugar refinery which was free from rats. He has kindly given me one of his mouse specimens, a mature female measuring 89 cm., which I cannot in any way distinguish from *G. neoplasticum*.

During the early stage of the formation of the embryo the eggs seem to consist of a thick barrel-shaped shell, containing the embryo enclosed in a vitelline membrane, which appears to protrude at the poles. The shell here, if formed at all, is very thin; later, however, by the time the embryo is fully formed, the shell at the poles becomes of almost equal thickness with the barrel-shaped portion, and the lines of demarcation become almost invisible (see fig.). Dr. Baylis has observed the same appearances in the ova of Alessandrini's human specimens and in those of the gongylonema of ruminants.

In 1914, Seurat described, under the name of *G brevispiculum*, a gongylonema found in the cardiac region of the stomach of the dwarf jerboa (*Lipodillus campestris*) in Algeria. His description and figures seem to agree with, and show only slight differences from, *G. neoplasticum*, and Hall says: "The principal and almost the only feature which distinguishes this species from *G. neoplasticum* is the presence of additional caudal papillæ in the male. The posterior extremity of *G. neoplasticum* is

figured with the bend to the left, which also occurs in *G. brevispiculum*. It appears quite possible that Fibiger and Ditlevsen (1914), in their excellent study of *G. neoplasticum*, may have overlooked some papillæ, and that a restudy will show that *G. brevispiculum* must be regarded as a synonym of *G. neoplasticum*. Until this point has been determined it will be safer to retain the two species, keeping in mind the possibility that they are identical. The fact that *G. neoplasticum* has been developed in such hosts as the rat, rabbit and guinea-pig, one of which is a notorious wanderer and cosmopolite, speaks for their identity in connection with their other features in common.

In the *Journal of Comparative Pathology and Therapeutics*, March, 1925, Dr. Baylis redescribed *G. verrucosum* (Giles, 1892), a gongylonema found by Lieut.-Col. G. M. Giles in the rumen of sheep in India, and later in an Indian ox (*Bos indicus*). He points out that Neumann's description of this species is erroneous, in that instead of the cuticular bosses being limited to the dorsal surface, as Neumann thought, they are confined to the left side of the body, ceasing abruptly at the mid-dorsal and mid-ventral lines, and that the single ala described by Neumann in his specimen is not dorsal but lateral, the ala of the right side being absent or, at all events, extremely reduced. Baylis points out that this kind of asymmetry is not unparalleled among parasitic nematodes. He cites the examples of *Streptopharagus* and *Arduenna* (genera probably not very distantly related to *Gongylonema*), where there is a single cervical ala on the left side. Among free-living nematodes even more striking examples of asymmetry may be found. In bunonema, for instance, there are one or two rows of large wart-like cuticular tubercles on the right side of the body only.

Dr. Baylis's description of *G. verrucosum* is based on female specimens collected by Mr. Frank Ware, F.R.C.V.S., in India. One measured 78 cm. in length and 0·45 mm. in thickness, another 88 cm. in length, 0·44 mm. in thickness. The ova measured 0·055 by 0·032.

G. spirale is the name given by Molin to a single male specimen of gongylonema found in the fallow deer (*Dama dama*). Neither his description nor his figures are of any value for diagnosis. *G. spirale* is probably a synonym of *G. scutatum*.

The same may be said of *G. filiforme* Molin 1857, found by Bremser beneath the tongue of the magot or Barbary ape (*Macacus inuus*). Neumann considered it "*très voisin de G. scutatum.*"

Rudolphi (synopsis 1819) mentions, under the name of *Spiroptera ursi*, certain nematodes twice found in the œsophagus of the brown bear (*Ursus arctos*) at Vienna. Dujardin (1845) states that they measured from 27 to 43 mm., were very slender, narrower anteriorly, the anterior extremity small with mouth orbicular, the posterior end (male ?) depressed, slightly blunt, fringed by a membrane which "*dans un seul individu, était beaucoup plus large.*"

Molin (1860) describes this species under the name of *G. contortum*.

In the *Journal of Tropical Medicine* (February 2, 1925), in a note following the publication of my Paris lecture on cancer, I stated that Prof Giulio Alessandrini, of Rome, had briefly reported, in 1914, a case of gongylonema infection in a young woman of Saracinesca, near Rome. Six worms were present, occupying sinuous galleries at the base of the tongue and about the frenum linguæ. Alessandrini suggested the name of *G. subtile* for this parasite, which he considered to be near *G. pulchrum*, but differing from it in being longer, more slender, the studded anterior portion more extended and the eggs smaller and more elongate.

A few weeks ago Prof. Alessandrini came to London to attend the Conference on sleeping-sickness and brought with him two of the three gongylonemas he had been able to obtain from the Saracinesca case. These worms differ in no way from specimens of *G. scutatum*, which are very common in the sheep of the Roman Campagna. Dr. Baylis has examined them very carefully and describes them fully in his paper.

I owe to my friend Prof. Alessandrini the following notes on his interesting case:—

The patient, I. O., a girl of eighteen years of age, had spent the first eight years of her life at Saracinesca, a hill village by the river Aniene, between Tivoli and Mandela; thence she had moved to the neighbouring village of Sambuci for about six years, then back to Saracinesca for two years, then to Tivoli for one year, and finally to Rome in March, 1913. On August 1, 1912, after a sojourn of ten months in Tivoli, the girl felt something like a hair in her mouth and drew out a worm which she threw away. A second worm she drew out on October 2, 1912, whilst at Saracinesca; a third at Tivoli on November 3, 1912, which was preserved by Dr. Allegri, of Tivoli, who had been consulted. The fourth worm was extracted also at Tivoli, but thrown away, the fifth was drawn out in Rome on April 5, 1913, and the sixth also in Rome on July 14, 1913. The last two worms were collected by Dr. Carrega, who gave them to Prof. Alessandrini for determination. The worms occupied sinuous galleries beneath the epithelium of the buccal mucosa, one at the base of the tongue, the others about the frenulum. Whenever the parasites protruded from their galleries, the patient felt the unpleasant sensation of having something like a hair in her mouth and endeavoured to draw it out, but the worm at once made resistance and usually, slipping through her fingers, withdrew into its gallery to protrude again later.

The patient was otherwise perfectly healthy, her menses had appeared at the age of 16½, and she had been regular until January, 1913, then irregular. She had suffered from eclampsia in her childhood. The mother had died of a tumour. Her father lived and was healthy, she had a brother and a sister both in good health.

During a short trip to Holland last spring, Dr. Bonne, Director of Laboratories in the Dutch Cancer Institute, kindly informed Dr. Reeser, Superintendent of the Amsterdam Municipal Slaughter House, that I should like to visit the

abattoir and possibly look for the presence of *Gongylonema* in Dutch breeds of cattle, sheep and hogs. When, on April 24, I called on Dr. Reeser, he informed me that Dr. Veenstra had opened up a large number of gullets of cattle and found the parasite in one. This was the first time that gongylonema was looked for and found in the land of the beautiful black and white cattle of Friesland, which are believed to be the direct descendants of the ancient Aurochs. Together with Drs. Reeser, Bonne and Veenstra, I examined many other gullets of cattle, sheep and hogs, but with negative result. At the Harlingen and Leeuwarden slaughter houses, with the aid of the local veterinarians, Dr. Bonne and I examined the œsophagus of about sixty sheep, but there again the result was negative. In one of the sheep examined there was the most intense infestation of sarcosporidia I had ever seen.

The gongylonemas found at the Amsterdam abattoir were typical specimens of *G. scutatum;* they numbered about twenty in the same gullet, males and females.

The distribution of *G. scutatum* seems to be almost as wide as that of its cattle hosts. It has been reported from North and South America, from many parts of Europe and Asia, from Africa and Australia. *G. neoplasticum* has a distribution as wide if not wider. Quite recently S. Yokogawa has described it from Formosa under the name of *G. neoplasticum var. orientale*, and as giving rise to a cancroid growth in rats.

SOME NOTES ON NEMATODE PARASITES FOUND BY Dr. WASSINK IN RATS AND MICE.

By H. A. Baylis, M.A., D.Sc.,

Department of Zoology, British Museum (Natural History).

(Published by permission of the Trustees of the British Museum.)

In an interesting paper by W. F. Wassink (1916), the observations previously made by Fibiger and Ditlevsen on the *Gongylonema* of rats have been confirmed and extended. Out of 625 brown rats caught in Amsterdam, none showed evidence of the presence of *Gongylonema*, but ninety-nine were found to harbour a worm in the stomach, which is referred to as a *Trichosoma* (i.e., *Capillaria*), and probably the same species as that observed by Fibiger (1913) in some of his rats in Denmark.

On the other hand, out of a further 625 rats caught in ships lying in Dutch ports, which had made voyages either to South America or the East Indies, five (all believed to be of South American origin) were found to be infected with *Gongylonema*. In addition to these, the stomachs of forty rats (*Rattus norvegicus* and *R. rattus*) were obtained from Paramaribo, Surinam, and sixteen of these contained *Gongylonema*.

Cockroaches (*Blatta orientalis* and *Blattella germanica*) obtained from several localities in Amsterdam, including a bakery and one sugar refinery, were also examined, and were found free from the larvæ of *Gongylonema*. In another sugar refinery, however, about one in every seven cockroaches (*B. orientalis* and *Periplaneta americana*) was found to contain *Gongylonema* larvæ. No rats, curiously enough, were known to occur in this refinery, but on obtaining and examining ten mice from the premises, Wassink discovered *Gongylonema* in six of them. By feeding rats with some of the cockroaches, the worm was shown to be capable also of infecting rats, and was determined as *G. neoplasticum*.

Specimens of *P. americana* obtained from Surinam, from the same locality as the infected rats already mentioned, were found to contain larvæ of *Gongylonema*. It is not stated whether larvæ were present in cockroaches from the ships coming from South America, but they were not found in those from ships coming from the East Indies.

These observations, as Wassink says, seem to lend support to the view expressed by Fibiger that the *Gongylonema* of rats has been introduced into European sugar refineries in cockroaches imported with raw sugar from the West Indies or America.

During a recent visit to Holland, Dr. Sambon was able to obtain, through the kindness of Dr. Wassink and of Dr. C. Bonne, the loan of specimens of the worms referred to in the former's paper, some of them being part of the actual material studied by Wassink. These specimens Dr. Sambon very kindly handed over to the writer for examination, and a few brief notes on them may be of some interest.

(1) *Hepaticola hepatica* (Bancroft, 1893). — The worms referred to as *Trichosoma* unquestionably belong to the same species as those obtained by Dr. Sambon and the present writer in Italy, and, as mentioned in an earlier paper (Baylis, 1925), determined as *Hepaticola hepatica*. Although this worm has usually been observed in the liver, it evidently not infrequently takes up a position in the pavement-epithelium of the anterior portion of the stomach, where its galleries contain masses of eggs like those found in the spaces excavated by the worms beneath the capsule of the liver.

(2) *Gongylonema* from rats and mice.—The material available consisted of mounted microscopic preparations of some of Dr. Wassink's specimens from rats (locality not specified) and one from a mouse, also a considerable number of spirit specimens obtained later by Dr. Bonne from rats from Paramaribo, Surinam.

Among the mounted specimens from rats there was unfortunately only one male. There were three female specimens, all fragmentary. The male specimen was obviously immature, the bosses at the anterior end being as yet quite undeveloped, and the accessory piece not yet chitinized. Two of the females, besides having lost their anterior ends, were mounted in Canada balsam, an unsatisfactory medium for most nematodes, and it was therefore thought inadvisable to pay any special attention to their measurements. Measurements of the single male, and of the anterior portion of one female, both mounted in a glycerine medium, are given in the table below.

The single specimen from a mouse was a mature female, whose measurements, so far as they could be obtained from the mounted worm, are also tabulated.

MEASUREMENTS (IN MM.) OF DR. WASSINK'S SPECIMENS OF *Gongylonema*.

Host	Rat		Mouse
	♂	♀	♀
Length	12·3	—	89·0
Maximum thickness	0·25*	—	0·36
Anterior end to end of œsophagus	2·8	4·8	6·0
,, ,, end of muscular portion of œsophagus	0·47	0·55	0·9
,, ,, cervical papillæ	—	0·143	0·15
,, ,, commencement of alæ	—	0·185	0·213
,, ,, nerve-ring	0·2	0·22	0·3
,, ,, excretory pore	—	0·45	—
Length of tail	0·17	—	0·3
Diameter of buccal rim	—	0·025	—
Length of pharynx	0·065	0·055	0·07
Cuticular striations, distance apart	0·005	0·01	0·02
Length of spicules, left	0·65	—	—
,, ,, right	0·1	—	8·4
Vulva from posterior end	—	—	—
Ova, length	—	+	0·0625-0·065
,, breadth	—	+	0·0375-0·04

* Specimen somewhat flattened under cover-glass pressure.

† In the portion of uterus available in this specimen, none of the eggs contained fully-formed embryos.

They show no departure from the usual dimensions of *Gongylonema neoplasticum*, except in the unusually long distance between the vulva and the posterior extremity. The position of the vulva, however, is subject to considerable variation in *Gongylonema*, and cannot be regarded as of specific importance.

The material from Paramaribo was obtained from eight different rats, and included a number of males, sixteen of which were measured. The lengths of the left spicules of these sixteen specimens varied between 0·3 and 0·64 mm., and the total lengths of the worms between 7·1 and 12·5 mm. Their other dimensions, and those of the females measured, fall between the extremes already observed for *G. neoplasticum*, as tabulated in the writer's earlier paper (1925), and further description is unnecessary. Some of the male worms were obviously immature, as shown by the imperfect development or absence of the cuticular bosses at the anterior end, and the feeble degree of chitinization of the accessory piece. It is significant, however, that none of the sixteen specimens showed a left spicule of more than 0·64 mm. in length. In the specimens from rats hitherto measured, the length of this organ has never been found to exceed 0·67 mm., a fact which, in spite of general agreement in morphological features (see the writer's earlier paper), makes it difficult to assume that the *G. neoplasticum* of rodents is specifically identical with the *G. pulchrum* of other hosts. Experimental evidence seems to be required before it can be decided whether or not we are here dealing with more than one species or race.

It may be mentioned here that while in Holland Dr. Sambon had the good fortune to obtain, at the slaughter house at Amsterdam, the œsophagus of an ox containing several specimens of *Gongylonema*. These have also been examined by the writer, and have been found to differ in no respect from the examples of *G. pulchrum* (= *G. scutatum*) already obtained from Italy and elsewhere.

OBSERVATIONS ON THE CULTURAL AND BIOCHEMICAL CHARACTERS OF *MONILIA CASTELLANII* (*CRYPTOCOCCUS CASTELLANII*) AND *MONILIA MACROGLOSSIÆ* (*CRYPTOCOCCUS MACROGLOSSIÆ*).

By SERGIO RE, M.D. Turin,
House Surgeon, Italian Hospital, London.

Monilia castellanii (*Cryptococcus castellanii*).—Castellani has made the observation that certain cases which clinically have all the appearances of ordinary severe furunculosis are in reality caused by yeast-like fungi, the staphylococcus playing only a secondary rôle. For the condition he suggested the name of "Furunculosis cryptococcica"; and as it principally affects the scalp, causing a purulent folliculitis, he also used the term "*folliculitis decalvans cryptococcica*." He has observed five cases: three contracted the affection in England and two in India. From the three English cases he isolated a yeast-like organism, identical in all the three cases, of which he has given a full description. He has, however, not named the organism, and I would suggest that the fungus be called *Monilia castellanii*. I will give later the reasons why I consider the organism to belong to the genus *Monilia* rather than to the genus *Cryptococcus*.

As regards the cultural characters of this organism, my work confirms the investigations carried out by Castellani. It is a yeast-like organism, Gram-positive, not acid-fast. It grows well on all ordinary laboratory media and very abundantly on glucose agar. On this medium the growth is at first white, but after a few days a peculiar, well marked, yellowish-brownish pigmentation with occasionally a reddish tinge appears. Gelatine and serum are not

Remarks	Growth on glucose-agar is white at first, then yellowish-brownish. No discoloration or only very slight in lead-agar	Growth on glucose-agar is permanently white. Usually well marked dark or black discoloration in lead-agar

liquefied. Litmus milk may be rendered slightly acid, but is not clotted. As regards sugar reactions, the fungus when recently isolated may not produce gas in any sugar, although it generally produces a slight acidity in glucose; after several transplantations, however, it usually ferments glucose and levulose with production of acid and gas. When grown on lead-agar no black discoloration of the medium is observed, or only a very slight one.

Botanical position of the fungus.—I follow Castellani's and Chalmer's classification of yeast-like fungi. The fungus is yeast-like, but no ascus formations are seen even in very old cultures. It should therefore be placed in the division of yeast-like fungi with no ascospores. This division contains the genera *Cryptococcus* Kützing 1833, *Torula* Persoon 1801, *Mycoderma* Persoon 1822, *Monilia* Persoon 1879, *Pityrosporum* Sabouraud 1895, which may be differentiated as follows:—

(A) *Mycelium absent*:—

(i) Vegetative cells, elongated, thick membrane, with bubbles of gas—*Mycoderma*.

(ii) Vegetative cells, roundish or oval:—

(*a*) *Several buds at a time*, each cell contains large globule of fat, non-pathogenic, no fermentation of sugars, thick membrane with no gas bubbles, often pigment-producing—*Torula*.

(*b*) *One bud only*, no thick pellicle on fluid sugar media, presence or absence of fermentation—*Cryptococcus*.

(*c*) *Not cultivated*, cells never show a double contour—*Pityrosporum*.

(B) *Mycelium present—Monilia*.

The yeast-like fungus isolated by Castellani in cases of pseudo-furunculosis generally appears under the shape of oval or roundish cells, some of which are budding; Castellani was, therefore, justified in placing it at first in the genus *Cryptococcus*, especially as the fungus at first had very little or no fermentative action on glucose. When grown, however, in certain liquid media a small amount of mycelium develops, and, moreover, the fungus after a time acquires a fermentative action on glucose and levulose. I am inclined, therefore, to place the fungus in the genus *Monilia*.

The genus *Monilia*, as understood to-day by medical mycologists, does not correspond to the original genus *Monilia* as defined by Persoon "Stipitata aut effusa byssoidea. Fila moniliformis articulata." The term Monilia has been greatly extended, especially by Pinoy, Castellani, and others, to cover every yeast-like organism having no ascospores and showing presence of mycelium, even in very small amount, in certain media.

Monilia macroglossiæ (Castellani).—From certain cases of blastomycetic macroglossia, Castellani has isolated from the deep parts of the lesions a yeast-like fungus which he called *Cryptococcus macroglossiæ* (*Monilia macroglossiæ*). The investigation I have carried out on this fungus has confirmed in a general way Castellani's description. The fungus is a yeast-like organism which is Gram-positive and not acid-fast. It grows well on all ordinary laboratory media, best on glucose-agar. Gelatine and serum are not liquefied. In litmus milk there is no change. When grown on lead-agar a well-marked black or dark discoloration, as first noted by Castellani, is generally produced. The fungus, even when it has been transplanted many times, does not appear to acquire any fermentative action on glucose or other sugars.

Botanical position of the fungus.—As mycelium though in small amount, is often present when the fungus is grown in certain liquid media, I consider the fungus to be a monilia rather than a cryptococcus

C = clot; G = gas; S = slight; O = negative result, viz., non-production of gas in sugar media, or of clot in milk, or of liquefaction in serum and gelatine; + = positive result.

as at first believed by Castellani. As it does not produce gas in any sugar it belongs to the *Monilia zeylanica* group. It differs from *Monilia zeylanica* in the cultures being white, and from *Monilia zeylanoides* in producing a well defined dark or black discoloration in lead-agar.

Conclusion.—My investigation on the cultural and biochemical characters of *Monilia* (*Cryptococcus*) *castellanii* and *Monilia* (*Cryptococcus*) *macroglossiæ* confirms the description of these two fungi by Castellani. As regards their botanical position, I am of the opinion that as in certain media mycelium is present although in very small amount, both fungi should be placed in the genus *Monilia sensu lato*, in the meaning of Pinoy and other mycologists, rather than in the genus *Cryptococcus*, as originally suggested by Castellani.

A Survey of the Turpentine Industry for Possible Larvicidal Instances (M. E. Barnes, *American Journal of Hygiene*, May, 1925).—Among the raw materials, products and by-products of the turpentine industry which were studied, larvicidal properties in sufficient strength to merit further investigation were found only in turpentine and in pine oil. Turpentine, after standing for some time, was found to be effective against both anopheles and culicine larvæ. It is too expensive, however, to be employed in anti-mosquito work. Pine oil was found to be effective against both anopheles and culicine larvæ and was further studied. The results of this study are incorporated in a separate paper, "The toxic action of oil films upon mosquito larvæ, with particular reference to pine-oil films."

Two New Cases of Human Creeping Disease (*Gnathostomiasis*) *in China, with a Note on the Infection in Reservoir Hosts in the China Area* (K. Morishita and E. Carroll Faust, *Journal of Parasitology*, March, 1925).—Five indisputable cases of human gnathostomiasis have hitherto been reported. Four of these are referable to *Gnathostoma spinigerum* and one to *G. hispidum*. Two new cases of human gnathostomiasis from China are added. The new cases deal with very young forms, one of which caused a typical "creeping disease." The other may have also caused the same disease. Four cases of gnathostomiasis interna are recorded from dogs and cats in China. Three of these were found in cats and one in a dog. One cat was autopsied in Pekin. The other infections occurred in the Hankow area.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these, with remittance, is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 ,, ,, ...	1	3	3
200 ,, ,, ...	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 ,, ,, ,,	2	6	0
200 ,, ,, ,,	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

FREQUENCY OF INTESTINAL FLAGELLATES IN TEMPERATE CLIMATES.

NOT very long ago the belief was general that intestinal flagellates were common in tropical and sub-tropical countries, but rare in the temperate zone. Observations carried out in recent years, especially during and after the Great War, 1914-1918, have clearly shown that the distribution of intestinal flagellates is cosmopolitan, although it may be said in a general way that the incidence of these parasites is greater the nearer one approaches the Equator.

Flagellates are of common occurrence in every country of Europe and America. Le Noir and Deshiens in a very interesting paper published recently in the *Archives des Maladies de l'Appareil digestif*, give the results of an investigation they have carried out in a thousand patients in the out-patients department of one of the Paris hospitals. They have found that 17 per cent. of the patients harboured *Chilomastix mesnili* and *Trichomonas intestinalis*; *Lamblia intestinalis* was also fairly often met with.

Several authorities have recently again raised the question of the pathogenicity of flagellates; and the suggestion has been made that they may be responsible for certain cases of obscure disorder of the digestive canal; cases of so-called flagellate diarrhœa have been placed on record by many observers, but some authorities are rather sceptical about the flagellates being the real causative agents of the condition.

Castellani and Chalmers, some years ago, came to the conclusion that flagellates when present in small numbers are probably harmless, but when present in huge numbers, as is at times the case, they are capable of causing intestinal disturbances.

The eradication of intestinal flagellates by means of drugs is most difficult. Methylene blue, first introduced by Castellani, seems to be useful in the case of trichomonas and chilomastix infections, but has no action on lamblia. Thymol, B. naphthol, turpentine, iodoform have been recommended. Recently stovarsol has been used, but the results have not been constantly favourable.

YERBA MATÉ.

Yerba maté is the usual South American term given to the infusion prepared from the leaves of *Ilex paraguayensis*, St. Hilaire. The leaves are previously slightly scorched, then broken down and subjected to strong pressure. A handful of this pressed foliage is infused in a small vegetable gourd shell called a *maté*, from which it is sucked hot or cold through a reed or metal tube about 10 in. long which is called the *bombilla*. At other times a small spouted vessel is used, the spout being perforated at its lower side with small holes which allow the fluid to escape while retaining the leaves. The infusion is passed round and several people drink it, using the same *bombilla* and this habit is considered by many observers to be an important means of spreading espundia, yaws, syphilis and angiofibroma contagiosum tropicum.

It is estimated that more than eighteen millions of people in South America drink maté as tea. There are several varieties of yerba maté; the best is the original Paraguayan. The Brazilian variety known also as *herva matte* is rather bitter and not so pleasing to the palate; it is prepared by using the crushed and fermented leaves of *Ilex gongonha* Martius and *Ilex theœzans* Martius. Maté is con-

sidered in the Argentine, Paraguay and Brazil to be a health-giving drink; to ward off rheumatism and to produce an exhilarating and at the same time soothing effect on the nerves. It is also considered to have very sustaining properties. The "gauchos" for instance, who work the whole day on the Argentine ranches rounding up cattle, do this often on nothing more than a cup of maté in the morning and another at midday. It is the principal beverage of all the rural working classes in the Argentine, in Paraguay and Brazil. Attempts have been made recently to popularize maté drinking in North America and Europe but so far with very little success. Although maté is a good beverage and containing very little tannin would suit meat eaters, yet it is very unlikely that it will ever supplant, even partially, tea drinking in these countries.

Annotations.

Significance of a Hæmoptysic onset in Tuberculosis (F. H. Trudeau, M.D., *Journal of the American Medical Association*, June 13, 1925).—In a study of 245 patients entering the Trudeau Sanatorium between the years 1911 and 1922, and having hæmoptysis as the first symptom, it was found only 10, or 4 per cent., failed to show other evidence of tuberculosis. One hundred and forty-nine, or 60·81 per cent., had a positive sputum, either while in the sanatorium or prior to entrance. One hundred and seventy-one, or 69·83 per cent., had definite parenchymatous Roentgen-ray findings. In 196, or 80 per cent., persistent râles were heard in the upper portion of the chest. Ten, or 4·08 per cent., had had at some time pleurisy with effusion, or developed this condition while in the institution. The prognosis in this type of case is no better or worse than in any other mode of onset of this disease.

Complaints of Patients under Antileprosy Treatment—III. Comparison of Creosoted and Non-Creosoted Chaulmoogra Ethyl Ester Preparations (H. W. Wade, *Philippine Journal of Science*, January, 1925).—Duration of the disease, which averages 8·3 years in the cases under treatment, seems to have little influence on the total incidence of complaints in lepers under treatment, though certain types of complaint tend to increase and others to decrease. There is indication that, in the interest of intensive treatment, it is better to give higher dosage than to depend upon regular injections, at least in a large colony. Plain chaulmoogra ethyl esters are again shown to be decidedly the least favourable of the preparations used as regards treatment factors, frequency of total complaints, and most of the complaint types. The addition of creosote (10 per cent. has been used here) to plain chaulmoogra ethyl ester reduces the local irritation to almost, though not quite, the same degree as does 0·5 per cent. iodine, and permits increased medication. The simple iodized drug is somewhat, though not markedly, better than the simple creosoted as regards amount of medication and frequencies of complaints. Which is to be preferred will depend on a comparison of the therapeutic effects. The combination of creosote and iodine has no distinct advantage and has certain disadvantages because of which its use is not justified unless it has an unexpected therapeutic superiority. The only noteworthy drawback for the creosoted preparations is an apparently greater tendency to cause respiratory-tract irritation. However, this indication may be due to a possible selection of cases showing evidence of pulmonary disease for treatment by these preparations, and must be controlled by further observation.

An Institutional Outbreak of Scarlet Fever. The Skin Test for Susceptibility (Alex. F. Robertson. Junr., M.D., *Journal of the American Medical Association*, June 13, 1925).—The use of the skin test for susceptibility to scarlet fever is of value in the management of an institutional outbreak Negative reactors occasionally develop scarlet fever. The immunity resulting from an attack of scarlet fever usually renders the skin test negative. Pseudo-negative reactors should be re-tested before final tabulation of results.

The Viability of Typhoid Bacilli in Shell Oysters (Edwin O. Jordan. *Journal of the American Medical Association*, May 9, 1923).—Shell oysters artificially contaminated with typhoid bacilli by floating for one hour in sea water to which typhoid bacilli had been added and then placed at ice-box temperature (from 5° to 8° C.) were found to contain living typhoid bacilli for as long as twenty-four days. There was no evidence of multiplication, and after the first few days a diminution in numbers was plainly apparent. Of the three strains used, one was found to survive to the twenty-first day, one to the twenty-second, and one to the twenty-fourth.

Therapeutic Action of Potassium Iodide in Experimental Syphilis of the Rabbit (Louise Pearce, *Archives of Dermatology and Syphilology*, July, 1925).—The regular administration at bi-weekly and weekly intervals of small doses of potassium iodide (0·006 and 0·003 grm. per kilogram) to rabbits infected with *Spirochæta pallida* has resulted in modifying the severity and in shortening the duration of the experimental disease as measured both by the character of the primary orchitis and of the general manifestations. The disease which developed in the rabbits treated with iodide resembles in many ways that of normal rabbits of relatively high resistance in which few or no secondary lesions arise. It is suggested that the therapeutic action of potassium iodide in experimental syphilis of the rabbit is associated with a stimulation or a reinforcement of the host's mechanism of reaction or defence.

Cosmetics (Hiram E. Miller, M.D., and Laurence R. Taussig, M.D., *Journal of the American Medical Association*, June 27, 1925).—Sufficient emphasis has not been placed on the usual components of cosmetics and the dermatoses that they may provoke. Many of the so-called eczemas in women, if carefully investigated, will be found to be cases of dermatitis venenata due to cosmetics. The aniline dye used as colouring matter in the bizarre tints of face powder, rouge and lip stick may cause a definite dermatitis. Hair dyes containing the vegetable pigments are seldom harmful, while those containing the minerals or aniline products may cause skin eruptions or general ill-health. The attempted removal of wrinkles by applying phenol to large areas of the skin surface may cause considerable facial deformity and even death. A dermatitis on the sides of the neck in women may be due to irritation from recently applied liquid nail polish that comes in contact with the neck when the patient sleeps with the hands under the face. Legislation should be enacted prohibiting the use of the aniline dyes in the manufacture of cosmetics, and the application of phenol for the removal of wrinkles by unlicensed charlatans and beauty specialists.

Mercurochrome-220 Soluble in Genito-urinary Diseases (F. H. Redewill, M.D., and James E. Potter, M.D.), *Journal of the American Medical Association*, June 20, 1925).—Mercurochrome-220 soluble is considered one of the most important new remedies for use in intravenous medication. This drug is excreted in large quantities by the kidneys and also secreted through the prostate, seminal vesicles and other glands of the genito-urinary tract. Thus this dye comes in direct contact with the inflamed areas of this tract, by way of the urine and blood-stream. To obtain the best results, this remedy should be given in small doses to avoid a too early saturation. Patients who respond best to intravenous mercurochrome injections have mild reactions. Acute rheumatism, synovitis, myalgia, neuritis, arthritis, and other manifestations as a result of absorption from the prostate and seminal vesicles as sites of focal infection have cleared up on the intravenous administration of mercurochrome. A large number of acute gonorrhœal urethritis, epididymitis, prostatitis and seminal vesiculitis cases cleared up rapidly with this medication. The drug should be freshly prepared and given every forty-eight hours. Given judiciously, mercurochrome has proved to be one of the most efficient remedies used in ambulatory cases; patients can be treated in the dispensary and the clinic.

Expressed prostatic fluid and seminal fluid has decided bacteriostatic action. Patients showing a hypersensitiveness for intravenous mercurochrome injections will secrete a proportionally greater amount in the saliva and gastro-intestinal tract than by way of the kidneys. By the use of diphenylcarbazid test of mercury in the seminal fluid, and the mercurochrome kidney function test, it is possible with the first intravenous mercurochrome injection to detect patients that are not suitable for the continuous use of this drug.

Shoe Dye Poisoning (C. W. Muehlberger, Ph.D. *Journal of the American Medical Association*, June 27, 1925).—A survey of the medical literature indicates that nitrobenzene or aniline poisoning resulting from the use of shoe dyes is a common occurrence. Reports of forty-seven cases previously published from Europe and the United States during the last twenty years have been collected. Nine new cases of shoe-dye poisoning are reported. Six of these cases are known to have resulted from the use of shoe dye that contained aniline instead of nitrobenzene as the solvent. These are the first cases of aniline poisoning from shoe dye to be reported in the United States. The chemical analyses of four commercial preparations of black shoe-dye are given. All these were found to contain nitrobenzene or aniline. The most important symptom is cyanosis without apparent cause occurring in a previously normal person. Other less important symptoms are vertigo, headache, weakness and nausea Shoes should be removed and the patient kept in bed until the cyanosis clears. Oxygen inhalation is without effect on the cyanosis. The only way that this type of poisoning can be adequately prevented is by State or National Health regulations prohibiting the manufacture and sale of toxic shoe dyes. It is recommended that nitrobenzene and aniline be replaced by non-toxic solvents in order to eliminate the danger of poisoning.

Diphtheria of the Skin (Shields Warren, M.D., and Lee Sutton, Jun., M.D., *Journal of the American Medical Association*, June 27, 1925).—The skin lesions of varicella in a 5-year old boy took on an impetiginous character and became infected with *Bacillus diphtheriæ*, probably tranferred from the nostrils by scratching. They gradually progressed to extensive hæmorrhagic crusted lesions covering about 49 sq. cm. of body surface. Death apparently was due to toxæmia, and the necropsy findings were consistent with infection with *B. diphtheriæ*. Virulent diphtheria bacilli were recovered from one of the skin lesions, and the histologic picture of the lesion is that of diphtheric ulceration. Sections stained by the Gram-Weigert method showed bacilli morphologically resembling *B. diphtheriæ*.

Cephalandra indica (Telakucha) in Diabetes (R. N. Chopra and J. P. Bose, *Indian Journal of Medical Research*, July, 1925).—In Bengal this drug has the reputation of having a remarkable effect in reducing the amount of sugar in the urine of patients suffering from diabetes mellitus, and even among medical practitioners in Calcutta a strong belief exists as to its efficacy in glycosuria. The results of the author's experiments with *Cephalandra indica* (*Telakucha*) are, that it contains an enzyme with amylolytic properties, a hormone, and traces of an alkaloid. None of these substances reduces sugar when administered subcutaneously to rabbits. Fresh juice extracted from the leaves, stem and root of the plant produces no reduction of sugar in the blood or urine of patients suffering from glycosuria.

The Ketogenic Diet in Epilepsy (M. G. Peterman, M.D., *Journal of the American Medical Association*, June 27, 1925).—Thirty-seven patients with essential epilepsy were treated for periods of from three to thirty months by means of a high fat diet sufficiently restricted in carbohydrate and protein to produce ketosis. In two patients no change was noted. One patient improved while under control, but was lost from observation. Three patients remained free from convulsions for from three to eight months, and were then not heard of. Twelve improved and nineteen were free from attacks from the institution of this treatment. Thirty-two are still being kept under observation. The general physical development was also considered to have been normal and exceptionally good in certain cases. Resistance to infection seems in no way diminished by this form of treatment.

The Epidemiological Importance of Diphtheria Carriers (James A. Doull and Hilario Lara, *American Journal of Hygiene*, July, 1925).—Summary and conclusions of this article are as follows :—

In a study of 758 clinical cases of diphtheria in Baltimore, it was found that of 2,799 family contacts not receiving prophylactic anti-toxin, 59 or 2·1 per cent. were attacked later than one and not later than thirty days following the onset of the primary cause. In contrast to this, investigation has shown that in the family contacts of 1,044 school carriers, estimated to number 4,665, only fourteen cases were reported within thirty days of the discovery of the carrier. After making necessary allowance for differences in age-distribution of the two groups of contacts, it is a conservative estimate to state that the risk of attack is ten times as great for family contacts of cases as for those in similar association with known bacillus carriers. Comparison of the attack rates in families of carriers with the prevailing attack rates in the general public of the city indicates that during the first month following the discovery of the carrier the attack rate in the family contacts is considerably higher than would be expected in a random sample of the city's population of the same age-distribution, whereas in subsequent months no such excess is indicated. The interpretation of the excess attack rate in carriers' families during the first month of observation is complicated by a number of considerations which are noted in the presentation of the data. Nevertheless, it seems reasonable to conclude, since our statistical observations are in agreement with many other general facts known regarding the epidemiology of diphtheria, that the families of known bacillus carriers do incur a risk of developing clinical diphtheria which, though small, is appreciably higher than that incurred by otherwise comparable families in which such carriers are not known to exist.

It should be noted, however, that the evidence cited justifies this conclusion only as regards carriers discovered in schools where clinical diphtheria was prevalent at the time, for among the family contacts of chance carriers, found in a random sample of school population, there is no evidence of any greater incidence of diphtheria than that prevailing in the general population of the city. The number of carriers of this kind observed, namely 104 "virulent" and 261 "avirulent," is, however, too small to justify any sweeping conclusions regarding the risk of attack to which their family contacts are subject.

This study fails to show any significant distinction between the risk of attack for those exposed respectively to carriers classified as "virulent," "avirulent" and "not tested." The fact that such are not brought out by an analysis of the data which we have presented does not, however, justify the conclusion that differences do not exist, and it may be that the study of a larger number of families would indicate that the risk of attack may vary according to the type of bacillus harboured by the carrier.

The Severity of Hookworm Disease in a Chinese Group, tested by Hæmoglobin Readings for the Anæmia, and Egg Counts for the Degree of the Infestation (Norman R. Stoll, Sc.D., and Hsien-Wu Tseng, M.D., *American Journal of Hygiene*, July, 1925).—Egg counts and hæmoglobin readings were secured from 337 Chinese, living in the mulberry growing region, near Soochow, Kiangsu Province, China. There were 64 or 19 per cent. negatives to egg count, with an average hæmoglobin of 66·7, 0·7 per cent. Schistosomiasis was absent and dysentery was not an important complication, but malaria was present. The malaria is held to account for the low average hæmoglobins of the hookworm negatives, and probably also influenced the degree of anæmia in the hookworm positives. By means of the co-efficient of correlation, there was shown to be a sound degree of direct correspondence between the size of the egg counts and the degree of anæmia (or, the other way round, a valid, negative co-efficient of correlation between egg counts and hæmoglobins). This correspondence is as significant as in Darling's worm count data. This, then, constitutes most important direct evidence on the validity of egg count data, "basis of formed fæces," in analysing community infestation for hookworm disease. It constitutes indirect evidence also on the validity of the egg count technique, and a general correspondence between egg counts and worm infestations.

The Effect of Storage on the Potency of Antivenomous Serum (L. A. P. Anderson and Rev. J. F. Caius, *Indian Journal of Medical Research*, July, 1925).—The authors conclude that as regards the neutralizing power of antivenomous serum against cobra venom, this serum, like all other sera, gradually loses potency on keeping during the first six to nine months. A sudden increase in potency, to a degree higher than that originally possessed by the serum, follows the preliminary deterioration. The enhancement of potency is marked after twelve to fourteen months' storage. The enhanced potency of aged sera is not directly due to the particulate matter thrown down by ordinary centrifuging.

The Significance of the Splenic-Index in Kala-azar Endemic Areas (J. Dodds Price and C. Strickland, *Indian Journal of Medical Research*, July, 1925).—These observations were carried out on children from the Salana Tea Estate in Nowgong District, from which the following conclusions have been drawn. Rare pathological conditions are of no importance in using the spleen-index for malariometry. Kala-azar is of importance, but when the *clinical* signs of the disease are *not well marked* the splenomegaly of a community living in a kala-azar infected area is due to malaria. When the clinical signs of kala-azar are well marked the cases must not be used in a malariometric spleen-index. For malariometry other cases only should be taken for a spleen count, and the index read in conjunction with a parasite-index of all members of the community. The malaria-parasite-index approximates to the spleen-index in large communities subject to a mild incidence of malaria manifesting itself in an acute or sub-acute form. Any discrepancy between the two indices is correlated with the size of the community, its degree of malariousness and the degree of the chronicity of the disease among the individuals of the community.

Factors which should Determine the Selection of an Anthelmintic in a Geographical Area (Fred L. Soper, M.D., C.P.H., *American Journal of Hygiene*, July, 1925).—Four hundred and nineteen cases were treated with carbon tetrachloride, oil of chenopodium, or a combination of these two drugs. Efficiency rates for such treatments were calculated for species and sex on the basis of per cent. removed by first treatment, as tested by the administration of 3 c.c. of oil of chenopodium. Among Paraguayan soldiers and prisoners the average hookworm infestation is high; among boys and girls of the asylum a much lower degree of infestation exists. Seven per cent. of 82,856 hookworms classified were *Ancylostoma duodenale*. The present ratio between *Ancylostoma* and *Necator* is probably due to three factors: early introduction of *Ancylostoma* by Spanish colonists; the absence of negro slaves; and the occupation of Paraguay by the Brazilian Army with its known heavy *Necator* infestation, following the Paraguayan war. In Paraguay, *Ascaris* infestation is relatively low (11·7 per cent.), being but one-fourth that of *Trichuris* (43·4 per cent). No judgment of the relative value of the anthelmintics used as ascaricides can be made from the present study. The efficiency of all combinations used is low for *Trichuris*. Correction of total efficiency rates for distribution of worm population by species and sex of each group failed to cause over 2·5 per cent. difference in such rate of any group. Correction of species efficiency rates for equal sex distribution caused no appreciable difference in *Necator* rates, where the number of worms was relatively large; a maximum change of 3 per cent. occurred in certain groups in *Ancylostoma* rates where the number of worms was small. Oil of chenopodium and carbon tetrachloride both possess a species and sex selective action on *Necator* and *Ancylostoma*. Both are more active against *Necator* than against *Ancylostoma*. Oil of chenopodium is more efficient for males than for females; carbon tetrachloride is more efficient for females than for males. The best results were obtained for *Ancylostoma* with 2·8 c.c. of a 9 × 5 mixture of carbon tetrachloride and oil of chenopodium (1·8 c.c carbon tetrachloride and 1·0 c.c. oil of chenopodium). The Stoll egg-count method gave the same per cent. total reduction in hookworm infestation in 150 cases following trial treatment, as did the more laborious worm-count method. This last method was shown to be superior to the Willis and Stoll methods as a means of diagnosis of the presence of the hookworm. The method is *indispensable for the determination of the degree and character of infestation* and the study of *sex and species selectivity of anthelmintics*. No serious toxic symptoms were noted in 419 cases of this series. The maximum doses administered were: 3 c.c. oil of chenopodium; 2·4 c.c. carbon tetrachloride; and 2·8 c.c. of a 9 × 5 mixture of carbon tetrachloride and oil of chenopodium. Five serious (two fatal) cases (four alcoholics and one child with heavy *Askaris* infestation) have been encountered in 36,000 treatments with an adult dose of 2·4 c.c. of 3 × 1 and 2 × 1 combinations of carbon tetrachloride and oil of chenopodium. Pregnant women may be treated with moderate doses of carbon tetrachloride without danger.

The Association of Bacillus Bronchisepticus and Bacterium lepisepticum with Rabbit Snuffles (Carroll G. Bull and Clara M. McKee, *American Journal of Hygiene*, July, 1925).—It was found that *Bacillus bronchisepticus* is by far the predominating organism in the bacterial flora of the nares and trachea of rabbits developing snuffles in our stock animal room, pure cultures of this organism often being obtained. *Bacteria lepisepticum* appeared in small numbers in the cultures from five of these rabbits. An acute and fatal form of snuffles attacked an entire litter of baby rabbits. *B. bronchisepticus* was abundant in the cultures from all these rabbits, but *B. lepisepticum* did not appear at all. Cultures made from the nostrils of eighteen rabbits in an isolated colony passing through an epidemic of snuffles gave an abundant growth of *B. bronchisepticus*. *B. lepisepticum* could not be isolated from any of the cultures. Cultures from one rabbit gave neither *B. lepisepticum* nor *B. bronchisepticus*.

Note on the Anæsthesia produced by Intra-Arterial Infection of Apothesine (L. P. Arland, *Indian Journal of Medical Research*, July, 1925).—The chief points noted in this paper are, that the anæsthesia was perfect and profound. There was present both motor and sensory paralysis. There was no sign of shock. Duration of anæsthesia was not sufficiently long to permit of any operation on the limb being performed. No bad effect was noticed during or after the injection. The anæsthesia was either due to (*a*) paralysis of the nerve-endings, or (*b*) to the paralysis of the nerve-trunks in continuity.

A Study of Trichomonas from the Guinea-pig (Misao Tanabe, *Journal of Parasitology*, March, 1925).—The trichomonas from the guinea-pig in Baltimore agrees with that described by Kuczynski, except that from the standpoint of size; one large and another smaller species seem to exist. An inner row of chromatic granules is present, although not so distinct as in *Trichomonas* from the mouse Anterior to the nucleus, there is a small number of chromatic granules. Posterior to the nucleus, there is usually a group of chromatin granules which often seems as if arranged in four or five rows.

The Fungicidal Activity of Certain Volatile Oils and Stearoptens (Harold B. Myers, M.D., and Clinton H. Thienes, M.D., *Journal of the American Medical Association*, June 27, 1925).—Thymol oil of cinnamon and oil of clove have been found particularly efficacious in destroying a pathogenic yeast-like organism responsible for an occupational dermatitis. The drugs mentioned have been found equally valuable in causing an immediate improvement, progressing to healing of infections apparently due to fungoid organisms of several types. The results reported warrant further trial of the volatile oils and stearoptens in infections due to fungoid organisms.

Ivy Poisoning. Preventive Treatment, with Special Reference to the Element of Individual Susceptibility (G. L. Krause, M.D., and F. D. Weidman, M.D., *Journal of the American Medical Association*, June 27, 1925).—It is confirmed that the discharge from the lesion does not disseminate the disease. The virus itself must come in contact with the part. Susceptible individuals may contract ivy poisoning at any time of the year, provided the juice of the plant comes in contact with the skin. As new findings it is reported that repeated attacks tend to shorten all the stages of subsequent attacks. Local immunity is not developed by repeated attacks of ivy poisoning. There is such a thing as absolute (and probably permanent) immunity against ivy poisoning. In series taken, two-thirds of the men who believed themselves immune were not immune. In 45 per cent. of the susceptibles it was necessary that some such defect in the epidermis, as scratches, should be present before a dermatitis would develop. It appears that all of the commoner laboratory animals are immune to this virus. Pruritus ani, transient, appeared in the majority of those receiving preventive treatment. In two subjects, hæmorrhoids were aggravated. The pain at the sites of intramuscular injections outweighs the danger of future attacks of ivy poisoning such as are only suppositions in the commoner walks of life. In a series of controlled subjects the preventive system of treatment of Strickler did not prevent. It is possible that the curative value of this system is likewise scant or *nil*, and that the beneficial results which have been reported are dependent on and ascribable to the variable susceptibility of different individuals and the varying intensity of the irritant as applied at different times.

Treatment of Gastric Ulcer by the Method of Duodenal Alimentation (A. L. Garbat, M.D., *Journal of the American Medical Association*, June 27, 1925).—In the treatment of gastric or duodenal ulcer by means of prolonged duodenal alimentation, stress should not be laid entirely on the exclusion of food from the stomach. Great importance is attributed to the frequent concomitant administrations of antacids or alkalis by mouth before each duodenal feeding, in order to neutralize or prevent the gastric secretion which is almost regularly associated with the duodenal alimentation. The two-tube method has shown that a reflow of duodenal feeding into the stomach occurs more frequently than is usually believed; this occurs with improper position of the tube, which cannot always be recognized, or with a patent pylorus of the stomach. Antacid therapy will help to minimize the disadvantages resulting from such regurgitation.

The Treatment of Amœbiasis by Oral Administration of Stovarsol (Foster M. Johns, M.D., and S. Chaille Jamison, M.D., *Journal of the American Medical Association*, June 20, 1925).—Forty-six patients with amœbiasis were treated with stovarsol with very favourable results. A series of twenty-seven patients was kept under observation for some time to determine the permanence of the "cure." Twenty-one patients have remained well and free from parasites for an average of 3·9 months. One patient rapidly relapsed within periods of from three to seven days. The results of treatment of amœbiasis with stovarsol are equal to any other drug or method of treatment ordinarily employed. It is reasonable to expect that better results will be obtained whenever the most effective method, with reference to dosage and duration of treatment, will have been determined.

Chronic Hereditary and Familial Hæmolytic Jaundice (Walton Forest Dutton, M.D., *Journal of the American Medical Association*, June 20, 1925).—The cases of chronic hereditary and familial hæmolytic jaundice with splenomegaly and hepatomegaly under study differ from the usual forms of hæmolytic jaundice. They differ in the very decided functional activity of the liver and its relation to the reticulo-endothelial system. During the periods of crises, the concomitants of ordinary obstructive jaundice, such as clay-coloured stools, choluria, mild pruritis and slight icterus are present. The blood picture is markedly characteristic, but at times exaggerated. This makes the diagnosis comparatively easy. An intimate study of these cases appears to implicate the extrahepatic bile passages and the reticulo-endothelial system. In the production of crises, the neuromuscular reflex apparatus of the bile passages plays an important rôle. A total spasm of the region of the sphincter of Oddi with contractions of the gall-bladder, which forces bladder-bile back to the columns of the liver cells, produces a toxic irritative process or defence reaction.

Effect of Various Agents — Ultra-violet Light, Vaccines, Turpentine, Neoarsphenamin and Autoblood Injections—on the Enzymes of Blood and Skin (Jay Frank Schamberg, M.D., and Herman Brown, B.S., *Archives of Internal Medicine*, May 15, 1925).—Ultra-violet light, in the strengths used by the authors from an Alpine lamp, appears to decrease the lipolytic activity of the blood-serum both in rabbits and in human beings. On the other hand, the proteolytic activity of the blood-serum appears to be increased. The intramuscular injection of therapeutic doses of turpentine in olive oil tends to increase the lipolytic and proteolytic power of the blood-serum both in rabbits and in human beings. Limited observations on the effect of subcutaneous injections of staphylococcic vaccines suggest that they tend to increase both the lipolytic and proteolytic activity of the blood-serum. The intramuscular injection of freshly drawn autoblood appears to stimulate an increase in the lipolytic and proteolytic activity of the blood-serum. Observations on two cases suggest that the intravenous injection of small quantities (1·5 c.c.) of distilled water tends to decrease the lipolytic activity of the blood and perhaps the preteolytic power. The exposure of rabbits to ultra-violet light from an Alpine lamp decreases the lipase and the protease in the skin of an animal. In summarizing, it may be said that injections of vaccines, turpentine and autoblood appear to increase the lipase and protease in the blood, while huge doses of neoarsphenamin and small doses of distilled water tend to decrease them. Ultra-violet light depresses the lipase and stimulates the protease.

Monilia as a Possible Etiologic Factor in Psoriasis (Moyer S. Fleisher, M.D., and M. Wachowiak, M.D., *Archives of Dermatology and Syphilology*, June, 1925).—In a series of thirty cases of psoriasis, the authors have found *Monilia* or monilia-like organisms in the fæces in 82 per cent., in the blood in 21 per cent., in the skin scrapings in 46 per cent. In normal subjects, *Monilia* was found in only 6 per cent. of 100 stools; on the skin of unexposed portions of the body (27 cases), and in blood cultures in no cases. It appears that the use of a vaccine prepared with these organisms is of some value in the treatment of psoriasis.

Value of Chlorin in the Treatment of Colds (Harold S. Diehl, M.D., *Journal of the American Medical Association*, May 30, 1925).—Most opinions as to the value of the various forms of treatment for colds have been made without careful analyses of results and comparisons with control series. In this study the results of the chlorin treatment of 425 students with colds are compared to the results of the medical treatment of 392 students. It seems that the beneficial effects from the chlorin treatment are all experienced within the first day after the treatment. The percentage of patients who recover within one day with the chlorin treatment is definitely higher than with the medical treatment; 19·5 per cent. of those having chlorin and 12·5 per cent. of those having medical treatment recovering in one day. Of the group with acute rhinitis 23·6 per cent. of the ones treated with chlorin and 6·7 per cent. of those with medical treatment recovered within one day. Of the entire series, 51·4 per cent. of those treated with chlorin and 47·9 per cent. of those given medical treatment recovered in three days; while 73·3 per cent. of those treated with chlorin and 72·6 per cent. of those with medical treatment recovered within a week. The large percentage of recoveries within three days and seven days under such a variety of medical treatments is evidence only of the self-limited character and short duration of most colds. The chlorin treatment apparently was more beneficial in acute rhinitis than in any other type of acute cold. The largest percentage of good results with the chlorin treatment was obtained when the patients were treated on the second or third day of the disease. Ill-effects that could be definitely ascribed to the chlorin treatment occurred only in persons subject to asthma. The results of the treatment of whooping-cough were somewhat encouraging, but not conclusive.

Results with the Skin Test for Susceptibility to Scarlet Fever. Preventive Immunization with Scarlet Fever Toxin (George F. Dick, M.D., and Gladys Henry Dick, M.D., *Journal of the American Medical Association*, May, 16, 1925).—The results reported show the practical value of scarlet fever toxin used in skin tests for susceptibility and active immunization for the prevention of scarlet fever. It has been demonstrated that the toxin may be administered with safety in doses large enough to confer complete immunity. Active immunity is developed within two weeks, and it lasts at least a year and a half.

The Value of Flumerin in the Treatment of Syphilis (James C. Fox, Junr., M.D., Georges H. Gildersleeve, M.D., and John F. Preston, M.D., *Archives of Dermatology and Syphilology*, June, 1925).—The requirements for the final acceptance of a new anti-syphilitic drug, as suggested by Stokes, seem to have been fairly well fulfilled in the case of flumerin. The points in connection with its chemistry and toxicity have been carefully studied. Its value in the treatment of rabbit syphilis, carefully controlled by the method of nodal transfer as a criterion of cure, has been thoroughly established. Also, its superior curative power, as compared with other mercurials, has been shown for experimental syphilis. So far as its clinical value in the treatment of human syphilis is concerned, there is substantial agreement between the opinions of the three groups of workers who have studied the drug; that is, flumerin is inferior to the arsphenamin group in therapeutic value, but superior to other mercurials

in common use. It should be used only in conjunction with the arsenicals or in patients shown to be intolerant or resistant to them. While the toxicity factor is not a grave menace, it must be carefully guarded against in using this drug. The chief disadvantage of flumerin seems to be that it complicates rather than simplifies a programme of anti-syphilitic treatment. The great problem to-day in the cure of syphilis on a large scale is how to keep the syphilitic patient under a prolonged sustained treatment. Incorporation of injections of flumerin twice a week in the interim between arsenical courses calls for such an expenditure of time, energy and money (on the patient's part) that the therapeutic gain must be definitely proved to be commensurate. In early syphilis, in which the importance of an intensive, sustained, combined arsenic and mercurial treatment is so vital to the future welfare of the patient—both for the production of a permanent clinical and serological cure as well as for the prevention of the tragic neuro-recurrence—the superior value of flumerin seems to outweigh the economic consideration.

Hæmophilia. Study of the Blood, the Clinical Course and the Heredity in Three Cases (Ed. C. Davidson and Irvine McQuarrie, *Bulletin of the Johns Hopkins Hospital*, May, 1925).—A typical, large hæmophiliac family is described in which fourteen proven cases of hæmophilia have occurred in eight generations. Detailed reports of two of the cases representing the sixth and seventh generations are presented. Two normal female members of the same family presented no evidence of the disease, either clinically or from blood examination. The hereditary transmission occurred in the family according to the law of Nasse. No occurrence of the disease in females and no transmission through the males of the family has been observed. Of the females capable of transmitting the disease, 83·3 per cent. are known to have done so. Among the potential hæmophiliacs 51·8 per cent. have proved to be bleeders. One typical case of sporadic hæmophilia is described. The clinical picture and the blood abnormalities are identical in the sporadic type and in the hereditary type of the disease. The blood-coagulation time and the prothrombin time in the cases of hæmophilia were from twice to twenty-five times as great as the normal. They both varied from time to time to a considerable degree in the case of each individual with hæmophilia. The finding by Minot and Lee of a qualitative platelet deficiency without a diminution in the number of platelets has been confirmed. The bleeding time, the capillary resistance, the nature of the blood-clot when finally formed, the amount of blood-calcium and the number of platelets were at all times found to be normal in the cases of hæmophilia studied. Blood transfusion is the most effective form of treatment for the hæmorrhage in hæmophilia and should be employed as a prophylactic measure preceding surgical operations.

Current Literature.

INDIAN MEDICAL GAZETTE,
July, 1925.

Cholera in Bengal: Past and Present (A. B. Fry).—This paper is written in answer to two questions put forward at a meeting of the Committee of the Office Internationale d'Hygiène Publique, i.e.: (1) Is Bengal nowadays the endemic home of cholera, as it used to be in the past? (2) Does Bengal still spread endemic cholera throughout India and thence to the rest of the globe? The author has reviewed the literature on the subject, and gives his own studies on the disease, the conclusions of which are as follows: India may still be regarded as the home of cholera and deltaic Bengal may still be considered the endemic home where endemic cholera is just as regular and severe as ever. That there is a fair body of evidence to show that cholera in the rest of India is dependent on cholera in Bengal, but owing to increased facilities for and rapidity of travel, it is not so easy to trace the spread. Why deltaic Bengal is the endemic home of cholera is not proved. It is obvious that density of population, conditions of humidity of air and soil, and of winter and summer temperature, are suited to the requirements of the infecting agent, and that the notorious carelessness of the people regarding their drinking water favour its spread; but we want to know to what extent the "chronic carrier" exists. That the deltaic region of Bengal is the place where cholera should be attacked. Of all preventable diseases cholera is the easiest to tackle, and could we get to grips with it in this region, we might ultimately wipe it off the earth. The author suggests intensive vaccination in a selected district and a very rigorous propaganda campaign. If this is successful, to extend it throughout the province. It is our very obvious duty to take the most stringent measures at the ports and frontiers to prevent the spread of the disease.

Canine Leishmaniasis in Bombay (R. Row).—This disease is rare in Bombay, and communications on the subject lead one to believe that resistance to leishmaniasis in the pariah dog is strong. The case here reported was a quasi-bulldog; it was found to have extensive ulcers on the lips, ears, nose and inner canthus of the left eye. There were also a number of non-ulcerated lesions on the inner side of the ears looking like shining buttons of the size of large peas. The character of the ulcers and the nodules suggested cutaneous leishmaniasis at a glance, although the ulcers had greatly altered in appearance by septic infection set up by constant scratching by the animal. The ulcers healed up in about six months under treatment at the Veterinary Hospital, Bombay, leaving not a single scar. The morphological, cultural and infective characters of the parasite seem to make it a distinct species from *Leishmania tropica* found in man.

Preliminary Observations on Acquired Diseases of the Heart and Aorta as met with in Bengal (Uma Prasanna Basu).—These observations are based on

446 cases examined by the author during the course of hospital and private practice in Bengal. From the statistics of the different varieties of cases it is evident that structural lesions of the heart and aorta due to acquired diseases differ widely from those seen in the clinics of Europe. The chief reason for this difference is the climate. The factor next of importance in the production of a degenerated myocardium is the poverty of the masses from dearth of industrial developments in Bengal.

A Note on the Efficacy of Neem-Battis *in the Destruction of Rats and Rat-Fleas in Rat Burrows* (C. D. Tiwari and R. B. Lal).—During experiments on disinfestation of houses by fumigation with cresol, &c., it was found that the fleas in the rat-holes were not killed and the rats were not at all affected. Experiments were therefore carried out by fumigation with *neem-battis*, as issued from the Punjab Plague Equipment Depôt, Jullunder. With this method the rats and the fleas on the rats in the burrows in the fields are killed in five minutes.

Cellular Elements in Cholera Stools and their Relative Importance in Diagnosis of the Disease (G. C. Maitra and R. L. Behari Ganguli).—In a total of 495 cholera cases, diagnosed bacteriologically, comma-vibrios were found microscopically in 84 per cent. of the stool films. In a total of 496 cholera cases 92 per cent. showed definite concentration of blood. In 6 per cent. of them the concentration was indefinite, and in 2 per cent. there was no concentration at all. Cytological elements in the cholera stool are constant and characteristic, and can be utilized as a reliable index in 98 per cent. of cases.

A Note on the Cultivation of an Entamœba from a Monkey (*Macacus rhesus*) (B. M. Das Gupta).—A monkey experimentally infected with *Trypanosoma evansi* died, and the post-mortem was carried out within four hours of death. Very scanty, sluggishly motile entamœba were found in the contents of the cæcum. No evidence of ulceration in the cæcum or in any other part of the large gut. Positive cultures of *E. nutalli* Castellani were obtained. The author has also cultivated *Entamœba histolytica* both from kittens experimentally infected and from the stool of a human case of amœbic dysentery.

Medical News.

CHINESE GRADUATES IN PRACTICE.

A recent census of the graduates of the former Union Medical College, Peking, China, shows that 27 per cent. of the graduates are in private practice, 23 per cent. in Government posts, and 39 per cent. in missionary work.

CERTIFICATION OF CURE OF LEPROSY.

The conditions under which lepers are released from the leprosarium at Carville, Louisiania, include special observation for one year, monthly bacteriologic examinations to show that the lepra bacillus is absent from the tissues and the certification of cure by a board of three medical officers stationed at the hospital. Four lepers who went to the Carville home a few years ago have recently been discharged. There are at present 236 leper patients at Carville.

THE CULION LEPER COLONY (PHILIPPINE ISLANDS).

At the present time there are 5,103 lepers in the colony; four of them are Americans, one is a European, one a Japanese, and seventeen Chinese. The total number comprises 2,487 men and 1,318 women.

New Preparations, Inventions, &c.

DIBROMIN (PARKE, DAVIS & Co.).

A crystalline synthetic compound containing approximately 56 per cent. of bromine in loose combination. When its solutions are brought into contact with infected tissues the bromine is slowly liberated and exerts a powerful germicidal action.

Dibromin is stable in the dry state; its solutions are easily made, are definite in strength, do not stain, do not irritate, and are practically non-toxic.

Dibromin is employed in dilute aqueous solutions, ranging in strength from 1 in 10,000 to 1 in 2,500. Such solutions may be applied by continuous irrigation, as in the treatment of extensive wounds, ulcerations, &c., and for infections of the urethra, bladder, or uterus. Weak solutions are suitable for use as mouth washes and as collyria in eye infections.

Dibromin is supplied in 6-grain capsules (in bottles of 10 or 50 capsules) for convenience in making solutions without weighing—the contents of 1 capsule added to 7 pints of water forms a 1 in 10,000 solution.

OLGAR (P. D. & Co.).

This preparation consists of highly purified liquid paraffin emulsified with agar. It has the appearance and consistence of thick cream and is agreeably flavoured. The paraffin is rigorously tested to ensure freedom from injurious by-products.

The administration of olgar is indicated in cases of chronic fœcal stasis and the various forms of auto-toxæmia resulting therefrom; in catarrhal conditions of the intestine, hæmorrhoids, &c. Its action, of course, is purely mechanical, it lubricates and soothes the intestinal mucosa, softens the intestinal contents, and facilitates peristalsis. The dose for an adult is one tablespoonful night and morning. It is supplied in 16-ounce bottles.

SILVER NITRATE SOLUTION CAPSULES (P. D. & Co.).

These capsules provide an exceptionally convenient means of always having at hand in aseptic condition the 1 per cent. solution of nitrate of silver for application to the eyes of infants at birth.

The capsules are formed of a special wax, and each contains about 5 minims of the solution, which is easily expelled by pressing the capsule between thumb and finger after an aperture has been made with a sterile needle. Two of these capsules are supplied in a tin together with a puncturing needle aud directions for use.

STORAXOL (P. D. & Co.).

This ointment is a combination of storax, resorcin, menthol, camphor, carbolic acid (5 per eent.) and precipitated sulphur in an emollient base of penetrative character. The parasiticide, antipruritic, antiseptic and analgesic properties of its constituents render storaxol of value in various skin disorders, e.g., chronic eczema, ringworm, pruritus, urticaria, impetigo, psoriasis. It affords one of the best means of treating scabies and parasitic affections of the scalp. It forms an excellent dressing for foul ulcers, and is reported to be very effectual in allaying the itching of piles. It is supplied in convenient collapsible tubes, also in jars containing 1, 5, or 10 pounds.

Original Communication.

FURTHER OBSERVATIONS ON PRURITUS ANI AND PRURITUS VULVÆ OF MYCOTIC ORIGIN.

By ALDO CASTELLANI, C.M.G., M.D., F.R.C.P.,

Director of Tropical Medicine and Dermatology, Ross Institute, London.

SINCE 1912 I have carried out a mycological and bacteriological investigation in practically every case of pruritus ani I have observed, and in a comparatively large proportion of cases, more than 20 per cent., fungi, usually of the genus *Epidermophyton* were found.

In 1923, in my paper on "Medical Mycology," published in *The British Medical Journal*, December 1, page 1037, I described as a separate entity "Pruritus Ani of Mycotic Origin." This publication attracted little attention and even in very recent articles on pruritus ani by various authorities the mycotic or fungal variety is not mentioned, although the so-called bacterial type (streptococcus pruritus ani) is often discussed.

It may perhaps be of advantage to give a brief general account of the condition, incorporating into it the result of my further researches on the subject.

Definition.—Mycotic (Phycotic) Pruritus Ani is a form of pruritus ani caused by fungi higher than bacteria (mycetes, higher fungi), generally fungi of the genus *Epidermophyton*, the same fungi which cause pruritus interdigitalis pedum (toe phytosis, dermatitis interdigitalis mycotica, mango toe) and also ordinary dhobie itch or tinea cruris. The condition is, in fact, as a rule a latent epidermophytosis of the perianal region without the usual objective symptoms of an ordinary active epidermophytosis being present.

Synonyms.—Phycotic pruritus ani, mycetic pruritus ani, mycotic pruritus ani, fungal pruritus ani; pruritus ani due to the higher fungi; epidermophytic pruritus ani.

Clinical Symptoms.—The patient complains of very severe pruritus, not, as a rule, continuously but at intervals. The pruritus is often worse at night, but the attacks of unbearable itching may come at any time. The inspection of the ano-perianal region in recent cases may reveal nothing at all except perhaps signs of scratching, but in most cases on careful examination minute, red, slightly raised, infiltrated patches may be seen in the perianal region, occasionally arranged into two curved lines. In a number of old cases signs of an eczematous dermatitis, due to scratching, are present, and streptococcus and other secondary bacterial infections may become engrafted on the mycotic condition.

When the secondary bacterial infection becomes very abundant, especially if many coli and proteus germs are present, the fungus may disappear completely or become extremely scarce. In some old-standing cases the skin is thickened and lichenified.

Illustrative Cases: *Case* I (Uncomplicated type).—This case has already been published by me in the JOURNAL OF TROPICAL MEDICINE. The patient, a Ceylon planter, came to consult me in October, 1924, he had been suffering from anal pruritus for six years and had tried numerous ointments and lotions without any permanent benefit. Denied ever having had dhobie itch or mango toe (dermatitis interdigitalis pedum). The examination of the ano-perianal region did not show anything abnormal, except on close examination a very few minute red patches which did not give the impression of an epidermophytic infection. Scrapings were made every other day for two weeks, and were examined microscopically in liquor potassæ; they were always negative except on one occasion, when a few spores and portions of mycelial threads were seen. After many failures a fungus was grown with all the characteristics of *Epidermophyton cruris*. An ointment containing salicylic acid, eucalyptus oil, mercury salicylate, bismuth subnitrate (Deek's ointment), cured the condition.

Case II.—Mr. A. G., aged 40, has never been out of Europe. Six years ago began complaining of pruritus ani after a sojourn of several months in the South of France. Was treated with various ointments without any distinct benefit. Came to consult me in February this year. The skin about the anus was red and somewhat thickened. The inspection of the inguino-crural region showed absence of dhobie itch and the patient denied ever having had it. On questioning him I elicited the fact that he had been suffering from pruritus interdigitalis pedum for several years; inspection of the toes showed a few cracks and slight peeling. From scrapings of the toes I obtained *Epidermophyton cruris* fairly easily, but scrapings from the ano-perianal region, made and examined daily, remained negative for nineteen days, when a few mycelial segments of a fungus were found. The fungus was grown with very great difficulty owing to the presence of numerous cocci and bacilli; it was *E. cruris*. In this case a sulphur salicylic ointment and a tar ointment answered well.

Case III.—Mr. N. B., aged 25, has been in the Far East for three years. He had dhobie itch two years ago, which he says was cured by using a Goa powder ointment. For the last six months he had severe pruritus ani. Consulted me two months ago. The examination of the ano-perianal region showed nothing except signs of scratching. After many attempts, *E. cruris* was grown.

Ætiology.—The cause of the condition is generally to be found in the presence of fungi of the genus *Epidermophyton*, the same fungi which produce ordinary tinea cruris (dhobie itch) and pruritus interdigitalis pedum; occasionally fungi of the genus *Trichophyton* may be present. The species of *Epidermophyton* found have been *E. cruris* and *E. rubrum*. It may perhaps be useful to touch briefly

upon the botanical characters of epidermophyton fungi:

Genus *Epidermophyton* Lang, 1879, *emendavit* Sabouraud, 1907.

Definition.—Trichophytinæ with mycelial filaments and spores present in the lesions, and with pluriseptate spindles present in the cultures. Do not attack the hair or hair follicles, but grow in the superficial layers of the epidermis.

Type Species.—*Epidermophyton cruris* Castellani, 1905 (synonyms *E. inguinalis*, Sabouraud, 1907; *E. castellanii*, Brooke, 1908).

Remarks.—The fungi belonging to this genus grow superficially on the skin without invading the hairs and hair follicles; certain authorities however state that they may infect lanugo hair; do not produce suppuration. Reproduction takes place principally by pluriseptate spindles, with, on the average, four to six cells. The septa, as noted by Pinoy, may not be complete, and the cavities may communicate. Spiral hyphæ, as found in most species of trichophyton, are absent; pectinate structures, as found in the microsporons, are absent; no spore-bearing hyphæ, with lateral conidia of type *Acladium*, as noted both in the trichophytons and in the microsporons. The cultures undergo rapid degenerative changes, losing their characteristics, and becoming covered with abundant uniform, long whitish duvet (pleomorphism). They are not inoculable into guinea-pigs, except Pinoy's *Epidermophyton simii*. The species so far known have been isolated from human lesions, except the epidermophyton discovered by Pinoy in monkeys.

TABLE OF EPIDERMOPHYTONS.

Genus.	*Species.*
Epidermophyton Lang, 1879, *emendavit* Sabouraud, 1907	*E. cruris* Castellani, 1905. *E. perneti* Castellani, 1907. *E. rubrum* Castellani, 1907.

These species may be recognized by their growth on Sabouraud's agar:—

(*a*) Colour: peculiar yellow ... ... *cruris*
(*b*) Colour: pinkish ... ... *perneti*
(*c*) Colour: deep red ... ... *rubrum*

For *E. simii* Pinoy, 1911, Chalmers and I created the genus *Pinoyella*.

Epidermophyton Cruris CASTELLANI, 1905.

Synonyms.—*Trichophyton cruris* Castellani, 1905; *Epidermophyton inguinalis* Sabouraud, 1907; *T. castellanii* Brooke, 1908.

Found first in cases of dhobie itch (tinea cruris) in Ceylon by Castellani, and later in France by Sabouraud. The fungus is very abundant in recent cases, extremely scarce in old ones. The mycelial tubes in recent cases are generally straight, have often a double contour, and the segments are somewhat rectangular, their breadth being 3½ to 4½ microns. Branching is not rare. The spores are rather large (4 to 7), roundish and have generally a double contour; they do not collect in clusters. In chronic cases degeneration forms of the fungus are met with; the mycelium may be banana-shaped, may show several constrictions, or long strings of ovoid elements may be seen.

This *Epidermophyton* grows well, but rather slowly, on glucose and maltose agars. The growth begins to be visible after four to eight days, the colonies being at first of a peculiar yellow colour, lemon-yellowish or orange-yellowish, occasionally with a greenish tinge. Later they become white, with pulverulent surface, and may be acuminate or crateriform. Pleomorphism, with abundant white duvet, develops quickly.

This fungus is the commonest species found in cases of tinea cruris in Europe, India and Ceylon. It is not inoculable into guinea-pigs. Attempts at reproducing the eruption in man by inoculating pure cultures have generally failed, but De Silva and others have recently succeeded in reproducing the disease.

Epidermophyton perneti Castellani, 1907.—This fungus has been described by Pernet. It differs from *E. cruris* by growing much more rapidly on Sabouraud's agar and by the cultures having a delicate pinkish colour, which is generally lost in subcultures. It is a rare fungus.

Epidermophyton rubrum Castellani, 1909. *Synonym*—*Trichophyton purpureum* Bang, 1910. — This fungus was described by me in Ceylon, in 1909, and by Bang in France, in 1910. On maltose agar the growth begins to appear four to six days after inoculation as a raised red spot, which gradually enlarges. At complete development the growth is of a deep red colour, either with a central knob or crateriform, and is partly covered with a white delicate duvet. In old cultures the white duvet is much more abundant and thicker, and may hide the red pigmentation almost completely.

On *glucose agar* (4 per cent.), which is the best medium for this fungus, the growth is of a very deep blood-red colour, and the red pigmentation may spread to portions of the medium itself. In old cultures abundant white, occasionally white-greenish duvet, is present. This may hide the pigmentation, but, scraping out the duvet, the red pigmentation will be found to be still well marked. On ordinary agar and glycerine agar the fungus grows fairly well, but there is no red pigmentation.

Trichophyton. — Very occasionally fungi of the genus *Trichophyton* Malmsten 1845, may be found. As, however, these cases are rare, and the botanical characteristics of the genus are well known, there is no need of entering into any botanical details.

Monilia.—In a few cases of pruritus ani I have found fungi of the genus *Monilia* Persoon and other yeast-like organisms, but I doubt whether they play an important part in the causation of the pruritus; they probably play the rôle of secondary invaders, similar to the rôle played by many bacteria, such as the streptococcus. A case of so-called streptococcus pruritus sent to me recently turned out to be a case of epidermophyton infection, due to *Epidermophyton cruris*. The streptococcus was abundantly present, but was not the actual cause of the pruritus. Streptococcus vaccine caused no improvement whatever in the local condition, while an antimycotic treatment with sulphur and salicylic acid cured it.

Diagnosis.—A definite diagnosis of mycotic pruritus ani cannot be made without fungi being found microscopically or by mycological cultural methods; a diagnosis of probability can often be made, however, on clinical grounds, the minute, red, infiltrated patches, fairly often seen on careful examination (with no oozing in uncomplicated cases) in the perianal region being suggestive, especially if the patient is suffering from mycotic dermatitis of the toes or gives a history of having suffered from dhobie itch or tinea cruris in the past.

Course and Prognosis.—The course of the condition is chronic, but periods of great improvement and apparent cure may alternate with periods of severe recrudescence.

Attention should be called to certain cases, fortunately few, in which, although after the fungus under appropriate treatment has completely disappeared, the pruritus still continues. This is observed in highly strung, very nervous individuals. Very difficult cases are also patients suffering from, or having a tendency to true eczema; when they become infected with the epidermophyton fungi, either the irritation caused by the fungi themselves or set up by the treatment to eradicate them may start an attack of eczema not only in the ano-perianal region but in many other regions of the body.

Treatment.—In uncomplicated cases with no secondary eczematous dermatitis an ointment containing precipitated sulphur and salicylic acid, 15 or 30 gr. of each to the ounce of vaseline, may be applied with care. A preparation which is often

efficacious is Deek's ointment, which consists of salicylic acid 4 parts, bismuth sub. 10 parts, mercury sal. 4 parts, oil of eucalyptus 4 parts, vaseline and lanoline sufficient to make up to 100 parts. It is interesting to note that long ago Deek found that this anti-mycotic ointment had a very beneficial action in many cases of pruritus ani, although the existence of a mycotic type of the condition was not known at the time. Collosol iodine oil is at times useful.

In certain cases an ointment containing 2 gr. of chrysarobin to the ounce of vaseline is efficacious, but it may occasionally induce a severe reaction and it stains, of course, the underclothing. It should not be used when there is any affection of the kidneys, and the patient should be told never to touch his face and eyes after applying the ointment.

A strong lotion of potassium permanganate (15 gr. to 1 dr. to distilled water 1 ounce) is occasionally useful.

When the pruritus is unbearable, painting the parts with a lotion consisting of arg. nitr. 15 gr., spir. æther. nitr. 1 oz., at times stops the itching, either immediately or after a short period of time, during which the pruritus may become intensified; this paint should be used with care.

In chronic cases X-rays treatment is to be recommended; it is often successful, though, unfortunately, not always.

When a weeping eczematous dermatitis due to scratching is present with severe acute symptoms of inflammation, it is advisable in most cases at first to give a soothing treatment such as lead or lead and opium lotion or a lotion containing 1 per cent. resorcin and 2 per cent. of boric acid, and warm sitz baths, liquor plumbi being added to the water in the proportion of 1 oz. for each pint, are soothing. As soon as the acute eczematous dermatitis has disappeared, or greatly improved, the antimycotic treatment should be started.

When the mycotic affection develops in an individual suffering from true eczema, the treatment is most difficult, at times almost hopeless; the continuous application of resorcin lotion (1 per cent.) or resorcin boric lotion (resorcin 1 per cent., boric acid 2 per cent.) or a salicylic lotion (1 in 1,000) is best in most cases. Later on, gradually, ointments may be used containing tar (such as sphagnol) or resorcin (2-5 per cent.) or salicylic acid (2-5 per cent.) or beta-naphthol (2 per cent.).

In neurotic individuals in which the pruritus persists after the mycotic affection has been cured, bromides in full doses, phenazon, belladonna, tinct. cannabis indica, occasionally quinine hydrobromide, are useful, but the treatment is most difficult.

Prophylaxis.—A useful measure after the daily bath is washing the ano-perianal region with tar soap or mild carbolic soap, dry the parts well and apply a mildly antiseptic powder such as zinc oxide, acidi borici and starch equal parts; or boric acid and talc.; or dermatol 1 dr. and talc. 1 oz., or bicarbonate and talc. (sodii bic. 1 dr., talci. 1 oz). The underclothing should be changed as often as possible.

Pruritus Vulvæ of Mycotic Origin.

This condition is very similar to pruritus ani of mycotic origin, and it is not rare to observe female patients suffering from both conditions.

Ætiology.—Mycotic pruritus vulvæ is caused by the presence of fungi of the genus *Epidermophyton*, occasionally of the genus *Trichophyton*, which remain dormant in the external region of the labia majora without giving rise to the ordinary signs of active dhobie itch. Not rarely yeast-like fungi of the genus *Monilia* may also be found—the fungi of vaginal as well as oral thrush—but in my experience it is rather doubtful whether they can alone give rise to severe pruritus, as under an appropriate treatment monilias may be made to disappear, but the pruritus persists. Monilias probably play the rôle of secondary invaders similarly to the many bacteria so often found in the condition among which are various cocci and coli organisms.

Clinical Symptoms.—The patient complains of very severe pruritus in most cases at intervals. The examination of the genital parts may reveal nothing at all, but at times a few minute, red, hardly raised infiltrated patches may be seen. In long standing cases an eczematous moist dermatitis often develops, due to secondary bacterial invasion. In chronic cases there is often a large amount of vaginal discharge, in which various bacteria are found, and fairly frequently monilia fungi.

Illustrative Case.—An elderly spinster consulted me some time ago for vaginal pruritus of some years' duration, which had been treated by different medical men in various ways without any distinct amelioration resulting. In the perianal region, on the perineum and on the labia majora a very few small reddish patches were seen, which, it was thought, might be due to secondary pyogenic infection produced by scratching. There was an abundant purulent vaginal discharge from the anus, with symptoms of proctitis. A complete mycological and bacterial investigation was carried out. From the scrapings of the perianal region and from the labia majora a fungus was grown with the characters of *Epidermophyton cruris* Castellani, 1905, the fungus which is the commonest cause of dhobie itch and pruritus interdigitalis pedum. In the vaginal and in the rectal discharge enormous numbers of monilias were present, with very few bacilli; cultivation showed the fungus to be a strain of *Monilia pinoyi* Castellani.

The following treatment was given: creosote was administered by the mouth. Tinct. iodi., which in this case did not give rise to any local pain or irritation, was freely applied once a day to the ano-perianal region, the perineum and the external surface of the labia majora. For the first three days hot alkaline irrigations (1 dr. of bicarbonate of soda to a pint of water) were given; afterwards twice a day an iodine irrigation (tinct. iodi. 1 dr., aq. ad Oij). Within two weeks the lady was completely free from the anal and vaginal pruritus; the purulent rectal discharge ceased entirely, whilst the vaginal discharge decreased, but did not quite disappear. The

monilias present diminished enormously in number, but did not disappear completely.

Prognosis.—The condition has no tendency to spontaneous cure, but periods of great improvement and even complete cessation of the pruritus may be noted.

Treatment.—This is on the same lines as for mycotic pruritus ani. In uncomplicated cases a salicylic-sulphur ointment or Deek's ointment half strength answers well, or painting with diluted tinct. iodine. When an eczematous dermatitis, generally due to vaginal discharge, is present local applications with lotio plumbi (liquor plumbi sub., 1 dr. to the pint), liquor carbonis detergens (2 dr. to the pint) are useful, and vaginal douching with iodine (tr. iodine 1 dr. to two pints) or potassium permanganate (1 in 5,000) should be carried out. Later tar ointments or pastes such as liq. picis min. 15, zinci ox. 2 dr., vasl. ad 1 oz., are useful. X-ray treatment is at times successful.

RELAPSING FEVER IN NORTHERN NIGERIA —A STUDY OF 300 CASES.

By W. E. McCULLOCH, M.B., Ch.B., Aberdeen.
West African Medical Staff.

THIS disease is a new importation into Northern Nigeria and was first found by Dr. H. Morrison, at Sherafurie, where he was working in the tsetse-fly investigation camp. Ten days later, on March 6, 1924, I found the first case in Kano Native Hospital, in the course of routine blood examinations of new cases that day admitted to hospital. The disease soon became widespread through the north, and to-day, fourteen months after its appearance, it is still exacting a heavy death toll. In November of last year I was sent to Katsina, and my series of cases is made up of 149 from Kano and 151 from Katsina. I have used the first 300 cases for ease in statistical computations, but on April 12, 1925, my total was 321 and I continue to get new cases at the rate of 10 per week. These extra cases are following the lines of the rest, and so nothing is lost by not including them.

Ætiology.—The spirochæte has been measured for me by Prof. Shennan, of Aberdeen, and he reports: "The length varies from 14 to 25 microns. Some are even longer, but they seem to be made up of two end to end. Most of them are round about 20 microns." The body of the spirochæte has anything from seven to twenty-one turns, and wavy, rather than curly, forms are the rule.

In 842 positive blood-films examined, no Balfour "infective granules" were seen either in the spirochætes or in the red blood-corpuscles. Serial films, at one-hour intervals, after injection with neokharsivan, were taken in six cases, and in none was any destruction or granulation of spirochætes seen. The change noticed was an obvious diminution of the spirochætes in each succeeding film. In two cases the spirochætes had disappeared at the end of an hour and the longest time for disappearance was seven hours. Four hours seemed to be about the normal time. The temperature always fell more slowly than the spirochætes disappeared. Seven hours was the average for the fall to normal. The fall always went on, however, to below normal.

Six guinea-pigs were inoculated with whole or citrated infected blood. The dose varied from 1 to 2 c.c. Two of the pigs were one week old and the other four were purchased as adults. In no case was any sign observable, and spirochætes were never recovered in their blood. The two young pigs were inoculated three times each at fortnightly intervals—in all cases with negative results.

One mouse was inoculated with whole infected blood. No spirochætes were recovered twenty-six hours later. Unfortunately this mouse disappeared on the same day and no more mice have been captured alive to carry on this experiment.

One guinea-pig had a drop of infected blood placed in the conjunctival sac of each eye. No result was obtained.

Spirochæta duttoni is inoculable into guinea-pigs, but in no case did I successfully inoculate the spirochæte at present under experiment.

Transmission.—March in Northern Nigeria is in the height of the dry season and very few ticks could be found. I found no *Ornithodorus moubata.*

Pediculus humanus could be collected by the test-tube full from some of the patients, and this was done. The lice were ground up in saline and examined in drop and stained preparations. Spirochætes were found in a stained film after 230 negative examinations. Long before this, however, the absence of ticks, the prevalence of lice, and the finding of infected lice in the Gold Coast epidemic, had made me take precautions against lice. The Native Administration prison in Kano usually contains about 550 inmates, and my first seventy-six cases in the series came from this institution. All new prisoners arrive lice-infested and it was not easy to get rid of the infection in the mud buildings employed.

Eventually the prisoners were lice-free on their weekly inspections, the case-incidence had dropped, but I still got two or three cases per week. A typical search of one cell before de-lousing of its inmates (52 males) gave me 168 lice, 2 bed bugs and 24 mosquitoes. All the lice came from the men, and the bed bugs and mosquitoes from the wall. Later on I could find no lice.

In Katsina there is a prison with 132 inmates, a training college with 43 inmates, and a provincial school with 42 inmates, and these people can be controlled. These three institutions are rigorously inspected, and not one louse has been found by me in five months' searching. Yet I have had 8 cases from

the prison, 4 from the training college, and 1 from the boarders in the provincial school, and 7 from the non-boarders who live in the town.

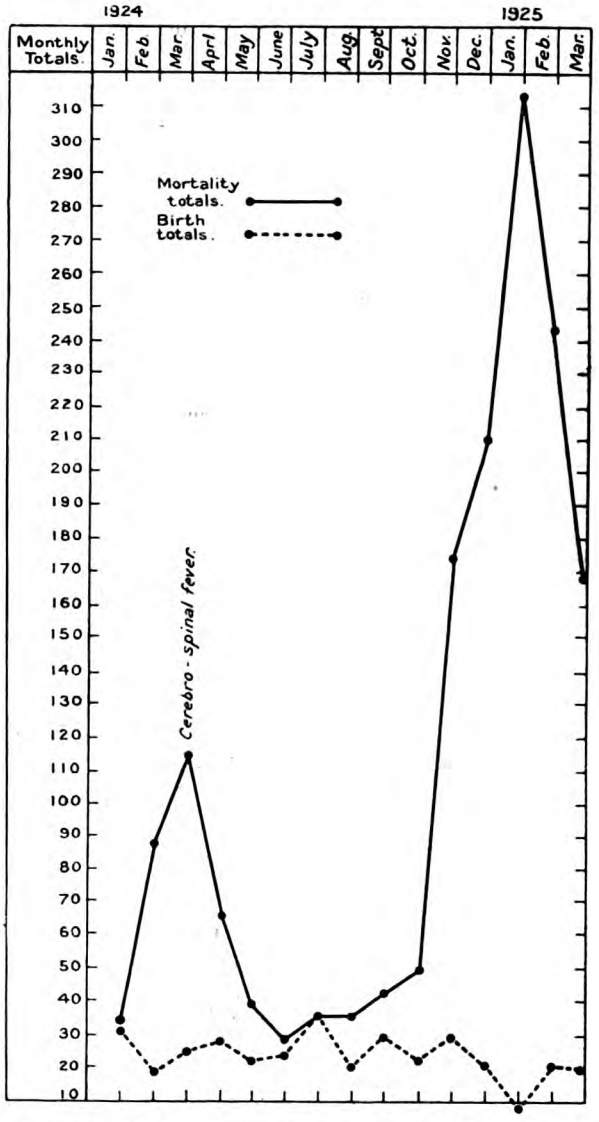
In these institutions we have people of quite different classes. The prisoners are naturally dirty and they are compulsorily kept clean. In the educational institutions the boys are very largely the sons of the Native ruling class, and they need no compulsion to keep themselves clean.

The absence of lice, and the presence of sporadic cases in these controlled places, suggested a search for the bed-bug. They are present in all Native buildings that I have had searched in Katsina. The people accept lice as a normal feature of their environment, but some have complained of the bed-bugs in the past few months. These bugs live in the mud walls of the houses, come out to feed at night (when they have been caught by me in great numbers), and retire to the crevices in the walls after feeding.

Saline preparations of *Cimex lectularius* have not shown any spirochætes, but twice have I seen a few granules which look like very small lymphocytes which are degenerating. They are fuzzy and the centre stains a pale blue. They are about one quarter of the size of a small lymphocyte and the structure is quite indistinct.

I have not attempted any human inoculation experiments—really the only material available—as there is one type of the fever, which I call the *adynamic*, which has been invariably fatal in my experience, and as I am not prepared to run the risk of acquiring this type, I am unable to ask a volunteer to take a chance.

Examination of bed-bugs is being continued, as I feel convinced that the explanation of the facts in the four institutions under control—the two prisons and the two schools—hangs on the implication of *C. lectularius* as the secondary transmitter of the disease.



The Senior Sanitary Officer, Northern Provinces, Dr. H. A. Allan, gave me the details of one family in Kano in which 25 died of relapsing fever in a household of 38 within 52 days, 2 men, 2 women, and 9 children remaining. No precautions had been taken against lice or bed-bugs and so that proves nothing as to transmission, but it illustrates the general and very high incidence-rate.

Age and Sex Incidence.—In Kano no children were seen suffering from relapsing fever. The average age of the infected seemed to be about 30 years. There were 145 males and 4 females.

In Katsina 38 children have been seen, the youngest being 8 months old. The average age of the infected seemed to be about 35 years. There have been 20 women and 114 men. These figures as to sex incidence have no significance in a Mohammedan population such as Katsina. The women are the great conservative force in Mohammedan Northern Nigeria and they will not have treatment with Western medicine. The death statistics of the town show an almost exactly equal mortality in males and females. The point is that women keep away from hospital and so do their children.

Extent of the Epidemic.—An approximately accurate calculation can be made as to the numbers involved. Katsina has a reliable system of registration of births and deaths, and the register is submitted to the Medical Officer every month. The names—householder, district of the town and district-head's name—are all inserted in detail, but no cause of death is ever given beyond "Cough," "Fever," "Dysentery"; nor does the Medical Officer certify the cause of death, as there is no compulsory registration.

A graph is appended of the Births and Deaths totals per month of Katsina Town from January 1, 1924, to

March 31, 1925. A review of the statistics available shows the average monthly birth total to be 47, and the average normal non-epidemic death total to be 35.

On September 30, 1924, the census was returned as 18,557 people. The birth-rate was therefore 30·3 per 1,000 and death-rate 22·7 per 1,000.

Relapsing fever reached the town in October and has been here since. Up to March 31, 1925, the excess deaths were 961, and as no other epidemic has been observed and all deaths are returned as "Fever" or

"Jaundice" (see below), I feel certain that all these deaths are due to relapsing fever. The astounding virulence of this epidemic is seen when we realize that the excess deaths for the period October, 1924, to March, 1925, represent 5·15 per cent. of the town's population. In Kano, during my nine months' experience of the disease there, the deaths were at least no less in proportion in a population of some 60,000. In the course of my duties I have visited points 108 miles, 52 miles, and 84 miles away from Katsina, and all in different directions. In all relapsing fever was rampant, with a very high mortality rate. No records comparable to the Katsina records are kept in any of these places, Kano, Malumfashe, Daura or Kazaure, and so the argument must develop by analogy and by the fact that all cases seen by me were undoubtedly relapsing fever, as I confirmed the diagnosis by blood examination on returning to Katsina.

Kano Province has an estimated population of 2½ millions and the disease is widespread throughout its area.

The Katsina mortality of 5·15 per cent. of the whole population is a fact. The mortality percentage has been reduced, because, up to March 31, there had been treated 151 cases in Katsina, of whom only 4 died. It seems conservative, therefore, to assume that the deaths in Kano Province have been at least 5·15 per cent. of the total population, which gives the astonishing total of 128,750 deaths to date. Verily, relapsing fever, the new disease, has assumed the "Captaincy of the Men of Death" by right of fitness for it.

The total deaths for Northern Nigeria will be far more than the above figures. The disease appeared early in Sokoto Province, and I had cases in Kano Hospital who were stricken on the day of arrival from Bornu and Jos. Bearing in mind the fact of an incubation period, these people must have been infected before reaching Kano.

I do not think it possible to estimate the total deaths in Northern Nigeria.

Mortality Rate.—Of those injected twelve died. Six were of the adynamic type which has proved invariably fatal. The other six all died suddenly, maybe because of the injection, maybe because of the grave dilatation of the heart, which is always present in a grave case.

Of 68 cases not injected 32 died—a mortality of 47 per cent. Kano prison furnished 52 of these cases, of whom 30 died—a mortality of 57·7 per cent. The other 16 cases consisted of 6 in Kano and 10 in Katsina, of these 2 died, a mortality of 12·5 per cent. These later cases were kept alive by massive doses of brandy and injections of strychnine, and so do not come into a consideration of average mortality. I believe the prison rate of 57·7 per cent. to approximate to the truth.

Birth Rate.—In Katsina this rapidly fell to 9 in January, instead of the average of over 40 per month in the preceding two years. This fall is explained by abortions of infected expectant mothers, and the deaths of others of them. I refer to this later.

The Blood in Relapsing Fever.—Leishman's stain was used for all purposes of diagnosis, and Giemsa for further investigations.

(*a*) *Spirochætes.*—In only three cases were no spirochætes found during the febrile period, but the blood-picture was typical. Usually spirochætes were present in enormous numbers and often 30 were counted in one field with a $\frac{1}{15}$ in. oil-immersion and a No. 4 C eyepiece. On one day ten positive slides were diagnosed in fourteen minutes, and except for the three negatives I have not had to search longer than ten minutes.

(*b*) *Leucocytosis* is always obviously present from the slide. The average of 62 counts (Zeiss-Thoma hæmocytometer) is 22,862. Three typical counts taken by chance from my notes on the same page are 25,000, 23,437 and 21,456.

In one case (Abeba ♀) a count was done on blood withdrawn about two minutes before death—it was 38,593. The patient was comatose, deeply jaundiced and absolutely collapsed.

(*c*) *Red Blood-corpuscles.*—They almost invariably stain poorly. Anisocytosis is marked, and they show a tendency to clumping. Hæmoglobin by a Talquist paper-test was 68, but I know that the papers were old. The patient's clinical condition soon convinces you, however, that a serious anæmia is present.

The red-cell count varied between 3½ and 6 millions and I did not continue the investigation.

(*d*) *White Blood-corpuscles.* — The blood of a relapsing fever patient passes through four typical phases :—

(1) The POLYMORPHONUCLEAR LEUCOCYTOSIS, when the disease is progressing towards its fastigium, nature is trying to deal with the invader by the use of troops already called up, and they are rushed to the front.

THE MONONUCLEOSIS.—As soon as the fever is well established, large oval cells appear in increasing numbers. In these the protoplasm is clear and translucent; the large nuclears stain very well and may be circular or horseshoe shaped; no granules are present. The cell is about 30 microns in diameter, but some are just larger than large lymphocytes. These cells are leucoblasts. Myelocites and lymphoidocytes also appear in varying numbers, and no attempt has been made to do a differential count of these cells, as all merge one into the other. The drain on the polymorphonuclears has been so acute that nature has to turn out primitive cells to deal with the infection.

(3) The LYMPHOCYTOSIS, when nature rests the storm troops and calls out the scientists to neutralize the poisons of the hiding invading host, an almost certain sign that no further relapse will take place. This picture is occasionally seen in relapses.

(4) The gradual return to normal with transient leucopænia of slight degree.

Chart No. 1 is that of a school-boy, Garba, and his series of slides illustrates the cycle.

Date	Temperature	Total white count	Polys.	Lymphs.	Leucoblast
Jan. 21	98·8	14,000	76	2	22
,, 22	103·8	18,000	52	2	46
,, 28	98·2	—	17	53·5	29·5
Feb. 1	105·4	22,000	34	21·0	45·0
,, 8	97·0	—	58	31·0	11·0

It is to be noted that, on the 30th, Garba had an injection of 0·3 grm. of neokharsivan and that on February 1 he had an alarming relapse. The blood-picture promptly reacted to the renewed stimulus as seen from the chart (p. 338).

A typical count of a case, treated symptomatically, on discharge from hospital is :—

Polymorphs	...	37 per cent.
Lymphocytes	...	60 per cent.
Leucoblasts	...	3 per cent.

The difficulties of a differential blood-count were well illustrated by the following case.

First count 200 cells :		Second count 200 cells, at edge of same film :	
Polymorphs ...	23 per cent.	Polymorphs ...	20 per cent.
Lymphocytes	66 per cent.	Lymphocytes	0 per cent.
Leucoblasts ...	11 per cent.	Leucoblasts ...	80 per cent.

The count done on the duplicate slide worked out as follows :—

Polymorphs	...	22 per cent.
Lymphocytes	...	43 per cent.
Leucoblasts	...	35 per cent.

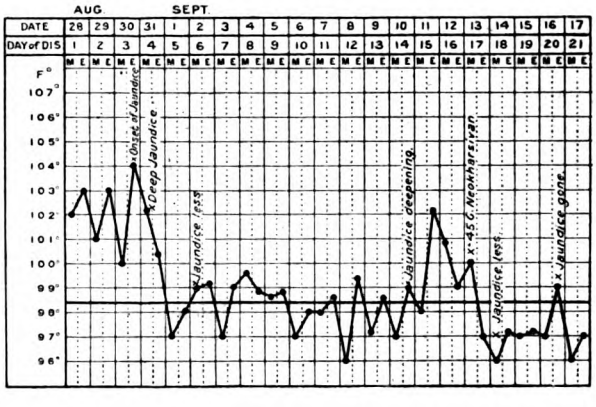
Since then I have never counted near the edge of a film nor have I counted less than 500 cells for the purposes of this paper. As would be expected, no lymphocytosis occurs after injection. The stimulus for the production of antibodies has ceased, and so none is produced.

A typical count in the injected on leaving hospital is :—

Polymorphs	...	84 per cent.
Lymphocytes	...	12 per cent.
Leucoblasts	...	4 per cent.

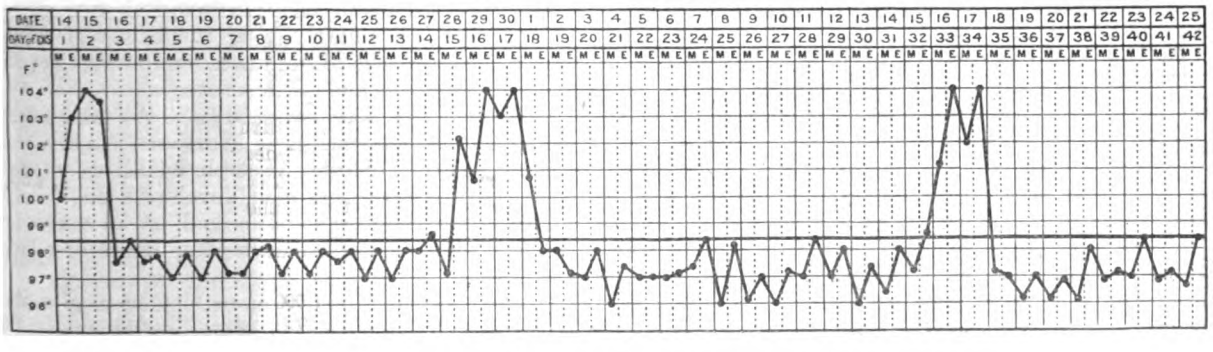
and it soon rights itself.

Malaria in Relapsing Fever Blood.—The average native blood-film shows malaria pigmentation, no matter for what disease the patient is admitted, but in relapsing fever this pigment disappears. I have not seen a case of malaria running concurrently with relapsing fever, although in one case *Plasmodium falciparum* rings were found in the blood during what I thought was a relapse ; no spirochætes were present. Quinine administration promptly stopped the fever. In relapsing fever the polymorphs present are usually very small thus showing that they are the children of overworked parents, and the point I want to make is that a lot of malarial pigment has disappeared from the blood and has presumably been stored in internal organs. The cerebral and cardiac symptoms can as easily be explained by the deposition of masses of pigment as by the clumping of spirochætes. Probably the two conditions are co-existent.



The Arneth count was of no use in prognosis. In the large majority of admissions with fever the count was around 56, and when it sank to 30 the patient was already so ill, clinically, that confirmation of his critical condition by this method would be merely academic. The range was from 78 to 29. I have not been able to interpret the results in any useful manner, and I have discontinued these counts.

Urine.—The urine was usually highly coloured and acid, with specific gravity 1010-1019. In 90 per cent. of all cases bile was easily recognizable. Albumin occurred in 12 cases not of the adynamic type, and was always a grave sign. Neokharsivan is not contra-indicated. Neither blood nor casts were found in any deposit. One of these patients died and all the others occasioned anxiety for some days.



Post-mortem findings.—The Native objection to this examination determined me to do none.

Clinical Features.

Incubation period.—One of my nurses (Chart No. 3), went down with the disease on August 28. I have no

doubt that he had been infected in the observation ward, where new admissions were de-loused. His wife (Chart No. 4) went down with the fever on

September 15. As the period of non-infectivity of the louse is eight days [2], that leaves an incubation period of anything up to nine days—if the bed-bug had nothing to do with this case. A very careful search of the house and of its inmates by myself revealed no lice and only one bed-bug on a native bed.

Prodromata.—This period lasts about sixteen hours. Always the first sign is intense frontal headache, which works up in a crescendo and totally incapacitates the patient. About twelve hours after the onset of headache there is commonly a sharp rigor—one in hospital lasted fifty-five minutes and showed a marked increase of blood-pressure during the period. The temperature cannot be taken at these times, but, in this case, at the end of the rigor the temperature was 100° F.

The presence of bile in the urine is so constant a feature of the disease that I examined the urine of several cases who came to the out-patients' department complaining of headache. Two cases of many that were positive to methylene blue and sulphur came into hospital, and one is the case of rigor already described. The other had a rigor lasting ten minutes. I now regard bile in the urine as an important prodromal sign; and 11 admissions to hospital, with bile in the urine and frontal headache, have all developed relapsing fever and so have been treated within two hours of the onset of fever. The other curious point is that all these cases developed their temperature between 6 and 8 a.m. No case developed jaundice.

The Fever.—Within four hours of the rigor the temperature is anything up to 105° F. The pulse is fast and bounding; the respirations preserve their ratio to pulse, and great pain is complained of in 45 per cent. of cases in lumbar region, thighs, and only in a few cases shoulders. Any food eaten that day is vomited.

In 4 per cent. of the cases the vomiting continues and is soon bile-stained. Diarrhœa sets in with the rise to a high temperature in 21·3 per cent. of the cases. In the majority, however, constipation is the rule. I tried to establish a relation between diarrhœa and cyst-passers, but constipated patients showed just as high a percentage of flagellates and *Entamœba histolytica* cysts. There is probably some relation to ankylostome infection, however, as thirty-two of the sixty-four diarrhœa cases showed ova without any special attempt at concentration of the eggs.

On the second day the patient is obviously very ill and the highest temperature is usually reached that evening.

On the third day the fever usually ends by crisis.

The longest pyrexia observed lasted five days (1 per cent). A pyrexia of four days occurred in 3 per cent.

Jaundice has been present in 70 per cent. of all cases and 92 per cent. of the untreated. It starts on the third day usually and is perfectly obvious within five hours of onset.

It remains stationary, if the patient is doing well, from the fourth to the sixth day, and then starts diminishing. Most cases are free in ten days from onset.

Liver is often tender but enlargement is very variable. Tenderness is a bad sign if injection is withheld.

Spleen.—The spleen was tender in 13·3 per cent. of cases. Enlargement is of course constant (malaria), but in *all* cases diminished under neokharsivan treatment, as did the few enlarged livers encountered. Splenic tenderness seems to be an important point in the diagnosis.

Heart.—In cases of good reaction (high temperature) the pulse never occasions any anxiety. On the second day some dilatation is obvious but compensation remains good. This dilatation is practically universal and is the cause of the grave weakness during convalescence.

Epistaxis occurred in 17·3 per cent. of the cases. It is always very copious and shows a great tendency to recurrence. It may come on at any period up to three days after injections of neokharsivan. Even one hæmorrhage, although promptly controlled, seems to set back the patient's convalescence several days. It is a sign which causes anxiety.

Hiccough is a bad sign, but only two cases who had it died out of twenty-six. It cannot be regarded as a sign of impending dissolution, although it is extremely intractable. In most cases it lasted for three days in spite of all known attempts at treatment, short of injection of the phrenic nerve, to which I could find no reference.

Relapses.—The most common period of apyrexia was nine days. The shortest period was five days and the longest thirteen. Only one case was seen which had two relapses, but several patients told me that they had two relapses before they came to me for a tonic. None of these had further relapses, so far as I know. The relapse was usually very similar to the primary fever. In almost equal numbers of those who had relapses differing from the primary fever the temperature was higher or lower than the first attack. But in none were the symptoms so severe.

Complications. — *Malaria and dysentery* have occurred immediately on onset of convalescence. Malaria has occurred only twice, but dysentery has been left in possession on six occasions.

Ankylostomiasis may have to do with the diarrhœa of some cases. A heavy infestation means a poor convalescence until the patient is sufficiently strong to have anti-helminthic treatment.

Bronchitis is so common that it may be regarded as a symptom of the disease. It is usually mild.

Pneumonia.—One case in hospital died of lobar pneumonia immediately after the crisis of relapsing fever. Six cases of broncho-pneumonia developed before the crisis and all recovered.

Pleurisy was seen seven times. As tuberculosis is prevalent in the natives of Northern Nigeria this is not to be wondered at. Tubercle bacilli were found in three sputa, and one man developed acute miliary tuberculosis and was discharged to be taken home to die. He died one month after onset of relapsing ever.

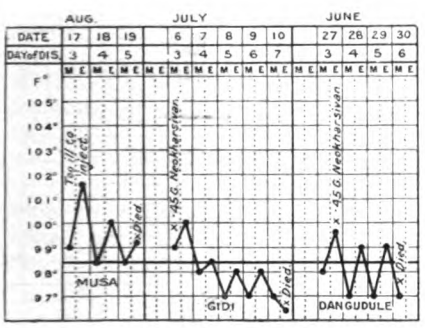
Iritis occurred in five cases. One case went on to phthisis bulbæ in spite of vigorous treatment. The other cases recovered without incident.

Stomatitis occurred in a large percentage of those treated in their houses. This is not a sign of relapsing fever, but merely conditioned directly by the absence of nursing and of the most elementary ideas of cleanliness.

Laryngitis occurred in twelve cases with aphonia in one.

Nervous Involvement.—Aphonia was present three times. The throat condition seemed normal. I was unable to get a view of the vocal cords as the patients were not in hospital.

Ptosis of the upper lid occurred twice.



Diplopia was seen once.

Delirium occurred three times in hospital and all cases died. They were very violent, always noisy, and all three died suddenly from cardiac failure, two on springing out of bed.

Coma was seen in all adynamic cases, but in no others.

Note on Adynamic Cases.

See Chart No. 5 where three tracings are shown. These cases differed from the rest in the absence of reaction to the infection. The temperature was always low in comparison with the majority of cases, and the heart was always extremely dilated.

The pulse was usually uncountable and most irregular.

Jaundice was always intense and the patients were never sensible when I saw any of them. Relatives always told me that they had fever for "about a day."

All cases sank into coma apparently within forty-eight hours of the onset of the illness. Injections had no effect on the result. The blood-count of Abeba —38,593—illustrates the delirium of blood production that goes on. This case is thus recorded in my notes: "October 21, 1924, Abeba, female, admitted absolutely collapsed; temperature, 96° F.; pulse 70, going up to 124 whilst being taken, then uncountable. Extreme jaundice of all mucous membranes. Brandy, 1 oz. statim; strychnine, $\frac{1}{100}$ gr. statim. Died before leaving bedside after taking slides and hæmocytometer blood. No history available as she was brought in by sanitary staff."

The differential count was as follows:—

Polymorphs 65 per cent.
L. lymphs 5 per cent.
S. lymphs 13 per cent.
Leucoblasts 17 per cent. Arneth index 50

The notes continue: "Microcytosis of the polymorph is extremely marked. There is either great immaturity (?) or degeneration (?): so much so, that the nuclei can with difficulty be distinguished in most of the cells: they seem to fuse with the rest of the cell, i.e., diffuse finely granular pigment. There is extreme increase of the platelets, whole fields being blotted out by their vast numbers. Death occurred two minutes after blood-film was taken however." The difficulty of distinguishing the cells makes the above differential count of no value. I am now inclined to believe that these cells were myelocytes of a very small variety.

In a second case, Dangudule, the total count was 28,000, and the differential count:—

Polymorphs ... 52 per cent.
Lymphs ... ... 17 per cent.
Leucoblasts ... 31 per cent.

The staining was again poor but more definition was obtainable. The "leucoblasts" really means "mononuclears," as a lot were myelocytes. I have had ten of these cases and none reacted to any treatment. As the blood-picture is markedly different from the "normal" cases, in the extreme microcytosis and the total numbers, it seems that the crux of prognosis is the staining reaction of the cells, this again depending on the degeneration, or immaturity, of the cells in the blood.

Stitt [3] mentions the "bilious typhoid of Greisinger" in Egypt, which is characterized by great tenderness of the liver, marked bilious vomiting, *late* jaundice, albuminuria, joint pains and a high death-rate. Many cases of adynamic relapsing fever were always too ill to give any symptoms, so that presence of pain could not be easily elicited. The liver was certainly tender, as was the spleen, in all cases, but rough handling only elicited movement or groans. Both organs were always enlarged. The jaundice was always *early*, however; albuminuria was present in six cases (not included in the others already cited). Spirochætes were seen in nine of the ten cases; but only after careful search. It seems to me that Greisinger's cases belonged to this type of relapsing fever, but I have not seen his report, and Stitt's note is the only reference to it that I know.

Diagnosis.—Epidemic jaundice and yellow fever had to be excluded at first. The response to the infection by rise of temperature, and corresponding pulse-respiration rise, were hopeful signs. The presence of the spirochætes and the immunity of guinea-pigs settled all my doubts. The early jaundice and rapid recovery of a patient after the crisis are important points. There was never any "coffee-ground" vomit, and the only hæmorrhages were from the nose. The effect of neokharsivan was always dramatic. The sense of well-being, however, is usually succeeded by depression owing to the weak anæmic state of the patient.

Dark-ground illumination has not revealed any spirochætes or spironemata in the urine of any of the 22 cases examined. This method of examination is being continued.

Prognosis.—A high temperature means a good

reaction and a safe convalescence later on. If the temperature goes up to 105° F. you have no worry; but if it remains round about 100° F. there is grave danger. Cardiac dilatation is practically universal, and it must be watched. As all febrile patients, except the delirious, are too ill to want to leave bed, sudden death should be easily guarded against.

It is to be noticed that a good pulse alone is no safe prognostic sign. One is guided by the temperature and the blood-picture. In one hour I have seen a good pulse become uncountable.

Immediate treatment gives the proper prognosis—recovery in all cases, practically speaking.

Treatment.—An intravenous injection of neokharsivan is given as soon as the diagnosis is made—provided there is any fever. I found that 0·45 grm. is the proper dosage for the vast majority of cases, and 0·6 grm. for very big men; 0·3 grm. does not cure. For purposes of cure it does not matter at what time of the febrile stage the injection is given, but the time of injection does affect the convalescence.

Patients injected on the day of onset have a much shorter convalescence than those injected near the crisis. Injections given during an afebrile period merely make the relapse of a milder type.

In collapsed cases, with a high temperature, I have been giving $\frac{1}{100}$ gr. of strychnine hydrochlor. mixed in neokharsivan solution with good effect. In two adynamic cases I tried this treatment, but it seemed to have no effect whatever.

Symptomatic Treatment.

High Temperature.—My first case of 105·4° F. was promptly sponged, and he as promptly reacted by developing broncho-pneumonia. The temperature had been reduced to 101·2° F., when manipulations were suspended, and twenty-four hours later he was extremely ill. Fortunately he recovered. Since then I have left all attempts at rapid reduction of temperature severely alone. I give brandy, ½ oz., every hour and push it until the temperature falls. I do not inject neokharsivan at a temperature above 104·6° F. without strychnine, as the induced crisis causes an acute collapse. In the only case which I injected at 105° F. the temperature dropped below the register of the thermometer.

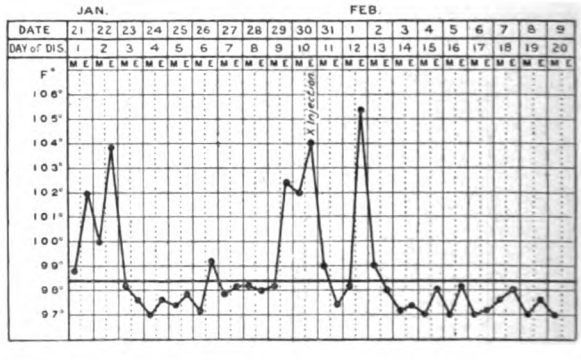
Collapse.—All cases must be watched after injection to see that the rapid crisis does not cause collapse. Brandy and, occasionally, hot-water bottles are unfailing preventives.

Hiccough.—Posture does not help. Tinct. iodi. mits. 3 minims two-hourly, controls some cases; turpentine, 1 oz. in mucilage, controls others. Most go on for three days and then stop. I always order digitalis, 10 minims q.i.d., if there is no temperature during the bouts; I think it prevents some of the exhaustion.

Epistaxis.—Packing with adrenalinized gauze has been of use. The most useful treatment is mopping and the continuous snuffing of tannic acid.

Pneumonia.—The following mixture has proved specific in my hands both in relapsing fever cases and in the others. I am indebted to Dr. Clive Sharp, of the West African Medical Service, for the formula:—

℞	Alcohol	... ...	2 dr.
	Liq. ext. glycy.	...	3 dr.
	Creosote	... ...	½ dr.
	Pot. iod.	... ...	2 dr.
	Aq. ad	... ...	12 oz.



One oz. t.d.s., add 1 dr. of ol. morrhuæ to each dose as ordered. I prescribe 1 oz. every two hours until irritation by the creosote is obvious, then give it every four hours. The chest is swathed in cotton wool and antiphlogistine, when I have it.

Dysentery carriers are treated during convalescence with E.B.I.

Ankylostomiasis is treated during convalescence.

Some Special Cases.

Garba, schoolboy, aged 13, Chart No. 1, is the same case as that discussed under blood-pictures. He illustrates the tendency, met with five times, for a disquieting rise of temperature to occur after injection. He was given 0.3 grm. of neokharsivan on January 30, and his temperature was normal all next day. On February 1, I was sent for at 10 p.m. as he

was extremely ill. His temperature had shot up from 98·6° F. at 6.30 p.m. to 105·4° F. His pulse was very good, but he was confused and talking of going home. Brandy, 1 oz., was given immediately and a special nurse put on. At 11 p.m. his temperature was 104·2° F., and I left the hospital. Next morning at 7 a.m. his temperature was 99·0° F., but he was very weak. A blood-film was taken at 10 p.m. on the night of February 1, and examined the next day. There were large numbers of spirochætes, which were the longest I have seen. It is the only slide which showed these organisms with 18-21 turns, and a slide at 7 a.m. on February 2 was negative. He made an uninterrupted recovery and was discharged back to the school on February 9 as I wanted his bed. Being at school, he remained under control. He has been quite fit since.

Kande, aged 30, wife of the nurse who got infected. Her chart is remarkable as the only one which showed two relapses. She refused injection and had only symptomatic treatment. Her illness was further remarkable for the great regularity of her three temperature curves, and the thirteen-day interval between her two relapses.

Her blood-picture was the first one which made the periodicity perfectly clear to me, as I had serial films taken for forty days. The film of September 15 showed a polymorphonuclear leucocytosis of 82 per cent. and that of October 25 a lymphocytosis of 68 per cent. In the afebrile periods the picture always showed a lymphocytosis being rapidly established, to be partially changed into a leucoblastosis in the relapse.

A Suggestion as to the Bionomics involved in this Epidemic.

There are several complex variables to be considered in any epidemic. In this one we must consider the environment of the human host, his resistance to infection, and the reaction which he is exhibiting to this new invader. We must also consider the conditions that obtain in the environment of the insect-host, its distribution and the extent of infection by the spirochæte. Further, we must consider the virulence of the causal organism and its power of "seeding" the population.

The environment of the people is bad. They live in houses constructed of mud, which have walls at at least one foot thick. There is never more than one window to a room, and it is very high up and only one foot by six inches in area; the doorways are usually about five feet by two feet, and often less than this.

The staleness and warmth of the atmosphere have to be experienced to be realized. There is never enough light to see a patient, and a lamp and a cigarette are always lighted before entering a native room.

The population is Mohammedan and so polygamous: this leads to overcrowding in the sleeping rooms, except in the houses of the better classes.

Water is scarce in the North, and the average native carries out only his ceremonial ablutions, which do not affect the lice on his body. In every way the ideal nidus for the louse is ready.

The resistance of the people is generally admittedly poor to all epidemic diseases.

The people are reacting to this infection by a primary leucocytosis and a secondary lymphocytosis. I believe that this has a special significance, which I shall discuss at some length.

The louse is not new to these people. It is a normal factor in their environment. The epidemic reached its peak in Katsina in January, which was the coldest month for forty years, according to the natives. For an insect-borne disease this seems very strange; but it is explained by the habits of the native in cold weather. He lights a fire in his house and sleeps near it. There is no attempt to ventilate the room, as the window and doorway are blocked up with mats. The temperature rises above the summer room-heat, as I have proved. The louse is not incommoded and it lives its normal life. The condition seems to be exactly comparable to those obtaining during typhus outbreaks in Russia during the winter.

The spirochæte is widely distributed through the North. It shows quite extraordinary virulence, as the death-rate of the infected is apparently about 57·7 per cent. The power of "seeding" the population appears to be high, as the adynamic cases have very little power to react, if any at all.

This new disease has invaded the country probably along several trade routes, as a reference to the map will show the difficulty of explaining otherwise the early widespread nature of the epidemic in far-away Sokoto.

The distribution and virulence of the spirochæte are both excessive; yet the disease seems to be reaching a state of equilibrium, as all epidemics do sooner or later. Why is this? The reason is the active immunization of the survivors of an attack, and the consequent drying up of reservoirs of the virus upon which the louse can draw. But I believe that I am watching more than that. I believe that I am watching the immunizing of a large part of the new generation.

I turn to my text-books and look up the discussion of immunity in the various diseases. All discussions bristle with "possibly," "it would appear," "it is probably explained," and I was struck with the idea that biological explanations are not invoked in an attempt to explain the facts. For instance Stitt [4] states, in the discussion of yellow fever, that "as proof that such immunity is not racial we may note that in Ecuador the natives of the endemic area about Guayaquil possess an immunity due to mild attacks in childhood; but the natives of Quito, 300 miles distant, where there is no yellow fever, do not possess it." As the disease is absent from one of the places compared, there is clearly something different in the environment. It seems to me that you cannot compare the reaction of two populations, one of which has had experience of the test object, while to the other it is entirely new. We should never talk of racial immunity until we know that the whole race lives under the same conditions environmentally with regard to a particular disease. To know this we must know the bionomics of the cause, of the insect host (if existent) and of the people.

The power to react to infection is inherent in all human beings. In this epidemic we see that the final, winning reaction is the production of antibodies. Now the infant is born with a polymorphonuclear leucocytosis, but a mild attack of an acute infection will quickly change the picture into a lymphocytosis. This is then the most primitive mode of fighting infection.

Relapsing fever has attacked a non-immune population in Nigeria. The environment of the people does not help them, and it is a war of primitives.

If ontogeny recapitulates phylogeny, it cannot be fortuitous that the infant's reaction is being repeated in this new disease. The Nigerian native is showing us man's primitive reaction.

Speaking biologically, the only reason that the attacked survive is to hand on their spark of Life. The two pregnant women whom I had in hospital were brought in because of threatened abortion, and both did abort. But I have treated convalescent expectant mothers who had recovered from the disease and

needed only a tonic. Unfortunately I did not make a blood-count or a differential count, as I had not yet formulated any opinions about immunity. No doubt these women reacted as all other uninjected cases did, by the rapid production of antibodies via a lymphocytosis.

The child *in utero* during the mother's illness will be born with the tendency to react to infection in exactly the same way that his mother has recently reacted. The antibodies in the mother's blood must have passed into the child's circulation, and I think it fair to presume that this pouring in of antibodies is bound to pull the trigger of the inherited tendency to produce still more antibodies. That means that the immunity of the infant is composed of two factors. The more immediately important is the passive immunity from the mother; the more ultimately important is the active immunity developed in response to the maternal danger signal.

The passive immunity may explain the remarkable immunity of the infant up to his sixth month from most of the infectious diseases. It is then exhausted, and, provided an infection is sufficiently heavy, the child has not enough active immunity to combat infection successfully.

We accept the conception of the survival of the fittest, and it seems to me that nowhere does this conception help more than in the organism's recovery from disease. It is inconceivable to me that the human organism can pass through such a crisis as it does in this epidemic without the impress being left on every tingling cell. The successful reaction must be recorded by nature, and its perfection, hereditary absolute immunity, is slowly built up by minute accretions from generation to generation. We must remember, however, that the very essence of the process is the continuance of the stimulus of antibody production; of course by the continued presence of the particular pathogenic organism.

Immunity is "racial" to trypanosomiasis in the game animals of Nigeria. Who can say that this immunity is extended to those animals which are not in a tsetse environment?

Stitt's example of yellow fever proves my point. Immunity is not racial, but an immediately heritable property which will appear racial when the process has gone on for an enormous period of time, provided that the whole race is in the same environment for that period.

I think that I have read of a tribe losing its immunity to some disease, but I have no reference to it in my notes. That is a process which I should expect to happen, as I believe immunity to be a character which is still being moulded by nature.

The text-books are very prone to postulate "mild attacks" of an illness in childhood to explain an adult immune population. They are quite right so far as they go, in my experience of malaria, but why should the attacks be mild? This is not explained.

The European comes to Nigeria a physically fit man. He is armed with mosquito boots, mosquito net, quinine, doctors to advise him and to keep the station clean; and yet he gets malaria. His first attack is usually a sharp one and he is temporarily an ill man. The native baby in the Niger delta arrives and is kept naked in a house set in a tropical swamp. The infant death-rate in Lagos, which is in the middle of numerous creeks, is 242 per 1,000. If we assume the infant mortality rate in the swamps to be half as much again, which I am assured is an excessive estimate, that means that six children in ten survive where a European, fully grown and fully protected, cannot live. Why do not all infants die? I can see no possible reason if it is not that they inherit a partial immunity to malaria. It is to be remarked that in these Southern pagan tribes it is the rule to starve the newly born for at least 48 hours, and some tribes extend the fast to as long as 96 hours. The effect on the child, who has just changed his environment more completely than it can ever be changed again, must be colossal.

These tribes, as far as is known, are holding their own; with the solitary exception of one which is disappearing under the influence of syphilis.

The Northern Hausa is to-day in exactly the same position with regard to relapsing fever as the European with regard to malaria. Neither has any inherited immunity to their new infection, and they must rely on their individual power of developing active immunity.

If the stimulus to immunity is persistent, from generation to generation, the immunizing process will go on to posterity, and the children will have "mild" attacks of disease, so that their passive inherited immunity and their active acquired immunity will in time create an insusceptible adult population.

It should be pointed out that every time that a case of relapsing fever is injected a biological offence is committed. The artificially cured cannot hand on his resistance, and we cannot tell what price his descendants will pay.

Summary of Paper.

(1) *Relapsing Fever* came to Northern Nigeria for the first time early in 1924.

(2) *The Spirochæte* is carried by the body louse, and possibly by the bed-bug as well.

(3) *The Spirochæte* is probably not *S. duttoni*. It corresponds more to *S. recurrentis* in the clinical course of the fever; in its non-pathogenicity to guinea-pigs, and in the absence of *Ornithodorus moubata* as a host.

(4) A clinical entity, the adynamic type, is superficially very like yellow fever, and it is probably identical with "the bilious typhoid" of Greisinger, in Egypt.

(5) The general *mortality rate* appears to be about 57·7 per cent., and probably more than 5·15 per cent. of the total population of Kano Province has been wiped out.

(6) Neokharsivan is specific, and, apart from adynamic cases, the mortality should not be more than 1 per cent. for all treated cases.

(7) The rising of the depressed birth-rate and the drop in monthly incidence of cases points to an active immunizing of the population, the most impor-

tant factor being the immunizing of the children *in utero*.

(8) This inherited immunity is passive. It explains the "mild" attacks in childhood which lead to an immune adult population, as regards any long-established endemic disease.

(9) The term "racial immunity" has tended to lead to confused thinking, as the all-important factor, the continued presence of the stimulus, is usually neglected.

(10) Therefore, immunity is most usefully regarded as being an immediately heritable property, which will become racial, if the whole race continues to live in the same environment as regards the particular disease.

I am deeply indebted to Dr. Connal, Director of The Research Institute, Yabba, for his constant willingness to supply me with stains, media and apparatus.

The Director of the Medical and Sanitary Services, Nigeria, has kindly granted me permission to publish this paper.

The Cultivation of Endamœba histolytica (William J. Boeck and Jaroslav Drbohlav, *American Journal of Hygiene*, July, 1925).—Two strains of endamœba were obtained in culture from two cases of amœbiasis, and were found to be morphologically identical with the endamœba in the fæces of the patients and with *Endamœba histolytica*. One strain, "K," was grown in cultures for eight months and eleven days, and another, "E," for three months. The most suitable artificial environment for the growth of *E. histolytica* was in either the Locke-egg-serum or the Locke-egg-albumin medium, at a temperature of 37° C. An initial reaction of the medium pH 7·2-7·8 was necessary. The cultivation experiments demonstrated that *E. histolytica* may, in the absence of a diet of tissue juices, extracts and red blood-cells, eat bacteria. Both strains, isolated in cultures, proved to be pathogenic for kittens, in which they produced acute dysentery, colitis and, in two kittens, a liver abscess. Prolonged cultivation did not influence the virulence of the amœbæ. The work reported by Cutler (1918) with respect to the cultivability of *E. histolytica* is confirmed by these experiments, but it was impossible to produce encystment under the conditions through which Cutler claims to have brought it about. The media used proved to be more suitable for the multiplication of *E. histolytica* than the blood-bouillon medium. Encystment occurred in a culture of the "E" strain of *E. histolytica* on one occasion only. The Locke-egg-serum and Locke-egg-albumin media have proved suitable for the cultivation of *E. histolytica*, *Chilomastix mesnili*, *Trichomonas confusa*, *C. gallinarum*, *T. gallinarum*, and has maintained *E. coli* and *Endolimax* for a period of three days.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these,** with remittance, **is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 ,, ,, ...	1	3	3
200 ,, ,, ...	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 ,, ,, ,,	2	6	0
200 ,, ,, ,,	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

THE JOURNAL OF

Tropical Medicine and Hygiene

SEPTEMBER 15, 1925.

THE HAYLING BRITISH MOSQUITO CONTROL INSTITUTE.

SOME five years ago the inhabitants of the central residential area of Hayling Island found it impossible to sit in their gardens in the late afternoon during

the summer and autumn. This was owing to the mosquito nuisance which had been increasing year by year, and had become intolerable. To combat this nuisance Mr. John F. Marshall, M.A., F.L.S. and F.E.S., assisted by Sir Richard Gregory, editor of *Nature*, founded the Hayling Mosquito Control Committee, which was the first organization in England to attack the mosquito from the " nuisance " point of view. The first task of the Control Committee was to discover what species of mosquitoes were the chief offenders, and for that purpose several thousands of mosquitoes were caught within the central residential area and identified. This preliminary research made by Mr. J. F. Marshall disclosed the interesting fact that practically the entire mosquito nuisance was caused by one particular species, namely, *Ochlerotatus detritus*, which breeds in brackish water.

Further investigations proved that the breeding places of the larvæ of *Ochlerotatus detritus* were about a mile and a half distant from the centre of the main residential area; that they were present in large numbers in stagnant salt or partly salt water; that the larvæ thrived not only in brackish water, but also in pure sea water, provided it was stagnant; and that the " hatching out " season of *Ochlerotatus detritus* was abnormally long in comparison with that of other British mosquitoes, the adults being produced continuously from March to November. Measures based on these facts were gradually introduced, and with the abolition or control of the principal accumulations of stagnant salt water the nuisance was successfully dealt with. The result has encouraged neighbouring sea coast district authorities to seek advice and guidance from Mr. Marshall to rid them of a similar mosquito nuisance. It was necessary for the advancement of the work that there should be a mosquito control laboratory and museum, and these were provided by Mr. Marshall in his house. But now, in view of a scheme of research on a wider basis, and the need of provision for practical training of students and others likely to be engaged in mosquito control, Mr. Marshall has had built at his own cost a fine institute called the Hayling Mosquito Control Institute and equipped it. This institute was opened on August 31 of this year by Sir Ronald Ross, Director-in-Chief of the Ross Institute and Hospital. There was a large attendance of members of the British Association and of residents on the island and neighbourhood. Sir Richard Gregory, who presided, said it was one of the glories of British science that some of its best work had been done by non-professional workers—men who had taken to the study of Nature purely for the love of it, and that the British Mosquito Control Institute was the outcome of work of that kind conducted by Mr. Marshall. In glowing terms he also described the results which had in the course of time followed the epoch-making discovery of the transmission of malaria through the anopheline mosquito by Sir Ronald Ross, whose work had placed Sir Ronald among the benefactors of mankind.

Sir Ronald Ross, in an interesting speech, said that when he began his work in India thirty years ago he could not obtain a single book or even a good article on the subject of mosquitoes of that country. Now they possessed much knowledge on the subject. But more energy was needed to act upon this knowledge. The work already done against disease caused by mosquitoes was only the beginning. The ultimate aim was to control not only mosquitoes, but all the dangerous and unpleasant pests which affected human beings and their crops and herds everywhere. After alluding to the objects of the Institute he remarked that mosquito control here would facilitate mosquito control in the most pestiferous regions of the earth, and the day might come when all those fertile tracts of the world now dominated and ravaged by King Malaria and King Mosquito would be laid open to civilization.

A vote of thanks to Mr. Marshall, proposed by Mr. T. Regan, President of the Zoological Section of the British Association, seconded by Colonel James, of the Medical Department of the Ministry of Health, brought an interesting ceremony to a close, and the three hundred guests had the opportunity of inspecting the Institute, which contains a demonstration museum, a laboratory, drawing and record offices, photographic rooms, a mechanical workshop and rooms for research workers.

S.

Annotations.

A Buffered Solution for Perfusion of Isolated Organs (R. N. Chopra and Sudhamoy Ghosh, *Indian Journal of Medical Research*, July, 1925).—Ordinary Ringer's solution and Tyrode's solution are unsuitable for perfusion of isolated organs, on account of the wide range in the variation of their hydrogen-ion concentration under experimental conditions (temperature of 37° C. to 40° C. and constant bubbling of oxygen). Variations in the hydrogen-ion concentration of Fleisch's solution are so small as to be negligible under experimental conditions. Fleisch's stock solution keeps indefinitely in a paraffined bottle in tropical climates.

Some Observations on Normal Sugar-Content of Blood and the Sugar Tolerance Test (S. L. Bhatia and G. Coelho, *Indian Journal of Medical Research*, July, 1925).—Blood-sugar was estimated in thirty-eight normal subjects, of whom eighteen were those who lived on a " mixed " diet, and twenty were pure " vegetarians," partaking of large quantities of carbohydrates. In the former class (non-vegetarians) the average blood-sugar was lower, tolerance for carbohydrates greater, and glycuresis less common than in the latter (vegetarians). The significance of these differences in the two classes of individuals is discussed.

Monilia Psilosis Ashford in Severe Anæmia associated with the Sprue Syndrome (Lawrence Weld Smith,

Philippine Journal of Science, April, 1924).—Eight cases of severe anæmia associated with the sprue syndrome were dealt with, and the *Monilia psilosis*, Ashford, 1914, was isolated from these cases, this being the first time it has been reported from the Philippine Islands. The specific nature of the complement fixation in sprue, using a watery extract of *M. psilosis* as antigen, was discussed. The histopathology of the peripheral blood was described, and on the basis of the blood-picture this anæmia was tentatively classified as aplastic.

Microbic Virulence and Host Susceptibility in Paratyphoid-enteriditis Infection of White Mice. The Effect of Selective Breeding on Host Resistance (Leslie T. Webster, M.D., *Journal of Experimental Medicine*. July 1, 1925).—The survivors of an experimental mouse typhoid infection, selected and bred for a number of consecutive generations, give birth to offspring which are more resistant to the disease than a random group of the same inbred race. The offspring of females most susceptible to this infection give birth to individuals which are more susceptible than a group of similar unselected mice.

Observations on the Possibility of Cure of Syphilis in Rabbits with Arsphenamine (Alan M. Chesney, M.D., and Jarold E. Kemp, M.D., *Journal of Experimental Medicine*, July 1, 1925).—The authors find that it is possible to treat syphilitic rabbits in such a manner as to render the lymph nodes incapable of transmitting infection to normal rabbits. The treatment should be begun either early or comparatively late in the course of the disease. If early, the animals are almost certain to be infected a second time, but if the treatment is begun late, they are almost uniformly refractory to a second infection. This refractory state in rabbits may possibly be explained by the existence of an acquired immunity which persists after the abolition of the disease, more than to the continuance of the first infection. It seems, under certain conditions, possible to reinoculate rabbits and, without producing any lesion at the portal of entry, produce generalized infection.

Biochemical Study of Resistance to Mildew in Oenothera (Joaquin M. Maranon, *Philippine Journal of Science*, April, 1924).—In order to discover whether or not there were definite correlations between chemical composition and reaction to mildew, chemical analyses were made of several resistant and susceptible hybrids and elementary species of *Oenothera*. These analyses were extended to other plants which had strains resistant and susceptible to other forms of powdery mildew. The resistant strains are higher in tannin and water-soluble acid, and in the majority of cases they are also higher in crude fibre than the susceptible ones. The susceptible strains are comparatively high in total nitrogen and total ash. The forms of nitrogen that are high in the susceptible strains during infection are the amino acids and nitrogenous compounds of non-basic character. The leaves of the susceptible plants are very rich in protein nitrogen when the plants are approaching senility. As compared with that of the resistant plants, the ash of the susceptible plants is exceedingly high in calcium and sulphur. The same correlation of chemical composition with disease resistance was found in all the strains examined, which comprised wild elementary species, reciprocal hybrids and mutations. Differences in chemical composition are found in both resistant and susceptible strains, before infection and after, and during the period when the leaves show chlorophyll degradation, indicating that the characteristic features of these two strains are constitutional. The chemical analysis made of the susceptible and the resistant plants of *Syringa vulgaris*, *Desmodium canadensis*, *Helianthus giganteus*, and *Solidago canadensis* confirms the findings in regard to *Oenothera*. An exception was found in the total ash and water-soluble acid contents of *Helianthus giganteus*, but the plants were wild and may not have been genetically as close as appearance indicated. Resistance in plants is doubtless due to a complex of interesting factors. Factors that increase tannin and acid and that decrease water-soluble nitrogenous compounds tend to build up immunity.

Malaria at Oude (Georgia): Study on Mountain Malaria (N. Roukhadzé).—Oude is a small village in the Caucasus, 1,100 metres above sea level, with a population of 3,000 people, nearly all agriculturists or horticulturists. The cultivated lands lie in the valley of the River Koblianistchai, 1-2 km. from the village and at an altitude of less than 50-100 metres. The percentage of the inhabitants with malaria is about 27·9, mostly attacked during the month of August; there are few cases in July and only 2 per cent. in spring. 40 per cent. of the malarial patients are between the ages of ten and nineteen years. It is well known amongst the inhabitants that it is chiefly those who work in the valley of the Koblianistchai who suffer from malaria; the women and children who never descend to the valley are rarely attacked. It was only in the valley, and in no other part of the village, that mosquitoes were found. Along the canals, where the water in August is 13-14°, culex were found in quantities, but no anopheles. At 1 km. to the east of the village more anopheles (*maculipennis*) than culex were found. About the middle of August the cold commences in the mountains, and it is then that the mosquitoes leave the plains to hibernate; this has also been noted in other parts. It is believed that at Oude the mosquitoes hibernate either in the trunks of the trees or under the dead leaves on the ground. With regard to parasitology, not one case of *Plasmodium malariæ* was detected among forty-two positive cases; in most cases *P.*

præcox was present. Another interesting fact is the spontaneous cure which often occurs at Oude.

Antispirillar Vaccinotherapy in Fuso-spirochætal Affections of the Skin and Mucosæ (R. Pons).—A saprophytic germ (*Spirillum*) of the human buccal cavity gives rich cultures on solid media. Subcutaneous injection of 2 c.c. of this culture, forty-eight hours old, causes a necrosis of the epidermis and dermis in the rabbit; there is putrid gangrene of the phagedenic ulcer type on the skin, and of the "noma" type on the buccal mucous membrane. The causation of necrosis by this germ led the author to believe that it probably played some part in ulcerous affections of the mouth and, in a general way, in fuso-spirochætal affections, and therapeutic experiments were carried out on human subjects suffering from tropical ulcer. The results were excellent: in forty-eight hours all pain had ceased, the inflammation had disappeared and the ulceration had greatly ameliorated. After three days there was no sign of necrosis, and after the fourth day cicatrization commenced.

First Experiments of Antituberculosis Vaccination of Infants in Cochin China and Cambodia (J. Bablet).—Good results have been obtained with antituberculosis vaccination. Children less than ten days old were given 1 cg. (in three doses) every three days, of B.C.G. cultures prepared according to Calmette's technique. Number of children vaccinated was 506. No trouble of any sort followed the ingestion of the vaccine. Antituberculosis vaccination is now generally used in Cochin China.

Leprosy and the Wassermann Reaction (Louis Simon).—In twenty-four cases of leprosy examined by the author the Wassermann test was positive; only one case was doubtful.

The Antimalarial Campaign at Gagri in 1923 *and* 1924 (N. Roukhadzé).—During the nineteenth century Gagri was the most malaria-infected place along the southern borders of the Black Sea. At the beginning of the twentieth century the Duke of Oldenburg founded a very fine climatic station there and, thanks to public hygiene and sanitary surveillance, local malaria did not surpass 10 per cent. After the revolution, however, through lack of surveillance Gagri became unhealthy, malaria increased, and in 1922 90 per cent. of the inhabitants were attacked. In 1923 the climatic station of Gagri was restored, and the stagnant pools and reservoirs, which were full of organic residue and animals (fish, frogs, snakes, &c.) were cleared. Conditions soon began to ameliorate and the percentage of malaria infection to decrease. The parasites found in the different seasons are the same all along the southern borders of the Black Sea; in winter *Plasmodium malariæ*; *P. vivax* in spring, and *P. præcox* in autumn. From the statistics it is seen that the percentage of parasite carriers always corresponds to the intensity of the malaria epidemic in the country; and that healthy people with splenomegaly furnish a larger number of parasite carriers than do normal people with a healthy spleen. The virulence of the epidemic in 1922 is accounted for by the presence in Gagri of numerous soldiers of the Red Army and refugees who had never previously suffered from malaria. The malaria parasites in this class acquire a special virulence and cause extremely grave clinical symptoms in cases of re infection, even in chronic patients. In 1924 the malarial campaign was continued on the same lines and excellent results have been obtained, and although the population is nearly four times as large as the previous year, only two primitive cases have been reported. Already, in 1904, *Anopheles maculipennis* and *A. bifurcatus* existed at Gagri, but to-day, thanks to the anti-malarial campaign, only the latter is to be found in the local forests.

First Experiments with "309" in Experimental Cases of Trypanosomiasis and in Human Trypanosomiasis (J. Laigret and M. Blanchard).—In these experiments "309" has shown a trypanocidal action comparable to that of Bayer "205" in experimental infections of guinea-pigs (*Trypanosoma pecaudi* and *T. gambiense*). The dose of 0·05 gr. per kilo of weight completely cures the infected guinea-pigs if the treatment is carried out during the first month after the first positive examination. Later the animal can be sterilized with 0·08 gr. per kilo. In the treatment of sleeping sickness "309," like "205," proves inferior to the arsenics. Peripheral sterilization is easily obtained, but it is of short duration; it also causes albuminuria in most cases. The preventive action of this product is also good. It has not yet been possible to prove the prophylactic action of "309" in man; one must first be sure of the renal troubles that the medication provokes. It is thought there might be a possibility of cure being effected by using atoxyl-309 mixed, and that it might be advantageous in reducing the number of re-infections.

The Hæmogregarina of the Horned Viper (Hæmogregarina seurati, *Laveran and Pettit*, 1911); *its Forms of Reproduction* (H. Foley and A. Catanei).—Of 154 vipers (*Cerastes cornatus* L.) 24 per cent. harboured hæmogregarina; the affection is more frequent among the large vipers. The different forms observed are minutely described.

The Second Case of Kala-azar in an Adult of Tunisia (Et. Burnet and F. Masselot).—Before the year 1925, kala-azar had never been observed in Tunisia in people older than nine and a half years. In the *Bulletin de la Soc. méd. des Hôp. de Paris*, of April, 1925, a case was reported in a woman of 26 years of age. The present case is a woman of 39 years, born at Marseilles, where she lived till the age of 5 years; she afterwards lived in Corsica and came to Tunis in 1906, where she was a nurse in the French hospital.

On the Frequency of Asthma in Tangiers (R Remlinger).—At Tangiers, as in most places, no age is exempt from asthma, and the two sexes seem to be about equally affected, and social conditions, professions, &c., seem to have no effect on the condition. Tangierian asthma is difficult to cure and is subject to many relapses.

NOTES ON THE CULTIVATION OF CERTAIN AMŒBÆ AND FLAGELLATES OF MAN, USING THE TECHNIQUE OF BOECK AND DRBOHLAV.

By J. G. Thomson, M.A., M.B., Ch.B.,
Director of Protozoology, London School of Hygiene and Tropical Medicine,

AND

Andrew Robertson, M.B., Ch.B.,
Assistant in the Department of Protozoology, London School of Hygiene and Tropical Medicine.

Material.

The material on which the following cultural observations were based was derived from several sources. The two cases of infection with *Entamœba histolytica* were patients in the Hospital for Tropical Diseases under the care of Dr. P. Manson-Bahr, to whom acknowledgments are due for his kindness in giving access to the infected material.

The *Dientamœba fragilis* culture was obtained from a colleague on the staff, and the remainder from medical men attending the general course of the School of Hygiene and Tropical Medicine. Accordingly, while the cultures were actually obtained in London, the infections were probably obtained in widely diverse parts of the world.

The medium used for the cultivation was the Locke egg albumin of Boeck and Drbohlav with certain slight modifications.

Cultivation of *Entamœba histolytica.*

The cultivation of *E. histolytica* proved to be a comparatively simple matter, when the difficulties encountered with the other human amœbæ are considered. Some of the blood and mucus from the stool was placed in culture tubes, incubated at 37° C. for twenty-four hours, and then examined. The amœbæ were very scarce, indeed, so scanty were they that it was only after prolonged search that one individual was found, nor did they increase in numbers at the subsequent examinations. Subcultures, however, were made and these proved to contain a considerably greater number of individuals. Thereafter it was simply a matter of daily transplanting some of the fluid from the base of the tube and from the surface of the lowest part of the egg slope to ensure a continuance of the strain. The amœbæ continued to increase in numbers until the experiments were terminated.

The first strain was isolated on March 25, and was discontinued on July 25, 1925, the cultures having been transplanted ninety-six times, in all 121 days. The initial culture of the second strain was made on June 14, and discontinued on July 25 also, the number of transplants being thirty-seven over a period of forty-two days. From the experience obtained with the other protozoa cultivated in this manner there seems no doubt but that the simplicity with which both these strains were maintained, was due to the fact that *Blastocystis hominis* was not present in the cultures.

Attempts were made to experimentally infect a kitten by rectal injections of the cultures, but with negative results. It is intended to repeat these inoculation experiments at some future date.

Owing to the fluid nature of the medium fixed and stained preparations were not particularly easy to obtain. Those, however, which were well stained showed amœbæ morphologically identical with those in the stools of the patients, except in one particular, viz., the cultural forms ingested bacteria. Boeck and Drbohlav succeeded in getting the *Entamœbæ* in their cultures to feed on red blood-cells when a quantity of blood was added to the medium. On the occasion when human blood was added to the cultures of the two strains under discussion no amœbæ were found with included red corpuscles.

Various other media were tried, but it was found that the strains, once established on the Locke egg albumin, did not progress so favourably on the others. Slopes of blood-agar were used, also agar, nutrient-agar and egg-agar slopes.

Encystment took place from time to time in the cultures. The cysts were always scanty, and their numbers did not appear to bear any relationship to the numbers of free amœbæ. No reason was apparent why cysts should appear in one tube and not in another. Age of the culture had seemingly no bearing on the question, since, owing to the bacterial overgrowth in the older tubes, growth, multiplication and encystment were inhibited. The cysts were found in tubes which were about forty-eight hours old. They had one, two and four nuclei, and had the characteristic rod-shaped chromatoid bodies.

Movement of *Entamœba histolytica.*

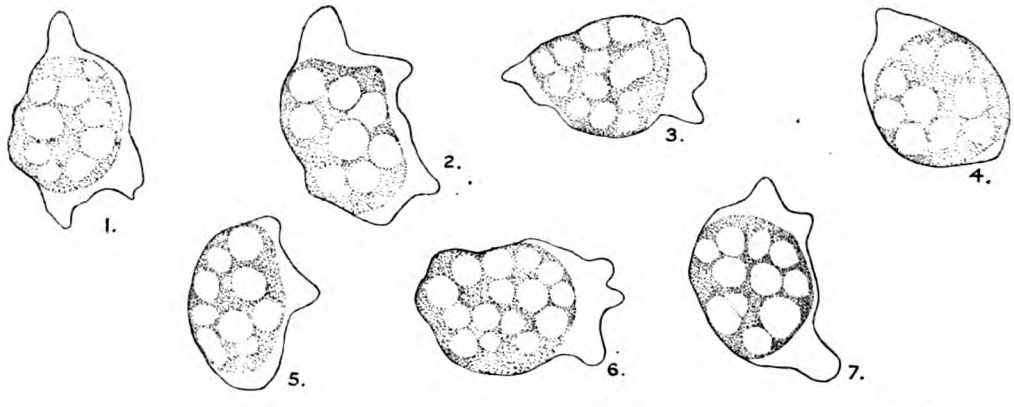
The different ways in which the various species of amœbæ moved was most striking, each having its characteristic mode of progression. For the purpose of observing the movements a warm chamber was used which enclosed the whole microscope.

When actively motile, *E. histolytica* became stretched out in a ribbon-shape with blunt rounded ends. The ectoplasm, while clearly differentiated from the endoplasm, yet tended to maintain the general outline of the amœba. That is to say the blunt, round, anterior end consisting of the ectoplasm was the same width as the remainder of the body. Movement was usually more or less direct, not as in some of the other species, indeterminate, and the distance covered considerable. The nuclear structure was always of the same type as that found in man, but the body showed greater vacuolation and also contained ingested bacteria.

Entamœba coli.

A strain of *E. coli* was maintained for sixty-nine days. Transplants were made daily. This culture, as were all the others, with the exception of the *E. histolytica*, was badly contaminated by *Blastocystis hominis*, which grew and multiplied at such a speed as to completely occlude all the protozoa present.

By making such subcultures practically every twenty-four hours, it was found that the amœbæ could keep pace with the growth of the *Blastocystis*. No cysts were found in the cultures.



MOVEMENT AND MORPHOLOGY OF *E. coli* IN CULTURE.

Morphologically, the specimens in culture did not differ from those found in fresh human fæces. They appeared to be very susceptible to changes in temperature, and, if placed on a slide which was more than three or four degrees below 37° C., they rounded up, and withdrew their pseudopodia. When actively motile, they showed a clearly marked differentiation between the clear hyaline ectoplasm and the coarsely granular endoplasm. In view of the old conception of *E. histolytica* having a much more clearly defined ectoplasm than *E. coli* the large amount of ectoplasm shown by the majority of the cultured *E. coli* was striking. They did not tend to progress over the slide, but moved about over the same spot, extruding their large, blunt, rounded pseudopodia in all directions. The movement was, in comparison with that of the other species, sluggish and ponderous. The body was usually rounded, and seldom adopted the wide ribbon or band outline of the *E. histolytica*, and, if it did, soon returned to the rounder or more compact shape.

Dientamœba fragilis: ITS CULTIVATION, MORPHOLOGY AND MOVEMENT.

A stool was obtained from a person who was known to be a carrier of this amœba and a portion was placed in a warmed culture tube very soon after the passing of the fæces. The following day there was a huge growth of the *Blastocystis*—in parentheses it may be said that it has never yet been found possible to find *Dientamœba fragilis* in a stool which did not have a heavy infection of these vegetable cells—but no amœbæ were discoverable. Subcultures, however, were made, and these also were without result, but on culturing for a third time, a few amœbæ were identified. They were approximately the same size as the blastocysts, and, using a low magnification, could quite easily be missed. Subsequently, the dientamœbæ grew fairly well, although it was extremely difficult to keep pace with the overgrowth of the blastocysts. The cultures, too, seemed to show a certain degree of periodicity as regards the numbers present. Making daily subcultures of approximately the same quantity of fluid each time it was found that the numbers of amœbæ increased daily for about five or six days, when they attained their maximum. They then dropped off suddenly, so that for two or three days it might be a matter of difficulty to demonstrate a single individual, and, next, gradually picked up again.

Previous observations on *D. fragilis* have shown that the ratio of binucleate to uninucleate individuals was about four to one. In culture the ratio was increased to five, sometimes six, or even more, to one. They tended to be uniform in size, and did not often show the same extremes as are found in human stools. The nuclear structure is the same as that previously described (Thomson and Robertson, 1923).

A. R. del.

FIG. 1.—Camera lucida drawings at a magnification of approx. × 1,600, of the successive shapes adopted by a single moving *Dientamœba fragilis* at intervals of from fifteen seconds to one minute.

The movement is characteristic. Text fig. 1 shows graphically the successive shapes adopted by one amœba. They were drawn with the camera lucida, the microscope being in a warm chamber at 37° C., and are as accurate representations as can be obtained by such means of continually moving organism. Dientamœbæ do not tend to cover a great deal of ground, staying, rather, in the same situation, extruding pseudopodia in an aimless fashion in all directions.

The pseudopodia are pushed out rather suddenly, but not to any great distance. In outline they are conical, and, as soon as the pseudopod has reached the extent of its travel, it usually widens, so that a flattened band of ectoplasm surrounds a considerable part of the circumference of the body. From

this wide, flattened, leaf-like (as Dobell, 1918, originally described it) pseudopodium, other conical processes may come out, still further accentuating the crenated leaf-like appearance.

No cysts were ever found in the cultures. The blastocyst infection, mentioned above, was so intense that the amœbæ were overgrown in a very short space of time, too soon, probably, to permit of cyst formation even supposing the other conditions were suitable. The method suggested by Boeck for ridding flagellate cultures of blastocysts by centrifuging the culture, allowing the tubes to stand for some minutes and then pipetting off the fluid containing a few flagellates, but supernatant to the blastocysts, was unfortunately of no avail in the present instance.

The characteristic degeneration of *D. fragilis* was well seen in these cultural forms. In one respect, however, they differed from the preconceived ideas of the amœba, viz.: they were much more resistant to external influences than the forms in the fæces. It is perfectly true that they are peculiarly susceptible to the influences of temperature variations, a fall of even a few degrees being sufficient to cause them to round up and withdraw the ectoplasmic projections, but if the temperature is raised again to 37° C. they will move as actively as before. Specimens have been kept under observation, with the microscope in a warm chamber, for three hours or even longer without any apparent change. Light certainly has an effect upon them resulting in a slowing of the movement, yet they will tolerate even a fairly strong illumination for at least half an hour, and still be actively motile. It seems a possible hypothesis, therefore, that the rapid death and degeneration of the amœbæ soon after leaving the body is due not so much to the adverse conditions of temperature, &c., as to the fæces constituting an unfavourable medium. If this should happen to be the case it might be the explanation why cyst formation does not, so far as is known, take place in the human body. Kofoid, 1923, reported the finding of the encysted stage in the fæces, and gave illustrations of uninucleate and binucleate cysts. Forms, similar to those he figured, have frequently been found in the cultures, and in cases of human infection, but it has not been possible to produce convincing evidence of their cystic nature. It seems much more likely that these are rounded up amœbæ with a thin layer of protective ectoplasm all round.

The Probable Cultivation of *Iodamœba bütschlii*.

Portions of fæces each having a heavy infection of *Iodamœba bütschlii* cysts were planted in culture tubes. On each occasion there was a rapid growth of amœbæ. Unsuccessful attempts were made to infect a kitten by rectal injections of the cultural amœba. It is accordingly impossible of proof that *Iodamœba* was cultivated on this occasion, although extremely probable. There were in fæces from both patients a few free, or, better, precystic iodamœbæ. A further reason why greater insistence is not laid on this claim to have cultivated *Iodamœba bütschlii* is the similarity between certain free-living forms and the amœba in question, and, while every possible precaution was taken to avoid contamination this could not be absolutely excluded. On the other hand, it is most suggestive that the same response was obtained on the two occasions, when cultures were made of iodamœba cyst cases, and on these occasions only. Lastly, the amœbæ in culture corresponded closely with the descriptions of free *Iodamœba bütschlii* in the literature.

Movement and Morphology.

The movement is very similar to that described in the case of *Entamœba histolytica*. A series of outline drawings, which were drawn in the same manner and at the same magnification as those of *Dientamœba fragilis*, of an amœba has been made to illustrate the method of progression. The amœba is usually stretched out in an elongated form, and is rather wider towards its posterior end, i.e., the end opposite the direction of travel. The pseudopodia are blunt, about the same width as, or a trifle less than the width of the body, and are composed of clear hyaline ectoplasm. The direction of movement is chiefly straight, and, if the amœba meets with an obstruction, it attempts to shove its way through rather than withdraw and change its line as *Dientamœba* would do. The body is vacuolated and may contain bacteria, &c. The nuclear structure does not differ in any way from that already described by many workers.

Cysts were never formed. In addition to the ubiquitous *Blastocystis* both cases also had *Trichomonas hominis*, and, indeed, this may serve as a good example of what may be termed a hidden or "occult" infection. Despite a careful search of the stools, by several individuals working independently, no trichomonas was found, and it was only after the cultures had been running some days that the presence of the flagellate was discovered. These flagellates gradually grew more numerous, but as they did so the numbers of the amœbæ declined until eventually a pure culture, pure in the protozoological sense, was obtained. At first the rapid growth of the amœbæ, the gradual increase of the flagellate, as if fighting an uphill battle, the eventual ascendency of the trichomonas and the final extinction of the amœbæ was most striking. The iodamœba culture ran for forty-six days over a series of forty subcultures before the amœbæ had finally disappeared. The second culture was discontinued after a shorter period.

Cultivation of *Endolimax nana*.

A strain of *E. nana* was obtained from one of the members of the General Class of Tropical Medicine, who had recently returned from abroad. The amœbæ, once they had become accustomed to the medium, grew fairly well, but the cultures always required careful watching. No cysts were formed. The culture was discontinued after nineteen days and the number of cultures was fifteen.

Morphology and Movement of *E. nana*.

The nuclear structure and cytoplasm did not differ in any essential from the fæcal forms. Just as the movement of the cultural *Iodamœba* closely paralleled that of *E. histolytica*, so does that of *E. nana* bear a resemblance to that of *E. coli*. The amœba tends to remain compact, while the wide pseudopodia are extruded in aimless fashion in all conceivable directions. It changes its situation but slowly, preferring to remain in one spot.

Cultivation of Certain Flagellates.

As noted above, no difficulty was experienced in getting *Trichomonas hominis* to thrive in this medium; it was not such an easy matter to get certain other intestinal flagellates to grow in it. *Chilomastix mesnili* was found to grow extremely well, when the expedient which will be described later in connection with *Tricercomonas intestinalis*, was adopted.

Tricercomonas intestinalis Wenyon and O'Connor, 1917.

The person in whose fæces *Tricercomonas intestinalis* Wenyon and O'Connor was found had been in England for about two months previous to the date on which his stools were examined. He was British by birth, but had been resident for some considerable time in the Federated Malay States. There was no history of his having suffered from intestinal disorder at any time, nor had his fæces ever been examined before for protozoa. The flagellates were present in considerable numbers in the fluid parts of the stool, and cysts, too, could also be found with a certain amount of difficulty, partly because of their small size and their scarcity, but more especially the ease with which they could be confused with the smaller *Blastocystis*, which were very abundant.

A quantity of the fæces was placed in a tube of Locke egg albumin, and incubated for twenty-four hours at 37° C., when it was found that the flagellates had increased in numbers, and many forms were in process of division. Subcultures, accordingly, were made, but these proved unsuccessful, no moving forms being found in twenty-four hours. The original culture, on the other hand, still contained numerous actively motile flagellates after eight hours had elapsed, so that the conclusion was arrived at that the medium was probably deficient in something which had been present in the first instance. Portions of human fæces each about the size of a pea, which had been sterilized by boiling, were added to fresh culture tubes, and these in turn were inoculated from the original culture. No difficulty was experienced after that in continuing the strain, but the flagellates did not thrive if the small portion of fæces was not added to each tube.

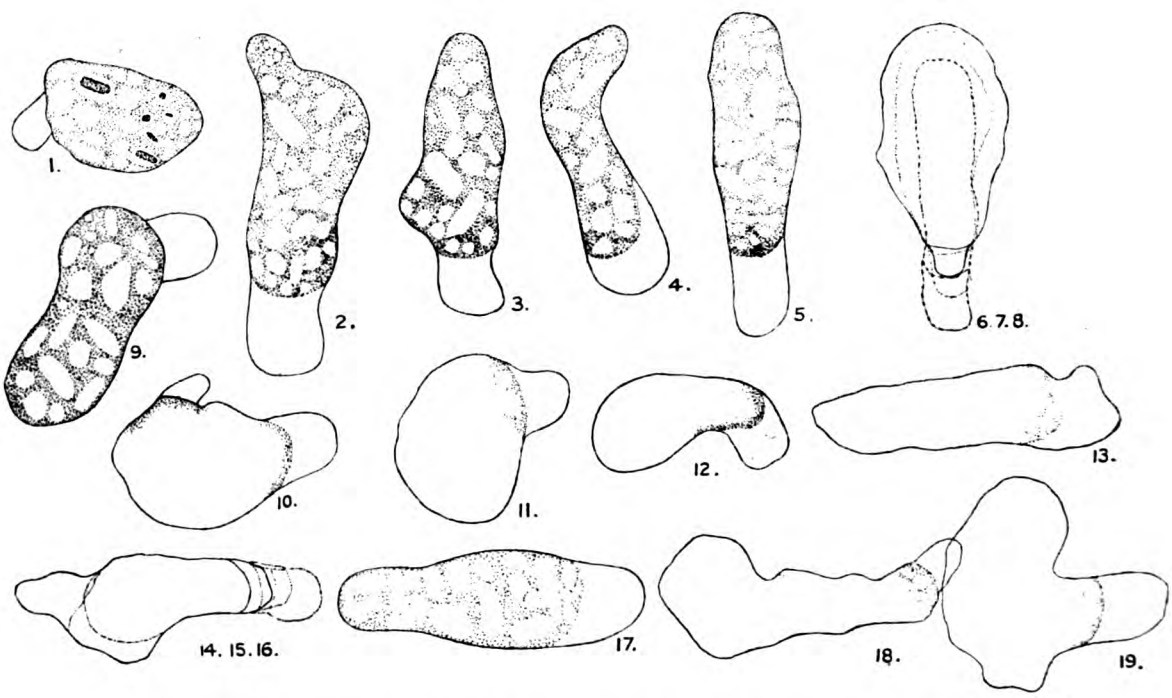


Fig. 2.—Camera lucida drawings at a magnification of approx. × 1,600, of the successive shapes adopted by a single moving amœba from a culture of human fæces containing *Iodamœba bütschlii*.

Morphology and Movement of *T. intestinalis*.

The morphological characters of this flagellate of the human intestine have been accurately described by previous workers. Dobell and O'Connor

(1921) raised the question of the identity of *Tricercomonas intestinalis* Wenyon and O'Connor, 1917, with *Enteromonas hominis* da Fonseca, 1915. It is quite clear from the study of the flagellates in the fæces and in culture that *T. intestinalis* differs from the description given by da Fonseca.

The free forms of this parasite show an extraordinary degree of motility. At first the movement of the flagella, and of the organism as a whole, is much too rapid to allow of accurate observation, but after an interval of about one and a half to two hours the quickness of the lashings is much modified. Dark ground illumination is very helpful in determining the nature of the movements. There are three anterior flagella arising close together from what appears to be a single blepharoplast. These do not work in unison, nor do they propel the organism in the same direction, but rather produce an erratic series of jerky movements towards whichever side the most recent flagellar propulsion has taken place. The fourth flagellum, which has a separate blepharoplast, leaves the body at some distance from the three anterior flagella, the intervening portion of the body being flattened and less liable to the amœboid movements shown by the remainder of the body. This flagellum is stouter and a trifle longer than the three anterior flagella, and its function seems to be more to steady and direct the body rather than to directly propel the organism. When the movement is studied in organisms which are fresh, the combined result of all the flagella lashings is, in addition to propulsion forwards, a peculiar vibratory motion which can best be described as "hovering."

Encystation has occurred in the cultures. The cysts were never numerous, nor did they in any way correspond with the number of free forms in the cultures. The peculiar granules, brown staining with iodine, which have been noted in a previous paper (Thomson and Robertson, 1925) as occurring in the cysts in fæces were present in the cultured cysts.

Giardia (Lamblia) intestinalis.

All attempts up to the present to cultivate *Giardia* have been negative.

Summary.

(1) The work of Boeck and Drbohlav on the cultivation of *Entamœba histolytica* and *Entamœba coli* has been confirmed.

(2) *Dientamœba fragilis* has been cultivated.

(3) *Endolimax nana* and *Iodamœba bütschlii* have also been cultivated, but experiments to inoculate kittens with the cultures were negative.

(4) *Trichomonas hominis*, *Chilomastix mesnili* and *Tricercomonas intestinalis* grow readily on the medium of Boeck and Drbohlav to which has been added a small quantity of fresh sterile human fæces.

(5) The movements and behaviour of the organisms in culture have been studied.

SOME OBSERVATIONS ON THE COMMON ENDEMIC FEVERS OF CEYLON.

By Eric C. Spaar, M.D., B.S., B.A.Lond., M.R.C.P.

Physician, General Hospital, Colombo; Lecturer on Clinical Medicine at the Ceylon Medical College.

The Malarial Fevers.

Malarial fever is by far the most prevalent fever in the island, so much so indeed that in very febrile illness it is a wise precaution to examine the blood for the presence of the plasmodium. The parts of the island in which the disease is most prevalent are the northern, the north-western, the north-central and the eastern provinces. In fact, the whole island with the exception of the south-western districts may be said to be malarious. If the incidence of the disease may be accurately gauged by the enlargement of the spleen noted in school children, according to Carter, now making researches for the Government in the country, there is a percentage of 60 to 70 in the northern half, and of 40 to 50 in the south-east. The hilly districts given over to the tea plantations are mostly immune. Practically every hospital in the island, however, is continually admitting patients suffering from the fever, owing to the fact that those afflicted rarely take sufficient treatment to eradicate the disease and are prone to frequent relapses. I am afraid medical officers do not sufficiently realize the importance of the prolonged treatment required to bring about a cure in malarial fever, while the ignorance and apathy of the public, and particularly the native villagers, are greatly to be deplored and are a great hindrance to all measures directed to the abolition of this scourge. In the Colombo General Hospital, for example, it is no exaggeration to say that at least a dozen cases of malarial fever are on an average admitted to the wards daily throughout the year, of which only an occasional one can be traced to having been infected in the city.

Breeding Grounds and Varieties of the Anopheles.—The island has not yet been thoroughly examined for a definite statement on this point, but Carter, of the Liverpool School of Tropical Medicine, who is at present engaged in researches for this pur-

pose, is hoping shortly to be able to publish the result of his findings. It is well known, however, that in the City of Colombo the anopheles has been found in more than one breeding ground.

Varieties of Fever.—Quite 80 per cent. of the cases of malarial fever in the island, certainly at the Colombo General Hospital, are of the benign tertian type, the other 20 per cent. consisting of about 18 per cent. subtertian and 2 per cent. quartan. A large percentage of these patients is really suffering from a relapse, as the notes of my cases prove, and must, therefore, most definitely demonstrate the haphazard way in which those afflicted carry out the necessary treatment, while on the other hand this observation augurs well for success in combating the disease if only some scheme could be devised for compulsory treatment for as long a period as a couple of months.

Mixed infection is not uncommon and generally consists in the grafting of a subtertian on a tertian infection, producing a continuous type of temperature that may be most baffling unless a careful examination of the blood has revealed the cause.

The subtertian infection, as is well known, may produce a very atypical fever differing in its manifestations according to the internal organ in which the parasite mainly sporulates, a feature to which Castellani has particularly drawn attention in an admirable and exhaustive description of the varieties in his "Manual of Tropical Medicine." In the island, as far as my personal observation goes, it is the cerebrospinal nervous system that is chiefly affected with symptoms of coma or of cerebrospinal meningitis, which is very fatal. Next in frequency is the gastro-intestinal type. Genuine blackwater fever is unknown, although the subtertian parasite is so frequently found as an infecting agent, notwithstanding the observations of Stephens. The only case I have heard of for the last eighteen years was undoubtedly one of malarial hæmoglobinuria.

Complications and Sequelæ.—Although many intercurrent diseases may be found during an attack of malaria, the complications are of no importance, but of sequelæ, those affecting the nervous system are not infrequent, while cirrhosis of the liver is fairly common and I have, moreover, met with three cases where diabetes has followed repeated attacks of malaria. The coincidence is certainly remarkable and worthy of close consideration since diabetes is so common in the island. In this connection it is worthy of note that Castellani and Whitmore have reported on two cases of glycosuria in malarial subjects where the urine was rendered sugar-free by the administration of quinine.

Chronic malaria is far too frequently met with in the island, and a percentage of ten among the hospital admissions for malaria is by no means too high. Resulting as it does from insufficient treatment of the acute disease, the importance of quinine treatment for a prolonged period should be more generally appreciated.

As far as my own observations go, the amount of chronic ill health due to chronic malaria is appalling. It is not only the enormous enlargement of the spleen, the enlargement of the liver and the profound anæmia that are so deplorable, but I have found chronic heart disease from myocardial degeneration and chronic Bright's disease far too frequently follow, to be a mere coincidence, when all other possible causes have been eliminated.

As regards treatment of the condition, I have found prolonged quinine administration with repeated courses of novarsenobillon intravenously to be the most satisfactory, although some benefit has also followed the use of a 1 : 1,000 solution of mercury perchloride intravenously, as I described in the Administrative Reports by the Commissioner for Medical Services for the year 1924.

Finally, as a preliminary to preventive measures on an extensive scale, the species of the anopheles acting as carriers are being carefully picked out, while it has been found that the *Gambusia affin* or "millions," the West Indian species, is prolific in breeding and vigorously attacks the larvæ wherever experiments have been made.

Intestinal Fevers.

Typhoid.—Of the various intestinal fevers typhoid is by far the commonest and prevails throughout the year, although its seasonal incidence is greater in the later months. The disease claims so many that in the City of Colombo a special hospital has been built and is maintained by the Municipality for receiving and treating only those so afflicted, and even so all the other general hospitals, too, are continually admitting quite a number of them.

There is no doubt in my own mind that the ætiology of enteric fever in Ceylon is bound up with the common house-fly, for not only does the seasonal incidence coincide with the height of the breeding season of the *Musca domestica,* but it is a fact that since the sewage of Colombo has been changed into a water-borne one there has been a marked decrease in its incidence. Only 709 cases were reported in the year 1923.

The type of fever is mostly of the mild or moderately severe form, running a benign course and terminating in three weeks with only occasional slight delirium and some gastritis and generally marked by constipation. This has been the particular feature of change that I have noticed for the past fifteen years. This statement does not imply, however, that a severe type with more serious complications running a longer course with relapses is not common, for every now and again these cases are being met with, and the medical man will be wise who is ever on the alert to notice early the changes which betoken the likely complications, for the disease still claims a high toll. Writing as I am, far away from statistics, it is not possible for me to give figures, but I should venture to say it was about 10 per cent.

Of the severer complications parotitis is certainly the most frequent, but I am not willing to subscribe to the opinion of writers of textbooks on medicine

that it is a very fatal one, for the majority of my cases have recovered. Hæmorrhage is next in order of frequency, about 15 per cent., and furnishes most of the deaths, marked toxæmia with severe nervous symptoms and heart failure being also of great import in a number of cases, as well as perforation.

On the whole one may say, however, that the disease is milder than it was two decades ago, and it would seem as if there has been forming a considerable degree of immunity in the indigenous native population. It is otherwise with Europeans, particularly if of recent arrival in the tropics, for in them the disease is usually more severe and is more liable to usher in grave complications.

Paratyphoid A Fever is not infrequent in the island where it was first reported by Castellani. About 3 per cent. of intestinal fevers only, however, belong to this group. The most frequent carrier is again undoubtedly the house-fly, but the bacillus can also live in the gall-bladder for a good length of time and be passed out in the fæces and so be a source of infection to others.

The disease runs a mild course in some cases, although I have known of one death at least in the island in private practice that was attributed to this germ.

Paratyphoid B Fever.—Although this fever is the common type met with in Europe, it is very infrequent in Ceylon. Not a single case in a series of 500 was due to it.

Paratyphoid C Fever of Hirshfield.—No case of this type, so recently described as occurring occasionally in Europe, has ever been observed in the island, although it is possible that some of the unclassified fevers in the island may turn out to belong to this group on investigation.

Parenteric Fevers.

These, as is now known by medical men practising in tropical and subtropical countries, are a group of fevers which clinically resemble the enteric group, but yield negative agglutination tests for typhoid, paratyphoid A, B and C. Castellani first showed, in 1905, that they are due to intermediate intestinal germs and, since then, their nature has been recognized by a large number of observers in India, the Philippine Islands, the Sudan, Egypt, parts of Europe and even in Great Britain. These fevers account for a large number of the so-called "Unclassified Fevers of the Tropics," and in Ceylon, at any rate, some of them are due to the *Bacillus columbensis* (Castellani, 1905) and the *B. asiaticus* (Castellani, 1904). The proportion of cases in the island I am unable to state, as unfortunately no attempt has been made to investigate their nature with any method, but that they occur frequently is undoubted from the number of cases of enteric-like fevers returned "negative" to the "enteric" group by the bacteriologist. It is suggestive that the number of deaths reported in 1923 from diseases classed as "pyrexia" was 5,024. Khaled has recently put down the incidence in Egypt of the most frequent "parenteric" fever to that of 10 per cent., which he states is of the "asiaticus" group, but in Ceylon half that percentage for the whole class would be more nearly correct.

The clinical course of these fevers is very like that of the "enteric" group, with a fever of a frequently irregular type and lasting for from three to nine weeks, but complications are rare and intestinal symptoms often lacking. The prognosis is on the whole very favourable.

Relapsing Fevers.

The island is happily free from the relapsing fevers commonly met with in Europe, Africa and America, whether the infecting vector is a louse or a tick. The only true relapsing fever that is frequently encountered is rat-bite fever, an account of which I have previously contributed to this Journal in 1923.

The specific spirochæte, however, causing the disease in Ceylon has not yet been found, and it must be left to future researches to decide whether it is the same as the *Spirochæta morsus murium* of the Japanese observers, in view of Rowe's findings in India. No instances of the relapsing fever of India due to the *Spiroschaudinnia carteri* have ever occurred.

The Kala-azars.

True kala-azar is not endemic in the island, but imported cases are seen, though very rarely. It was on a patient who had contracted the disease in India that Castellani first tried tartar emetic, with good results, in 1914.

What are known as the pseudo-kala-azars are, however, by no means infrequent, inasmuch as they resemble the true disease in the association of anæmia, emaciation and splenomegaly, although no specific parasites have ever been found. That the syndrome constitutes a clinical entity is very probable from the fact that cases have been reported from the Philippine Islands, India, Egypt, Northern Africa and South America. In one case of this type, Castellani found protozoal bodies in the spleen after death, which he named *Toxoplasma pyrogenes*.

Dengue and Allied Fevers.

Dengue first appeared in the island about the year 1905, coming from China via Burma and Singapore. The disease is very prevalent in the low-lying sea coast towns during the prevalence of the south-west monsoon, that is from May to September, and has not been known to prevail inland.

We now know from the experiments organized by the Medical Department Research Board of the United States Army, and conducted by Siber, Hall and Hitchens, as published in the *Journal of the American Medical Association*, April 18, 1925, that the *Stegomyia fasciata* is the only carrier, fully confirming the results obtained by Deland, Bradley and McDonald. A patient suffering from the disease is infective to the mosquito for the first three days, the virus takes eleven days to become mature in the body of the mosquito before its bite can infect a non-

immune human being, and the mosquito is thought to remain infective during the remainder of its life.

As to the type of the disease in Ceylon, it runs its usual course, producing a saddle-back type of temperature, severe head, arthritic pains and slight bronchitis being very common. On the whole I think, however, that the attacks are not as severe in recent years and that the disease is tending to be milder. The joint pains especially seem to be much less severe than formerly.

Seven-day Fever.—Seven-day fever, described by Sir Leonard Rogers, in India, is now known to be the same as dengue fever and needs no further mention.

Yellow Fever is unknown in the island. Seeing that this disease is only transmitted by the bite of the *Stegomyia fasciata*, there is a constant apprehension that the disease may one day be introduced into the island and cause a widespread epidemic with a heavy toll of life, for the stegomyia is a very common mosquito in the sea-coast towns.

The mechanism of transmission in the two fevers being so alike, it has been further suggested that the infecting organism of dengue fever may fall into the same group as that of yellow fever and be a filterable virus present in the peripheral blood, and capable of causing the disease by infection with the blood, while clinical resemblances have been claimed before mild attacks of yellow fever and typical cases of dengue.

Filarial Fever.

This is a very frequent type of fever in the island where elephantiasis is so common. Its importance lies in the fact that it is often thought to be malarial in nature, particularly at an early stage of the disease and before any elephantoid changes have occurred. Especially is this the case when there is no pain complained of in the affected lymphatic area, and only a careful examination will reveal the inflamed vessel. The attack often commences with a rigor and a high temperature. In other cases, especially by the uninitiated, the true nature of the fever is not understood and patients will insist that they are suffering from erysipelas, but the affection is not of a streptococcal origin. The correct diagnosis rests on the history of the case and the possible finding of a hardened lymphatic as a cord when the attack has subsided.

Plague

has undoubtedly come to stay in the island, or rather Colombo, for since the first case was discovered by Castellani, in 1914, when Director of the Bacteriological Institute, other cases have ever been recurring. The endemic area is only Colombo, and whenever a stray case has occurred outside the capital, infection has always been traced to that source. The truth of this may be seen from the Report of the Principal Civil Medical Officer for the year 1921. In that he states: "The total number of cases reported was 187, with 171 deaths. Of these 187 cases, 184 occurred in Colombo, of which 145 occurred in the first quarter of the year."

From this report we further learn why the island is so comparatively immune from the disease in an epidemic form, when the neighbouring continent of India has been devastated by it. In the early part of the year the maximum temperature, especially at night and in the mornings, is many degrees lower than in the so-called hot weather, and even in Colombo this may be and often is in the seventies, and we know that while the bacilli in the flea are virulent at a temperature of 70°, they rapidly disappear from its stomach at temperatures above 85° and are then ineffectual. There is also another reason. Hirst has pointed out that the commonest rat-flea in Ceylon is the *Xenopsylla astia*, Rothschild, and this flea is said to bite man with great reluctance at temperatures above 80°.

As regards the type of the disease in the island, the bubonic form is by far the commonest, quite 70 per cent. of the cases falling into that category. Next in frequency is the primary septicæmic type, 9 per cent., and 1 per cent. pneumonic. By this is meant primary pneumonic plague with frothy, slightly blood-stained sputum or liquid hæmorrhagic sputum and often no characteristic pulmonary physical signs, and has to be distinguished from pneumonia secondary to bubonic plague with definite sticky and rusty sputum. The two types last mentioned are, of course, always fatal, as elsewhere.

Fevers due to Helminth Infections.

Only these two types are at all important. The most frequent is that associated with infection by the hookworm. A type of fever is produced that is either intermittent or irregularly remittent. In the latter case it is often thought to be enteric, but the differential diagnosis presents no difficulties. The intermittent type being the commoner must be carefully distinguished from malaria, especially in view of the fact that the *Ankylostomum duodenale* is such a common intestinal parasite. Anæmia and enlargement of the spleen are also found in both infections.

The fever in ankylostomiasis, it is worth remembering, is believed by Castellani to be of bacterial origin and due to the entry into the blood-stream of intestinal bacteria through the small wounds in the intestinal mucosa produced by the worm. That this is a likely theory may be seen from the fact that the fever often continues, even after the parasitic infection has been got rid of.

In infection by the *Ascaris lumbricoides*, too, there is sometimes produced a fever which resembles typhoid, which however consistently gives negative results to agglutination of that germ.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these, with remittance, is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

THE JOURNAL OF

Tropical Medicine and Hygiene

OCTOBER 1, 1925.

THE TREATMENT OF ORIENTAL SORE.

ORIENTAL sore has a patchy geographical distribution and has caused various local names to be applied to the condition. A few may be quoted: Delhi boil, Aleppo boil, Biskra boil, Baghdad boil, Ulcera de Bauru (Brazil), Bouton d'Orient, Chancre du Sahara, Dermatite Ulcéreuse Circonscrite (Corre), Mycosis Cutis Chronica, Lupus Endemicus, Cutaneous Leishmaniasis.

Three species of leishmania are known to occur in man morphologically similar but pathologically different, namely, *Leishmania donovani,* Laveran and Mesnil 1903, causing kala-azar; *L. infantum,* Nicolle 1908, causing infantile splenomegaly; and *L. tropica,* Wright 1903, with its variety *L. americana,* causing cutaneous leishmaniasis.

The infectivity of this organism has been definitely proved by direct inoculation both in man and animals. Neither race, age, sex, occupation nor social condition materially affects susceptibility to infection. Insect carriers have long been subject to suspicion, but, up to the present, no insect has been definitely demonstrated to be the true host of *L. tropica.*

After an inoculation period variously stated in days, weeks or months, ulceration of the skin commences and slowly extends so that it may eventually occupy an area several inches across, though usually it presents a diameter of about one inch. After a period varying from two to twelve months, or even longer, healing commences by granulation, but the process is often slow and interrupted. Healing is eventually complete, but much scarring may result. It would appear that a tropical sore produces a definite immunity, so that, as a rule, second attacks do not occur.

Many and various are the forms of treatment which have been advocated for this condition. Excision of the sore has been advised. Various antiseptics have been employed, either as lotions, powders or ointments. These include perchloride of mercury, carbolic acid, permanganate of potassium, tincture of iodine, boric acid, silver nitrate, protargol and methylene blue. Salvarsan and atoxyl have been used without any good result. X-rays, light treatment and carbondioxide snow have all been more or less favourably reported on. More recently good results have been recorded from the injection into the base of the sore of gradually increasing doses of emetine hydrochloride.

The most successful results, however, have been achieved by the use of tartar emetic, which has been described as a specific for this condition, and of phosphorated oil. The former is best administered in the form of intravenous injections, using a 1 per cent. solution in saline solution or in distilled water. It may also be given by intramuscular injection, but this method suffers from the drawback that solutions of tartar emetic, as of other antimonial salts, are painful and apt to induce the formation of abscesses. Lastly, tartar emetic may be locally applied as a 1 per cent. ointment or as a 1 per cent. lotion, but the local application of tartar emetic in powder, which has been recommended, should be avoided on account of its extreme painfulness.

Phosphorated oil in the form of the oleum phosphoratum of the British Pharmacopeia was first advocated by Castellani in 1923. He had found that the use of this preparation by subcutaneous injection was practically painless, and, provided small

doses were employed, there was no risk of phosphorus poisoning, either immediate or delayed. Good results have been recorded from its use in several cases. It is essential that the phosphorated oil should be of recent preparation. It is now placed on the market in very convenient ampoules by Martindale. Its mode of employment is as follows: When the ulceration is well marked the oil is simply applied directly to fungus and margins of the ulcer, after removing the scab, and this simple treatment alone was found to answer admirably in several cases. When the lesion is a nodular one and there is little ulceration, in addition to the direct application of the oil, subcutaneous injections should be given. In carrying these out a sterile 20 minim all-glass hypodermic syringe is used, three to five minims of the recently prepared phosphorated oil are drawn in and then injected around the lesion by inserting the needle of the syringe under the skin round its margin; two or three drops of oil are then dabbed on the surface of the ulcer. This procedure is repeated once or twice a week, according to the amount of local reaction which ensues. If this is severe, as only very occasionally happens, the injections should be discontinued for a time and hot boric fomentations applied.

Subcutaneous injections of phosphorated oil have also been employed at Castellani's suggestion in other conditions, such as rickets and osteomalacea, and, as an adjuvant to quinine and arsenic, in certain cases of chronic malaria cachexia. It has further been suggested that this method of treatment might also be tried and found of benefit in other forms of leishmaniasis, as well as in certain cases of ulcer of non-leishmania origin, as, for example, granuloma inguinale, ulcus tropicum and certain persistent tropical ulcerations of obscure origin.

F. E. T.

Annotations.

Treatment of Hookworm Disease with a Mixture of Carbon Tetrachloride and Ascaridol (W. G. Smillie, *American Journal of Tropical Medicine*, January, 1925).—Carbon tetrachloride in diminished doses, when used in the treatment of hookworm disease, has a selective action upon female hookworms and does not remove ascarides. Ascaridol, the active principle of chenopodium, in diminished doses has a selective action upon male hookworms and is remarkably efficient in removing ascarides. A mixture of the two drugs does not increase their toxicity toward the host, since carbon tetrachloride has a specific action upon the liver, whereas ascaridol affects chiefly the central nervous system. An anthelmintic approaching the ideal for field treatment of hookworm disease is obtained by administering 2 c.c. of a mixture containing 4 parts carbon tetrachloride and 1 part ascaridol. The mixture is highly efficient, comparatively non-toxic, easy to administer and inexpensive.

Mercurochrome in the Treatment of Chronic Malaria (D. B. Avison and Byrom Koo, *The China Medical Journal*, May, 1925).—The treatment of chronic malaria by a single intravenous injection of mercurochrome (0·003 grm. per kilo of body weight in a 1 per cent. solution) has given a cure of 100 per cent. of cases treated by the authors. Patients admitted to the hospital in the morning with the diagnosis of chronic malaria and given a sufficient dose of mercurochrome have been discharged the same day apparently cured. Where the conditions permit, the treatment may be safely given in the patient's home. The average native patient should be admitted to hospital until the chill or vomiting reactions are over.

The Concentration of Quinine in the Circulating Blood (H. W. Acton and R. N. Chopra, *Indian Journal of Medical Research*, July, 1925).—The results of these investigations are as follows: The administration of alkalies before quinine enhances the rate of diffusion through the mucous membrane of the small intestine, so that the concentration of quinine is almost doubled in the mesenteric blood. The rate of diffusion of quinine is lessened when the substrate is acid, as in the stomach, or when the mucous membrane is congested or diseased (e.g., gastritis), so that the concentration of quinine is considerably reduced from the normal. The concentration of quinine is greater in the mesenteric blood than in the systemic blood, probably owing to the absorptive action of the liver. The increase in the cure rate of quinine following the alkalies is dependent on the greater concentration of quinine in the blood, and not to the slight alterations in the pH of the blood. The difference in the cure rate of the three different malarial fevers is dependent on the concentration of quinine coinciding with the site of sporulation. Thus quinine is very effective in malignant tertian infections as sporulation occurs largely in the mesenteric vessels. The absorption of quinine is dependent on physical laws, increasing when as excess of OH-ions is present at the surface of the cell-membrane, and diminishing when an excess of H-ions is present.

Notes on Selective Media for Gonococcus and Pneumococcus (Nand Lal, *Indian Journal of Medical Research*, July, 1925).—In these experiments gonococcus and pneumococcus showed greater yields on trypsin blood-agar and on potato blood-agar than upon simple blood-agar. Gonococcus gave the best yield upon trypsin blood-agar and the addition of potato juice to the trypsin blood-agar made comparatively little difference as compared with trypsin blood-agar alone. Pneumococcus followed the same course as gonococcus more or less closely, but gave definitely the largest yield on potato trypsin blood-agar. The effect of age was to reduce the value of medium from the point of view of yield.

Tryparsamide in the Treatment of Neurosyphilis (Udo J. Wile, M.D., and Lester M. Wieder, M.D., *Journal of the American Medical Association*, June 6, 1925).—Continued observations with a larger number of cases and over a longer period of observation has proved the value of tryparsamide in producing clinical betterment in almost 30 per cent. of a carefully selected group of cases. In the main, clinical improvement was not paralleled by striking changes in the spinal fluid, many of the most strikingly improved patients retaining, after protracted treatment, the changes in the fluid that were found at the original examination. In a small group of cases in which spinal fluid change was noted, clinical betterment was found to be associated with such improvement. When improvement occurred clinically, this was indicated in a large majority of the cases during the first and second course of treatment.

Note on the Incidence of Kala-azar on the Pusa Estate (D. F. Michael, *Indian Journal of Medical Research*, July, 1925).—The climate of Pusa consists of a dry and a moist season; during the dry season, October to May, humidity is relatively low. For a varying period of anything from a week to a month just before the break of the monsoon in June, the air becomes exceedingly hot and dry. The water supply is from masonry wells which are disinfected once a week with electrolytic chlorine. The standing population is made up entirely of the staffs of the various sections of the institute, school, public works department, &c., and their families, and numbers about 800. In addition there is a floating population of about 500, who live in the neighbouring villages. In spite of the good sanitary conditions, &c., kala-azar has made its appearance in Pusa. All the cases that have so far occurred have been among Indians. From observation of these cases the author concludes that kala-azar appears to be essentially a house infection and in a lesser degree a site infection. The disease is undoubtedly associated with unhygienic modes of living. Young children are particularly susceptible to the disease. A point worthy of consideration is that an insect vector is not primarily responsible for the spread of the disease. Its transmission by mechanical means does not necessarily exclude the possibility of a blood sucking insect harbouring the parasite. The incidence of the disease seems to be more marked between the months of October and March and is highest during December, January, February.

The Bactericidal Power of the Blood of Rats as a Measure of their Immunity to Plague (R. H. Malone, C. R. Avari and B.P.B. Naidu, *Indian Journal of Medical Research*, July, 1925).—Using the technique of Heist and Solis-Cohen a definite correlation has been shown to exist between the bactericidal power of the blood of rats and their immunity to plague. The animals experimented upon include (1) rats obtained from the City of Madras, (2) artificially immunized Madras rats, and (3) rats obtained from the City of Bombay; the highly susceptible to plague, the highly immune, and those possessing various grades of immunity inherited or acquired in an endemic plague centre. With the standard test virus employed 2 per cent. of Madras, 33 per cent. of Bombay and 97 per cent. of the immunized Madras rats were found to be immune of plague. Rats of any category which possess a high grade (*a*) of hæmo-bactericidal power are able to survive the test virus and may be considered as immune to plague. In the case of rats from the City of Madras, which as a class have neither inherited nor acquired immunity to plague, a low grade (*c*) of hæmo-bactericidal power indicates certain death in the event of infection with the test virus. Susceptible rats do not respond equally to equal immunizing doses of dead and living plague virus. Seventy-six per cent. develop a high grade (*a*), 18 per cent. a medium grade (*b*) and 7 per cent. a low grade (*c*) of bactericidal power. Three per cent. of those which have survived one standard dose of living plague virus succumb to a second dose. Similar results may be expected in man. While the bactericidal power of the blood serves as a means of measuring the immunity, it is not a true index of the *total* immunity to plague. These experiments have suggested the presence of an additional factor in the immunity of rats to plague, which is probably to be sought for outside the blood stream (tissue immunity, or antiblastic immunity).

As a definite relation exists between the bactericidal power of the blood of rats and immunity to plague, it may be possible by this or some similar technique to measure directly on man the protection likely to be afforded by various kinds of plague vaccines, the proper dosage to be employed, the duration of immunity and the effect of reinoculation, as well as to throw some light on the mechanism of natural and acquired immunity to plague.

Further Observations on Malaria made during Treatment of General Paralysis (Warrington Yorke).—The general bearing which these observations and considerations have on the question of the best means of treating malaria are as follows: Treat the attack with a few moderate-sized doses of quinine and await developments. If a relapse occurs repeat the treatment, and so on. Avoid the use of excessively large doses, or of prolonged courses of quinine; there is no evidence that anything is to be gained from excessive quininization and it may well do harm. Whether or not relapses occur depends on the reaction of the patient himself and on his capacity to develop immune-body, attention to such factors as general health, diet and avoidance of exhaustion are probably of great importance. Whether the systematic administration of daily doses of quinine as a prophylactic is desirable is considered

a very open question. Quinine has no true prophylactic action and it is quite possible that its administration for long periods may render more unsatisfactory the treatment of the infection when it does develop. Probably the point can only be decided by comparing over a period of several years two groups of persons, in one of which quinine is given prophylactically, whilst in the other the attacks of malaria are treated as they occur in the manner described.

Abstracts.

HOOKWORM INFECTION AS INFLUENCED BY THE WEARING OF SHOES.[1]

By Nelson C. Davis.

After studying intensively the problem of hookworm infection in the south-central region of Brazil, Smillie emphasized among other findings a correlation between intensity of infestation and amount of contact with humid earth of the fields. He also pointed out the great protective value of shoe-wearing among the labourers.

The data here presented were collected during a short campaign upon the Ilha dos Marinheiros near the city of Rio Grande on the extreme southern littoral of Brazil. The inhabitants of this island are agriculturists and fisher folk, largely Portuguese immigrants and their immediate descendants.

In a series of 458 cases we made worm counts following treatment. In Table I this series is divided according to sex and age, showing the number of hookworms and ascarides recovered in each subgroup.

It will be seen that the peak of ascaris infestation occurs in both sexes between the ages of 6 and 10 years. It is also noteworthy that the average for the females is greater than that for the males in nearly every age group.

Ignoring for the moment the sharp rise of uncinaria infection in the age group "51 to 55 years," the highest incidence among males occurs in the group "16 to 20 years," the highest incidence among females in the group "11 to 15 years." As will be noticed the curve of infestation rises sharply in the period "6 to 10 years." According to the observation of Smillie, it is during these years that the children of both sexes begin to work in the fields and to acquire their hookworms concomitantly.

Among the male population the average infection remains high up to the age of 60 years. The decided rise at the age of 50 may be eliminated by taking an average of the two groups "46 to 50 years" and "51 to 55 years" giving 169 for the ten-year period. In a similar manner the corresponding groups among females may be averaged, smoothing the curve to 50·9 for the ten years. Averaging these age groups is more or less justified because many of the middle-aged people are ignorant of their exact age and say, "about fifty years"; the nurse then uses his judgment and puts down 50 to 51 years, depending on the age-group to which the individual appears to belong.

Table I.—Average Number of Hookworms and Ascarides per Person at Different Ages.

Age Group years	Males			Females		
	Persons in group	Hookworms per person	Ascarides per person	Persons in group	Hookworms per person	Ascarides per person
1 to 5	29	2·8	7·2	30	4·8	8·3
6 to 10	35	44·1	13·8	25	32·4	20·5
11 to 15	29	137·0	5·7	21	70·4	6·7
16 to 20	40	220·4	1·35	20	64·75	3·3
21 to 25	21	213·6	3·4	22	44·4	7·4
26 to 30	23	197·8	0·18	14	9·93	4·4
31 to 35	19	182·6	2·94	12	8·9	6·0
36 to 40	33	174·8	1·6	12	11·1	4 0
41 to 45	12	185·0	0·25	7	40·4	6·3
46 to 50	11	86·6	4·8	7	9·9	16·0
51 to 55	12	244·6	2·8	11	77·0	1·1
55 to 60	7	164·1	5·6	1	1·0	0·0
Over 60	2	52·0	0·0	3	0·66	0·33
	273	146·7	4·5	185	33·7	8·0

It seems reasonable to suppose that persons attacked by large numbers of worms may appear older than those supporting small numbers, and thus be thrown oftener into the class "51 to 55 years."

Table II considers the same series of cases, subdivided as in Table I, and shows the number wearing shoes at each age. It should be mentioned that a large percentage of the so-called "shoes" are nothing more than wooden-soled slippers. The majority of the field labourers habitually go bare-footed; shoes are not considered necessary, and some types of Brazilian foot gear appear to be an actual hindrance at work.

Although Table II indicates the use of shoes before the age of 15, it is very doubtful if any of these children wear shoes a greater part of the time. A glance suffices to show that shoes are not popular

[1] Abstracted from *The American Journal of Tropical Medicine*, vol. v, No. 1, January, 1925.

among the males in any age group. Before the age of 15 the infection in girls has reached its peak; at about this time many of them either start homes of their own or take up the duties of their mothers, and, with indoor work, begin to wear shoes or slippers more consistently. From the age of "16 to 20 years" onward a fair percentage of the women are found to wear shoes; the infection rate also begins to decline. However, the girls are already infected, and, as Smillie pointed out, it may take several years to lose an infection; hence, the rate remains high up to the age of 25. Beyond the age of 25 there is a sharp decline, and not only is the general rate low, but the rate among the women wearing shoes is appreciably lower than among the others. This difference might be shown in tabular form but the small number in each age group scarcely justifies a subdivision.

Although during the rush of harvest seasons many women of all ages may be found doing farm work, this practice is much more common among those outside the child-bearing age. Many women rear their families to a stage of responsibility and once more take an active part in the out-door work. With their re-entrance into field labours, the women in many instances again discard their shoes. In the age group "46 to 50 years" we find only one woman out of seven admitting the use of shoes; if we average the ten-year period—46 to 55 years—we find 38·8 per cent. wearing shoes.

It is our opinion that the wearing of shoes is the greatest factor influencing the degree of hookworm infestation upon the Ilha dos Marinheiros. It is true that the persons most highly infected are usually the labourers who come into contact with soft, moist earth of the fields, but it does not necessarily follow that these same fields are the source of their infections. Although the native of Ilha dos Marinheiros may sometimes defæcate in the cultivated fields, the custom, as near as we can observe, is to frequent certain very definite localities, for example, a clump of bushes on the uncleared land or a bamboo thicket. The men and women often go to separate places. At the initiation of our work there was not a single latrine among the 1,500 inhabitants of the island.

Table III presents the results of some larval isolation experiments carried out with apparatus and technique comparable to that described by Cort. We always had at hand cultures of human hookworm larvæ for comparison in doubtful cases, but it is improbable that in the samples examined we were able to differentiate the larvæ infective for humans from similar forms potentially parasitic for lower animals.

TABLE III.

Recovery of larvæ from the soil.

Origin of samples	Total samples	Samples positive for Uncinaria	Total worms recovered	Uncinaria larvæ recovered
From public paths and uncultivated door yards	14	3	90	4
Door-step of Post where men cleaned their feet before entering the house	3	3	435	10
Cultivated fields	11	1	313	2
Thickets habitually polluted by the inhabitants	12	9	2,788	67

To account for the great increase of infestation between the age of six and ten years we have but to study the habits of the younger children. Most of the youngsters have not a highly developed sense of modesty and feel no compunctions about promiscuous defæcation. Later they begin to frequent the localities used by their parents and there become infected; this occurs about the same time that they commence to work in the fields. Since the sexes so frequently use separate localities, the girls are not exposed to the same intense soil infestation that falls to the lot of the boys; it is quite likely that this difference would be wiped away in the course of a few years, however, were it not for the protective influence of the shoes more frequently worn by the females.

We are quite aware that these conditions are not general throughout Brazil, or even throughout the State of Rio Grande do Sul. There are farmers in the colonies who deliberately fertilize their fields with human excrement; no doubt such fields are very generally infested, provided the soil conditions are favourable for larval development.

TABLE II.—PERSONS WEARING SHOES, WITH AGE DISTRIBUTION.

Age groups	1 to 5 years	6 to 10 years	11 to 15 years	16 to 20 years	21 to 25 years	26 to 30 years	31 to 35 years	36 to 40 years	41 to 45 years	46 to 50 years	51 to 55 years	Over 55 years	Totals

SUMMARY.

In an analysis of hookworm counts made on the Ilha dos Marinheiros, State of Rio Grande do Sul, Brazil, a rather definite correlation is found between the intensity of infection and the amount of shoe-wearing among the different age groups of both sexes.

It is indicated that infections are contracted in this particular area, not so much by prolonged contact with the humid earth of the fields as by relatively shorter exposure to highly infected spots of pollution.

Although there is an intricate system of paths and trails, there are no real roads on the island. Many paths lead through, or close to, the thickets habitually polluted by the inhabitants. Our table shows that three-fourths of the thickets examined were infested, and that larvæ had no doubt been carried from these areas by the feet of passers-by, secondarily contaminating some of the paths and even the very doorstep of the Post. The cultivated fields, on the other hand, although not extensively examined, appear to have been comparatively free from dangerous contamination. It seems reasonable to suppose that a few minutes spent in a highly infected area would be more disastrous than hours in the open fields. Conditions upon the Ilha suggest those described by Cort as existing in Trinidad.

TWO NEW CASES OF HUMAN CREEPING DISEASE (GNATHOSTOMIASIS) IN CHINA, WITH A NOTE ON THE INFECTION IN RESERVOIR HOSTS IN THE CHINA AREA.[1]

By KAORU MORISHITA and ERNEST CARROL FAUST.

FROM the medical and zoological points of view it is of especial interest that the nematodes of the genus *Gnathostoma*, which are naturally found in various animals, occur occasionally in man, causing disease. Five indisputable cases of *Gnathostoma* in man have hitherto been reported and all from Eastern Asia.

The first case was reported from Siam by Levinsen (1887) who studied a specimen collected by Dr. Deuntzer from the abscess of a native woman and described it as *C. heiracanthus siamensis* n. sp. This was an immature female of *Gnathostoma*. The second case was that of Dr. Kerr in Siam, who removed a parasite from the cutaneous node of a native. The parasite was studied by Leiper (1909) who stated that it was an immature male, identical with that of Levinsen, and must be referred to the genus *Gnathostoma* with the specific name *Gnathosthoma siamense* (Levinsen). Later, Leiper (1911, 1913) discovered that *Gnathostoma siamense* was synonymous with *Gnathostoma spinigerum* Owen (1836), a view which is now generally accepted. The above-mentioned cases, therefore, are concerned with *G. spinigerum*. The parasite of the third case was obtained by Samy (1918) in the Malay States from a thenar abscess of a Chinese coolie and also referred to *G. spinigerum*. The fourth case was reported by Tamura (1919) in Japan. He treated a typical "creeping disease" of a Japanese just returning from a long sojourn in China, and removed a parasite which he referred to *G. siamense* (= *G. spinigerum*). The fifth case was indigenous to Japan and has recently been reported by one of us (Morishita, 1923, 1924). The patient was a male Japanese, 43 years old, who had lived in Tokyo. In 1923 he had "creeping disease" in the left thenar and was operated on by Kinoshita, who excised a part of the cutaneous tissue containing a parasite which was brought to Morishita for identification. The worm, though unfortunately partly damaged, was undoubtedly a young form of *Gnathostoma hispidum* Fedchenko. This species is a parasite generally found in the stomach of the wild and domesticated pigs, and had never been reported before from human beings. This was, therefore, the first case of *G. hispidum* in man.

In addition to these, Ikegami (1919) reported an interesting case from Amoy, China. This case dealt also with "creeping disease" in a male Chinese, caused by a worm which was referred by him to a species of *Echinorhynchus*. From his descriptions and figures the worm seems however to be a young form of *Gnathostoma* and shows a close resemblance to the specimens from the new cases described below. As the parasite in this case is, however, not determined with certainty it is not reckoned by us among the cases of human gnathostomiasis.

Out of the five above-mentioned cases four dealt with *G. spinigerum* and only one with *G. hispidum*. In man they were always found in cutaneous foci, causing abscesses, tumors, or "creeping disease." Furthermore, the specimens which occurred in man were always immature. *Gnathostoma* cannot settle down to develop to maturity in any organ of an unsuitable host like man, but wander in the host's body, especially in the surface region causing various cutaneous diseases. This statement applied also to the new cases which are here recorded.

PROTOCOL OF NEW CASES.

(1) This case was treated by Dr. Fujita of the Hankow Dojin Hospital. The patient was a male Japanese, 26 years old, who went to China in March, 1919, and the following year had "creeping disease" in the region of the right shoulder. On December 13 of that year Dr. Fujita excised the affected part and found a small nematode therein, which he afterwards brought to Morishita for identification. The specimen is a small immature one mounted in balsam.

Description of the Worm.—The body is cylindrical, anteriorly truncated, posteriorly conical, with a maximum length measurement of 2 mm. by 0·29 mm. in maximum diameter which lies a little behind the middle of the body. The head bulb is provided with four rows of single posteriorly directed spines. The number of spines in each row is 40 to 46. The spines measure about 0·01 mm. long by 5 mm. broad at the base. The integument has neither transverse nor longitudinal striations. The cervical sacs are cylindrical with a length of 0·23 mm. to 0·3 mm. The club-shaped œsophagus measures 0·72 mm. long by 0·16 mm. wide in maximum diameter, and is surrounded by the nerve ring about 0·1 mm. from its anterior end. The intestine is fairly regular and is followed by the conical rectum. The anus lies 0·075 mm. from the caudal extremity. We have made observation on the genital organ.

From a merely casual study this specimen carries no body spines; it might seem reasonable to refer it to the genus *Echinocephalus* Molin. But *Echinocephalus* occurs, as a rule, in the intestine of marine fishes, has marine bivalves (*Margaritifera margaritifera*, Pinna, sp.) as intermediate hosts, and has never been seen in mammals. Moreover comparison with the specimen of Case 2, which bears body spines, though very

[1] Abstracted from the *Journal of Parasitology*, March, 1925.

minute, and which shows, excepting this point, a close resemblance in morphology to the specimen of Case 1, leads us to conclude that the specimen in question is referable to a species of *Gnathostoma*, in which the body spines have not yet developed because of immaturity. The clinical details of this case will soon be reported from Dr. Pujita's clinic.

(2) This case was treated at the Hankow Dojin Hospital by the late Dr. Kawano, who obtained a specimen from a male Japanese. The specimen is mounted in blood, now dried and partly damaged, and is labelled "cause of endemic disease." No other data are available. Dr. Fujita, who brought this specimen to Morishita, stated that the "endemic disease" may mean "creeping disease."

Description of the Worm.—The specimen is much shrunken, thick, cylindrical, 1·93 mm. long by 0·44 mm. broad in maximum diameter which lies a little behind the middle of the body. The head bulb, 0·12 mm. long by 0·21 mm. broad, bears four circular rows of spines, and is partly retracted into the so-called circular collar of the body. The number of the spines in each row is about forty. The spines are about 0·02 mm. long by 5 mm. broad at the base.

The integument of the body shows many transverse striations and annulations due to shrinkage. The anterior part for about 0·246 mm. from the cephalic end of the body proper is covered with weakly developed, uncleft, posteriorly directed spines. The œsophagus is thick, club-shaped, and measures 1·04 mm. long by 0·18 mm. broad in maximum diameter. The anus is 0·055 mm. from the caudal tip. The tail projects as a small process. The genital system is still undeveloped. This specimen carries body spines. By reason of this fact the parasite is readily identified as *Gnathostoma*, and excepting this point is closely related morphologically to the specimen of Case 1. Both specimens may, therefore, be assumed to belong to the same species, the specimen of Case 2 being more fully developed than that of Case 1.

As to the specific name of the specimens, however, a definite decision cannot be reached, since they are so young that the structure of the body may be changed and the number of the circular rows of spines on the head may increase with the growth of the body. Notwithstanding, from the cases hitherto reported in man and their distribution, we believe that these specimens may be young *G. spinigerum*.

The nematodes of the genus *Gnathostoma* play an interesting rôle as human parasites. The forms found are always immature and cause only cutaneous diseases, while the adult forms occur in the stomach of the host, also causing pathological changes. These facts warrant the division of gnathostomiasis into two categories: gnathostomiasis externa or cutana for the cutaneous diseases caused by immature *Gnathostoma*, and gnathostomiasis interna for the stomach diseases in animals caused by adult *Gnathostoma*.

In connection with the human cases of gnathostomiasis cutanea recorded from China it is of interest to note the frequency of gnathostomiasis in dogs, cats, and hogs in China. From autopsies on eighty-five dogs from Central and North China only one case of gnathostomiasis was found, numerous gnathostomes, identified as *G. spinigerum*, having been taken from a large stomach tumor. In fifty-eight examinations of cats two have been found positive for this infection. A third positive case has been found by Dr. C. McA. Wassel. Among several hundred hogs examined in Peking and in the Central Yangtze Valley no infection with *G. hispidum* has been observed. The dog and two of the cats found infected were autopsied at Wuchang, across the Yangtze River from Hankow, where the two human cases recorded in this paper apparently incurred the infection. The infection in the third cat occurred in Peking; cat autopsied by Dr. H. E. Meleney.

With reference to the route of invasion of the host it seems not unreasonable to believe that there is a free-living stage which is infective through the skin. The presence of the worms in the cutaneous tissues of man, who is only a semi-suitable host, seems to give a clue in accord with this hypothesis, since after invading the skin such worms were apparently unable to continue their course of migration through to the habitat where the adult worm is wont to develop in the appropriate host.

Conclusions.

(1) Five indisputable cases of human gnathostomiasis have hitherto been reported. Four of these are referable to *G. spinigerum* and one to *G. hispidum*.

(2) Two new cases of human gnathostomiasis from China are added. The new cases deal with very young forms, one of which caused a typical "creeping disease." The other may have also caused the same disease.

(3) Four cases of gnathostomiasis interna are recorded from dogs and cats in China. Three of these were found in cats and one in a dog. One cat was autopsied in Peking. The other infections occurred in the Hankow area.

Current Literature.

Bulletin de la Societe de Pathologie Exotique. June 10, 1925.

A Case of Cerebrospinal Meningitis due to Pfeiffer's Bacillus (Jousset and Girard).—The patient, aged 14 years, was suddenly taken ill on August 8, 1924, with very severe headache and vomiting. He had previously been in very good health, and there was nothing worthy of note in the history of his antecedents. There was stiffness in the neck and abundant diarrhœa. He was taken to the military hospital at Antananarivo the next day. The signs of Kernig and Brudzinski were positive; blood negative for hæmatozoa. Pfeiffer's bacillus was cultivated from the cephalo-rachidian liquid. Most cases of meningitis in Madagascar are due to the meningococcus or pneumococcus, but in this case cultures of both were negative, and antimeningococcus serum had no effect. The patient was

cured and left the hospital September 25, 1924, in very good health.

Yaws at Costa Rica (S. Fallas and T. von Bulow)—Yaws, or framboesia, exists in Costa Rica and is to be found chiefly along the south-west coast of the country bordering on Panama. The natives distinguish it from syphilis and call it "bouba." Clinically, its characters are different from those generally described in yaws. The serologic Bordet-Wassermann reaction is constantly positive. The period of incubation appears to be at least three months. In treatment the arsenobenzols act rapidly on the external manifestations, but complete cure is only obtained by an intensive treatment; the minimum number of doses has not yet been determined.

Treatment of Parasitic Intestinal Affection by Tetrachloride of Carbon in Capsules (Stevenel).—Tetrachloride of carbon in gelatine capsules has proved of great value in the treatment of ascaridiosis and uncinariasis. It is not so expensive as the other medicaments, is more efficacious than thymol, and has a toxic effect on the human organism. In cases of trichocephaliasis, however, thymol is preferred.

Contribution to the Study of "309" Fourneau in Animal Trypanosomiasis (R. van Sageghem).—"309" has proved more efficacious in the treatment of animal trypanosomiasis than "205" Bayer. Its action on *Trypanosome congolense pecorum* and *T. cazalboui vivax* is very rapid. With doses of 2 grm. per 100 kg. of weight the trypanosomes disappear from the peripheric circulation, but relapses occur within seven days.

Mixed Infection by Schistosomum mansoni and S. hæmatobium in a Case of Amœbic Dysentery (E. W. Suldey).—This interesting case of double infection occurred in a child of ten years of age complaining of pain in the abdomen. The child was very weak, anæmic and extremely thin. Examination of the stools showed (1) numerous *Entamœba dysenteriæ histolytica*; (2) *Bilharzia* eggs. Schistosomes were also found in the urine, besides living *miracidiums*. The amœbiasis was soon cured by emetin, but the medicament had no action on the bilharziosis; the dysenteric syndrome, however, disappeared. This case shows the value of microscopical examination of the stools for correct diagnosis.

A Case of Ainhum in the Right Leg (Mme. L. Delanoe).—The patient from the age of three to four years had had suppurating sores on the two elbows and right knee, which spread along the arms and thigh. The right foot began to swell, and later phlyctenæ covered the whole of it; it was very painful. It was diagnosed as a case of ainhum and the operation performed was very successful.

Arterial Tension and Blood Viscosity in Beriberi in the Annamites of Cochin China (M. L. R. Montel and T. van An and Dang van Cuong).—In Annamites suffering from beriberi the arterial tension (maximum, minimum and, above all, differential) is much higher than in normal subjects, and even higher than malarial patients. This increase in the arterial tension is useful in the diagnosis between chronic malaria and chronic beriberi. The blood viscosity is also greater than that found in Europeans.

Urinary Amœbiasis (M. Petzetakis).—Two further cases are described of amœbic cystitis cured by emetin. The patients, aged 35 and 60 years, were both Greeks. The amœbæ found in the urine vary in size, from 10 to 40 microns, and are very often motile. Staining of the amœbæ was not very satisfactory, although various methods were used.

Epidemiological Notes on Oriental Sore in Algeria (L. Parrot and H. Foley).—The number of cases of oriental sore is apparently increasing in all quarters of Algeria. In the region of Tell, cutaneous leishmaniosis has been observed in eight different localities during the last three years; three cases are described in this paper. It is interesting to note that while oriental sore exists in epidemic form in the region of the Sahara, the cases in the region of Tell are sporadic. At Biskra the sores are multiple, at Tell the majority of cases have only one sore; this is accounted for by the great number of insects in the former region.

First Results on the Investigation of Tumours observed in Cochin China (Lalung-Bonnaire and J. Bablet).—During the years 1922 and 1924 anatomopathologic examinations were carried out on 368 hospital patients; of these, 33 had benign tumours and 84 malignant tumours. 90 per cent. of the patients were Annamites. Both sexes are about equally affected. The ages vary between 27 and 72 years. The Bordet-Wassermann was positive in twelve cases; there were eight cases of tuberculosis. Cancer of the stomach is very rare. Epitheliomas originating in the buccal mucus are far from rare. Sarcomas are met with chiefly in children and young men. Lymphoblastic sarcomas of the neck are very frequent and rapid evolution, and often coexist with syphilis. From these observations it is seen that the Annamites of Cochin China are as susceptible to cancer as the white race. All the varieties of malignant tumours have been met with, and the number of epitheliomas of the genital organs is surprising. Tumours of the cervico-facial region are also very frequent and exceptionally malignant.

An Epidemic of Glossitis observed in Senegal (M. Nogue).—The epidemic occurred in December last year in a great number of school children at Dakar. In most cases the lesions appeared only on the tongue; sometimes there was only one plaque and at other times several, varying in colour from pale pink to a bright red. Very rarely the upper lip and the inside of the cheeks are affected. Lesions are frequently to be seen on the labial commisura. In intensive cases the condition is very painful, and there is difficulty in eating and speaking. The condition has no effect on the general health. It appears only in the cold months, but its real origin is as yet unknown; it is a contagious disease. Chlorate of potash in compressed tablets has a remarkable therapeutic action on the condition.

Original Communications.

ON THE IDENTITY OF *GONGYLONEMA SUBTILE* ALESSANDRINI.[1]

By H. A. Baylis, M.A., D.Sc.,

Department of Zoology, British Museum (Natural History).

Published by permission of the Trustees of the British Museum.

Professor Giulio Alessandrini, of the University of Rome, published, in 1914, in a paper (1914) which has, unfortunately, been largely overlooked by parasitologists, the first well-authenticated record of the occurrence of a nematode of the genus *Gongylonema* as a human parasite. In his paper, which was only a brief preliminary note, intended to be followed later by a full description of the parasite (which, however, has not yet been published), Professor Alessandrini describes the occurrence of six worms in the mouth of a girl near Rome. He indicates his opinion that the species is a new one, for which he proposes the name *Gongylonema subtile*. What is perhaps most interesting of all, he anticipates what we now know, thanks to the researches of Fibiger and Ditlevsen (1914), Ransom and Hall (1915, 1917) and Seurat (1916 *a* and *b*) to be the facts of the life-history of *Gongylonema*, by suggesting that it requires an intermediate host, and that this may be a coprophagous insect. He also wisely remarks that, while no definite pathological effects have hitherto been connected with the occurrence of *Gongylonema* in animals, the view held by Piana that this worm may, by its burrowing, assist the introduction of pathogenic organisms, cannot be lightly set aside.

Following Dr. Sambon's (1925) reference to the work of Professor Alessandrini, the writer communicated with the latter, requesting the privilege of being allowed to examine his extremely interesting specimens. As a result, on the occasion of his presence in London to attend the recent International Conference on sleeping sickness, Professor Alessandrini gave the writer the honour of a personal visit, bringing with him two of the three specimens he had obtained from the case already mentioned.

The writer's study of these two specimens consisted chiefly in taking a series of careful measurements, for comparison with those of the *Gongylonema* occurring in other hosts. All the other recent records of the occurrence of *Gongylonema* in man—Ward (1916), Stiles (1920, 1921), Ransom (1923)—have apparently been concerned with immature specimens, and the specific determination of the worms has therefore been impossible. A very important feature of the case described by Professor Alessandrini is that all the three specimens obtained by him were mature females. It is unfortunate that no male was available, but the examination of adult females makes it possible for the first time to adduce some real evidence of the identity of the species. It has already been suggested by Ward (1916) and by the present writer (1925 *a* and *b*) that the human *Gongylonema* might prove to be identical with *G. pulchrum* Molin of the pig, while, in the writer's opinion, the *G. scutatum* (Müller) of ruminants, and probably other supposed species, are also identical with *G. pulchrum*.

Of the two specimens of *G. subtile* seen by the writer the larger (which may be called specimen A) contained only immature unsegmented and shell-less eggs, of which the largest measured about 0·0375 mm. x 0·0175 mm. The smaller (specimen B) contained a rather limited number of eggs with shells either fully formed or in process of formation, but none of them were quite ripe. There were none in the vagina, and most of the eggs seen appeared (probably through rupture of the uterine walls) to be lying in the body-cavity. The contents of these eggs were either undergoing segmentation or showed early stages in the formation of a vermiform embryo. No fully-formed, coiled embryos were seen, so that none of the eggs were ready for laying. A hitherto unnoticed peculiarity was observed in some of the egg-shells. The shell appeared, in some cases, to be differentiated at each pole into a kind of cap. This character is difficult to see in fully-formed egg-shells of *Gongylonema*, the shell usually appearing entire and of almost equal thickness everywhere. It was found, however, on comparing the earliest uterine eggs from some specimens of the *Gongylonema* of the sheep, that at a certain stage in the formation of the shell, while it is still relatively thin, there may be an appearance as if the poles were formed separately from the middle portion. This appearance becomes obscured later as the thickness of the shell increases. As regards the size of the eggs, Professor Alessandrini informed the writer that his chief reason for regarding *G. subtile* as a distinct species was that the eggs measured by him were only 0·041 mm. in length and 0·028 mm. in width, whereas those of *G. pulchrum* varied from 0·052 to 0·07 mm. in length and from 0·03 to 0·035 mm. in width. The drawing shown to the writer by Professor Alessandrini indicated, however, that the egg figured was an immature one, with unsegmented content, and it may be suggested that the most mature eggs had not been measured. The writer's measurements of the largest eggs of specimen B, as will be seen, are quite in accordance with those of *G. pulchrum*.

The writer's measurements of Professor Alessandrini's specimens are tabulated below, side by side with those of females of *G. pulchrum*, which have been given in previous papers (1925 *a* and *b*). *G. pulchrum* appears to grow larger in ruminants (where it is generally called *G. scutatum*) than in swine. For this reason, in order that the comparison may be quite fair, the measurements of specimens found in pigs and in ruminants are given separately. It should be understood, however, that in the writer's opinion both columns refer to the same species, which has a fairly wide, but continuous, range of variation in size.

It should be mentioned here that each of Professor Alessandrini's two specimens had suffered a rupture of the cuticle at one place in the œsophageal region, and in each case part of the œsophagus

was protruding. In specimen A part of the glandular portion of the œsophagus had been damaged, and for a short distance only its cuticular lining remained. In specimen B the glandular portion of the œsophagus was severed, and a small part of it may have been missing. The rupture of the cuticle appeared to have occurred at the level of the excretory pore in this specimen, and for this reason the position of the pore and of the nerve-ring could not be determined. The measurements of the œsophagus were arrived at by measuring it in sections, including those portions which protruded through the body-wall.

	PULCHRUM		SUBTILE	
	From ruminants	From pigs	Specimen A.	Specimen B.
Length	74—145	37—54·3	55	45·5
Maximum thickness	0·275 —0·53	0·19 — 0·35	0·32	0·38

,, breadth	0·025 —0·037	0·03 — 0·035	—	0·03 —0·037

It will be seen that the measurements give no ground for assuming that *G. subtile* is distinct from *G. pulchrum*. The evidence might have been still more conclusive had it been possible to examine a male of *G. subtile*. Failing this, however, the writer believes, with all deference to Professor Alessandrini, that this species must fall into synonomy with *G. pulchrum*.

The importance of this conclusion is obvious. We know already that *G. pulchrum* is extremely common in domestic animals in some parts of the world, and we know also that its life-history involves an intermediate host in the shape of an insect. The insects known to be capable of acting in this capacity are several species of cockroaches, the mealworm beetle and its larva, and several kinds of dung beetles of the genera *Aphodius* and *Onthophagus* and their larvæ; while it is extremely probable that various species of *Blaps* are also implicated. The insects become infected by swallowing the eggs of *Gongylonema* contained in the fæces of the final host. These give rise to larvæ which become encapsuled in the insects' tissues, and the final host becomes infected by ingesting, either purposely or accidentally, the infected insects. Since, therefore, the human *Gongylonema* appears to be identical with that of the pig, sheep, goat and ox, it is clear that the chances of human infection are greatly increased by proximity to these animals. All that is necessary is the accidental ingestion of some insect that has fed upon the fæces of an animal infected with the worm, and this may be by no means a rare occurrence where, as in many country districts of Italy, man habitually lives under the same roof with his large domestic animals.

In conclusion, the writer wishes to express his most sincere thanks to Professor Alessandrini for allowing him the opportunity of studying his material, an act of courtesy which, it is believed, may be important in its results.

ON THE IDENTITY OF *HETERAKIS NEOPLASTICA*, WASSINK.

By H. A. BAYLIS, M.A., D.Sc.

Department of Zoology, British Museum (Natural History).

(Published by permission of the Trustees of the British Museum.)

Dr. W. F. WASSINK (1916) has given the fullest existing account of the condition known as nodular typhlitis in pheasants, caused by a nematode worm of the genus *Heterakis*. The species of *Heterakis* usually met with in the cæca of pheasants affected

with this disease is considered to be *H. isolonche* von Linstow, 1906. Von Linstow's (1906) original description of this species did not mention any lesions caused by it. Later, however, the lesions were associated with it by Lucet and Henry (1911) who gave a new description of the worms observed by them, which they determined as *H. isolonche*. In addition to the literature dealing with the occurrence of this condition in Europe,[1] an account of its occurrence in America has recently been given by Schwartz (1924), who also determined the worms as *H. isolonche*, but gives no new description of their morphology.

Besides an excellent account of the pathological effects of the presence of the *Heterakis*, Wassink has given a detailed description of the worms found by him. Some of these were of exceptionally large size, and, as a result of his morphological study of them, Wassink was led to suggest that they were of a different species from the *H. isolonche* of von Linstow. He pointed out, at the same time, certain slight differences between the descriptions of von Linstow and of Lucet and Henry, and considered that the latter's specimens were probably not *H. isolonche*, but belonged to the same species as his own. To this, in a later publication (1917), he has given the name of *H. neoplastica*.

Through the kindness of Dr. Wassink, and of Dr. C. Bonne of the Nederlandsch Kankerinstitut, Amsterdam, the writer has had the opportunity of examining specimens of the worms found by the former. A comparison of the various descriptions had already given rise to some doubt as to the validity of the new species, and it may be said at once that this doubt has not been removed by a study of the material. In the writer's opinion, *H. neoplastica* should be regarded as synonymous with *H. isolonche*. The following table shows the measurements (in millimetres) given by Wassink, by Lucet and Henry, and by von Linstow respectively. (The measurements in square brackets have been calculated from figures expressed by von Linstow as fractions of the total length.)

	Author and date :— Wassink, 1916		von Linstow, 1906		Lucet and Henry, 1911	
	♂	♀	♂	♀	♂	♀
Total length	15·0	17·0	7·8	9·3	7·5 —9·0	9·0 —12·0
Maximum thickness	0·55	0·6	0·48	0·47	0·38—0·4	0·425— 0·47
Length of œsophagus (including bulb)	1·9	2·1	[1·15]	[1·1]	1·2 —1·35	
Length of œsophageal bulb	0·37		—	—	—	—
Width of œsophageal bulb	0·21		—	—	0·26—0·3	
Length of tail	0·64	1·2	[0·6]	[1·29]	—	—
Length of spicules	1·8		1·41	—	1·4—1·75	—
Distance of sucker from posterior end	0·95	—	—	—	—	—
Diameter of sucker	0·14	—	—	—	—	—
Length of eggs	0·065—0·067		0·073		0·07 —0·075	
Width of eggs	0·035—0·04		0·044		0·042—0·046	

It should be mentioned that the hosts from which von Linstow and Wassink obtained their material were chiefly golden pheasants (genus *Thaumalea* [=*Chrysolophus*]). The birds studied by Lucet and Henry were Manchurian pheasants (*Crossoptilum manchuricum*) and a common pheasant. Wassink's largest specimens, upon which his description is based, appear to have come from hybrids between two well-marked varieties of the golden pheasant, known as *picta* and *obscura*.[2]

In order to complete the measurements given by the earlier describers, for comparison with Dr. Wassink's specimens, the writer has taken a few additional measurements from specimens determined as *H. isolonche*, from the Indian horned pheasant (*Tragopan satyra*) and Monál (*Lophophorus impeyanus*). These specimens were of average size (not exceeding the total lengths given by Lucet and Henry).

The dimensions of the œsophageal bulb were found to vary from 0·25 mm. × 0·17 mm. to 0·3 mm. × 0·25 mm. in males, and from 0·24 mm. × 0·19 mm. to 0·3 mm. × 0·25 mm. in females. (The first figure given in each case is the length, the second the width. The former cannot be very accurately measured, as the passage from the cylindrical portion of the œsophagus into the bulb is gradual, and the slight difference in histological structure between the two parts is not always very apparent.) The length of the tail in the males varied from 0·5 to 0·6 mm., and in the females from 0·95 to 1·35 mm. The diameter of the caudal sucker of the male ranged from 0·09 to 0·13 mm., and its distance from the posterior extremity from 0·6 to 0·76 mm.

The specimens kindly submitted by Dr. Wassink for examination comprised three males and five females. The largest male was about 13 mm. long, the largest female about 15 mm. The detailed measurements of these eight specimens were in general agreement with the figures published by Dr. Wassink, but showed a considerable degree of variation, and sometimes even exceeded his maxima. Thus the lengths of the œsophagus (including bulb) were as follows: males, 1·6, 1·75, 1·85 mm.; females, 1·75, 1·75, 1·9, 1·9, 1·95 mm. The length of the œsophageal bulb varied from 0·4 to 0·45 mm., and its width from 0·25 to 0·3 mm. The tail of the male varied in length from 0·7 to 0·8 mm., that of the female from 1·52 to 1·75 mm. The suckers of the three males were respectively 0·13, 0·14 and nearly

[1] Full references to the earlier literature will be found in the papers of Lucet and Henry, Wassink and Schwartz.

[2] These forms are not now generally regarded by ornithologists as specifically distinct.

0·15 mm. in diameter, and situated at 1·06, 0·96 and 0·9 mm. from the tip of the tail.

It will be seen from these measurements that, apart from the fact that some of Dr. Wassink's specimens were unusually large, and that the dimensions of their parts were more or less proportional to their total length, there is really a considerable amount of variation throughout the series, and that it is unsafe to assume that the extremes represent specific differences.

Taking in order the points of supposed difference between Dr. Wassink's *Heterakis* and *H. isolonche*, we have to consider:—

(1) *The total length of the worms.*—Dr. Wassink's measurements are admittedly derived from a single male and a single female, and these were evidently two of the largest available. Judging from the accounts of individual cases, they came probably from Case IV or Case V, which were hybrid golden pheasants. In Case I (apparently not a hybrid) the maximum lengths observed appear to have been 13 mm. (female) and 9 mm. (male), and these are scarcely above the average for *H. isolonche*. Probably every helminthologist will recall instances of considerable variation in size met with between different collections of nematodes of the same species, particularly if they came from different host-species. It is, in fact, noticeable that nematode parasites habitually grow larger in one kind of host than in another, and it seems conceivable that in the present instance there is some factor in the offspring of crosses between the two varieties of pheasants that specially favours the growth of the worms. It is of great interest to notice that Dr. Wassink also found, in some of his pheasants, specimens attributed to the common *H. papillosa* of exceptionally large size (males 15 mm., females 17 mm. in length).

(2) *The spicules of the male.*—Dr. Wassink points out that in his specimens the spicules, when extruded, were crossed, and that in this they agreed with Lucet and Henry's figure and not with von Linstow's. It is true that when far extruded the spicules are frequently crossed, but this is not so in all specimens even in the same batch, and in any case von Linstow's figure shows both spicules pushed to one side in an unnatural manner, and this has evidently been brought about by manipulation, such as pushing the cover-glass in order to roll the tail into a suitable position for drawing. Dr. Wassink further notes that there is a marked difference in shape and width between the right and left spicules in his specimens. In those sent to the writer, the spicules were always retracted, but in the writer's own examples the left spicule is somewhat longer than the right, has a thicker shaft and much broader alæ.

(3) *The cuticular striations.*—Wassink observes that his specimens agree with those of Lucet and Henry in having transverse striations, which were absent in von Linstow's specimens. Von Linstow, however, although he uses the expression "Cuticula glatt," does not state definitely that striations were absent, or even that he could not detect them, though the latter may very well have been the case. The striations are often very faintly indicated, especially in well-extended specimens, and in the examples studied by Lucet and Henry they are said to have been placed at intervals of not more than 2 microns.

(4) *The caudal papillæ of the male.*—Lucet and Henry appear to have overlooked a small postanal pair of subventral papillæ, which may, owing to their position, have been hidden by the spicules, if the latter were always extruded as in their figure. Otherwise all the descriptions, as regards the number and arrangement of the papillæ, are quite easily reconciled.

(5) *The "papillæ" in the vulvar region of the female.*—It is mentioned as a point of resemblance between Wassink's *Heterakis* and that of Lucet and Henry that, in addition to several papillæ behind the vulva, there is sometimes one in front of it, whereas von Linstow states that there are two or three behind, and mentions none in front. These "papillæ," however, as has been pointed out by Baylis and Daubney (1922, p. 289) for *H. isolonche*, and by Baylis (1923, p. 11) for *H. monticelliana*, are very variable in number and position, some females (especially the younger specimens) having none. There can be very little doubt that they are actually caused by the suckers of the males in attempting copulation, and they cannot, in the writer's opinion, be regarded as a specific character.

For the reasons that have been detailed, the writer concludes that the proposed separation of *H. neoplastica* from *H. isolonche* is not justified, the facts showing only that there is a greater amount of variation in size between individuals of *H. isolonche* than had been observed prior to the appearance of Dr. Wassink's work.

For their courtesy in affording facilities for the study of this interesting question, the writer wishes to express his sincere thanks to Dr. Wassink and Dr. Bonne. Thanks are also due to Dr. Sambon, who brought Dr. Wassink's work to the writer's attention.

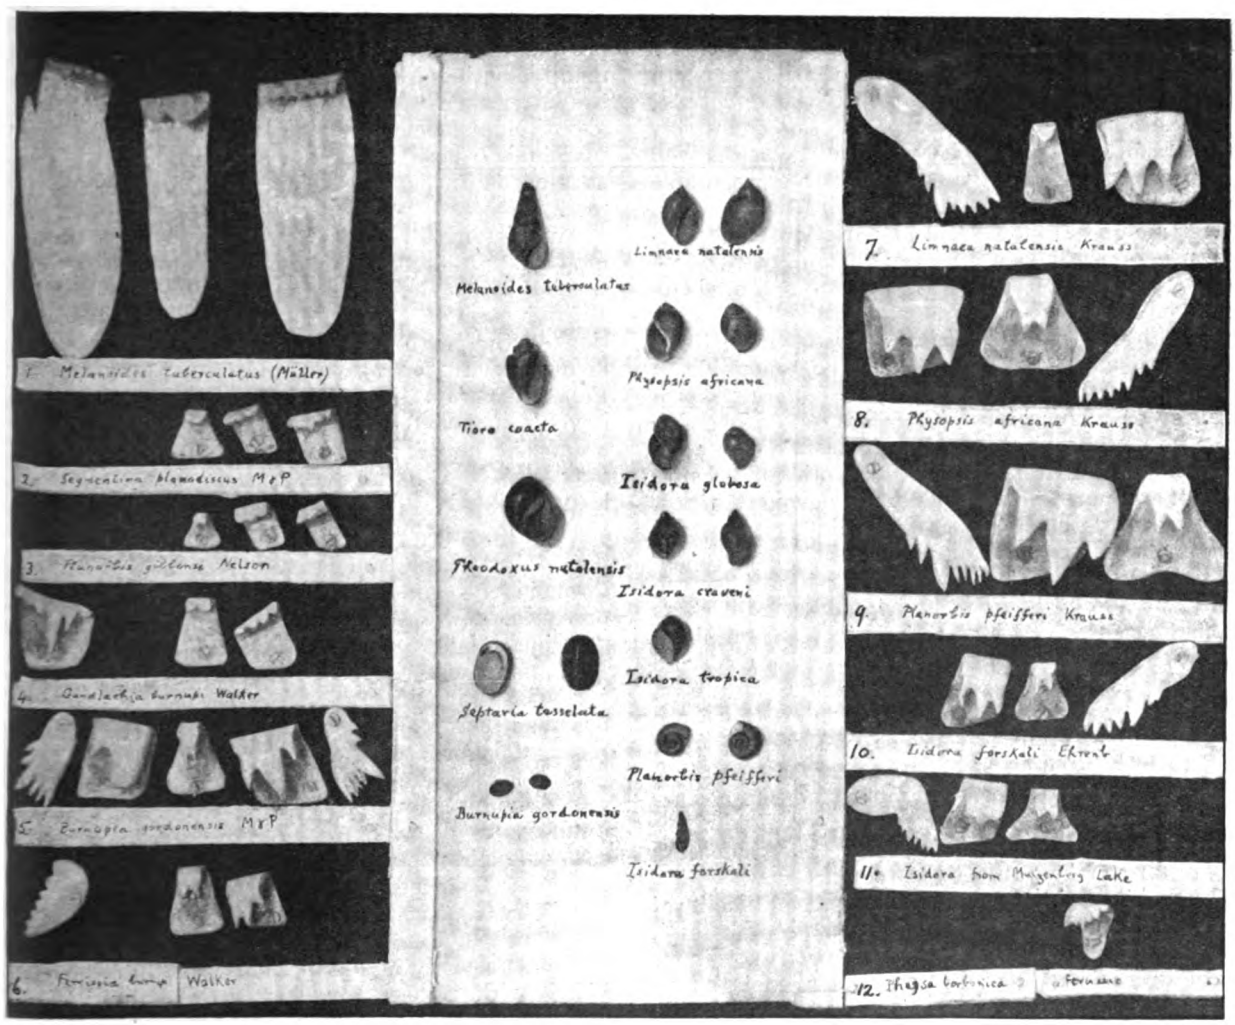
A CONTRIBUTION TO THE STUDY OF THE RADULÆ OF FRESH-WATER MOLLUSCA.[1]



By F. G. Cawston, M.D.

Considerable interest has been added to the study of those fresh-water mollusca of South African swamps which serve as intermediate hosts of the trematode parasitic worms, since a careful microscopic study reveals the fact that the identity of some species may be determined partly by the appearance of the teeth.

If an example of our fresh-water mollusca is set aside in a clean glass test-tube containing a little appropriate food, it is possible to observe the ribbon-like structure containing the teeth scratching the surface of the food like a rasp.

In order to determine the characteristic appearance of the teeth, it is necessary to examine the radulæ at the various stages of development. Microscopically, teeth characteristic of the adult radula are to be seen even in the embryonic radula.

Unlike some species which possess the same number of teeth in each row, each of our hosts

Photographic plate, showing lead models of typical teeth of various fresh-water and lagoon mollusca, made from camera-lucida sketches. (No. 1, × 500; Nos. 2, 3 and 7 to 12, × 375; Nos. 4 to 6, × 750; shells, half natural size.

The teeth are attached to a ribbon-like structure called the radula; this is broader in fresh-water species than is usual with lagoon and land species, where it is more often curled up and shaped like a watch-spring.

for trematode parasitic worms, with the exception of *Melanoides tuberculatus* (Müller), has rows in which the number of teeth varies, and, as there are from 120 to 150 rows of symmetrically placed teeth, with as many as 50 teeth in all but the most anterior rows, the majority of mature individuals possess from 7,000 to 10,000 teeth.

The teeth are arranged like a harrow, and, if seen

[1] **Read before the Congress of the South African Association for the Advancement of Science, at Outshoorn, C.P., July, 1925.**

from the side, many of the individual teeth present the appearance of a finger-rest or picture-hanger.

The teeth of *Oncomelania nosophora* Robson, the intermediate host of *Schistosomum japonica* Katsurada, like those of *Tomichia ventriculosa* (Sowerby) Reeve from Muizenberg, C.P., present small ridges from which cusps arise. In the South African hosts for schistosoma, these ridges have developed into broad overhanging processes—the "crown" of the tooth. Many of these crowns are a quarter of the size of the whole tooth. At the marginal border of the radula, the cones which grow from the edge of the crown of each tooth consist of a number of small denticles; so that the elongated crowns present the appearance of outstretched human hands. As the centre of the radula is approached, these denticles tend to coalesce, so that the lateral teeth possess but three undivided cones, the endocone, the mesocone and the ectocone. The relatively great breadth of the radulæ of these species is well suited for covering a large surface of their vegetable food. Although, in different examples of the same species, there is a good deal of variation in the appearance of the cones, the crown and basal plate are remarkably constant. Except for the angle of the basal plate, it is not possible to tell the marginal teeth of *Physopsis africana* Krauss from those of *Limnæa natalensis* Krauss; nor is it possible to differentiate them from those of *Isidora tropica* (Krauss) or *Planorbis pfeifferi* Krauss. Nevertheless, the central tooth of *L. natalensis* can readily be distinguished from that of the others, because it is tall and narrow and is generally devoid of cones. The central tooth of *P. africana* is almost triangular and usually possesses two cones, whilst the bicuspid central tooth of *I. tropica* and *P. pfeifferi* is constantly broader still. The individual teeth of these species measure 1/30th mm. in height. Careful examination that I have made of several thousand teeth has failed to reveal the presence of decay. Indeed, it would appear that the more the teeth are used to scratch the surface of food the more perfect they become.

As development proceeds, more and more rows of teeth are added posteriorly and more and more marginal teeth appear in each row, thus increasing the length and breadth of the radula.

The habit of boring holes through the shells of other mollusca results in much injury to the teeth of *Rhaciglossa* and accounts for the extraordinary length of their radulæ; however, this habit is unknown amongst the cercariæ-carriers of South African rivers. It is difficult to understand why some other species possess such long radulæ; this is very evident in some lagoon species. It is very unlikely that the posterior portion of these radulæ are ever brought into play except in those rare instances where the anterior portion has been torn off by crabs or by other natural enemies in the lagoons. Such an occurrence must be exceedingly rare in fresh-water species, in view of the rapidity with which the foot is withdrawn into the shell at the slightest sign of danger.

The intermediate hosts of South African trematoda feed on waterweeds and are less exposed to attacks from their natural enemies than lagoon species. Lagoon inhabitants feed on coarser food and suitable teeth are provided. Many of the small Planorbinæ have teeth with well-marked cusps, but without cones. Elongated cones are more liable to injury from coarse food than the short cusps. The cones of *M. tuberculatus* (Müller) can be bent back without breaking them.

A careful examination of the radula of some examples from Mauritius which had been identified for me as *I. borbonica* Férussac revealed about 120 rows of almost identical teeth, each provided with about six small cusps. The species represented proved to be *Physa borbonica* (Férussac) which is readily distinguishable from *I. tropica* Krauss; for the latter species possesses a central bicuspid tooth, about eight tricuspid laterals and from 18 to 21 marginals whose cones are divided into as many as nine denticles, one being much larger than the rest.

Amphistoma were isolated from South African mollusca first at Potchefstroom in 1918. The species responsible being identified by Mr. H. C. Burnup as *I. schakoi* Jickeli. From an examination of the teeth, the species would appear to be identical with *I. tropica* Krauss, as Monsieur Paul Pallary considers it to be. Since then amphistoma have been isolated from *I. tropica*, *I. forskali*, *I. natalensis* and *I. craveni* Ancey. The last species may also be a variety of *I. tropica* and possesses identical teeth.

Conclusions.

(1) The central and lateral teeth are the first to form in the embryonic radula. As development proceeds, new laterals are formed from the inner marginals, by a coalescence of their denticles.

(2) Fresh-water species are exposed to less injury than the inhabitants of brackish water in lagoons; their radulæ are broader and shorter than those of lagoon species.
